The hot wire immersed in an infinite fluid medium is the most common geometry for transient thermal-conductivity measurements. The wires are used simultaneously as electrical heat sources and resistance thermometers. Differences between various instruments are based on the geometry of the cell and the power-forcing function that is used during the measurement. Useful forcing functions include impulse, step, and ramp power. The fundamental working equation for the transient hot-wire techniques assumes that the heat is generated from an infinitely long line source. The line heat source has no volume and no radius, and so there is no thermal lag and all of the heat is dissipated by conduction into the fluid medium. The fluid medium is assumed to be infinite, which implies that the transient thermal wave does not penetrate to the cell boundary during the time frame of the experiment. The rate at which the thermal wave penetrates into the fluid is directly related to the thermal diffusivity of the fluid. Thus, the outer-boundary radius does not need to be very large for liquids, which typically have quite small thermal diffusivities. Transient hot-wire cells are designed to approximate the line-source solutions as closely as possible with wire diameters ranging from 4 to 25 μm. The smallest diameters, 4–7 μm, are preferred for gas-phase measurements. Deviations between the actual heat transfer and the line-source solution are treated as time-dependent corrections to the experimental data such that

$$\Delta T_{\mathrm{id}}(t) = \Delta T_w(t) + \sum_i \delta T_i(t), \tag{44}$$

where ΔT_{id} is the corrected temperature rise, ΔT_w is the experimental temperature rise, and δT_i are the corrections to the temperature rise for nonideal heat transfer. The article by Assael *et al.* (1991) provides a detailed discussion of the various corrections associated with the transient hot-wire technique.

The line-source solutions are similar for the three cases of impulse-power, step-power, and ramp-power forcing and are described by Mohammadi *et al.* (1981). The ideal model for impulse-power input is

$$\Delta T(t) = \frac{q^0}{4\pi\lambda t}\exp\left(\frac{-r_w^2}{4at}\right), \tag{45}$$

where q^0 is the total heat content of the pulse, t is the time that has elapsed since the pulse, and r_w is the wire radius. For the case of a step power-forcing function, the long-time solution is

$$\Delta T(t) = \frac{q}{4\pi\lambda}E_1\left(\frac{r_w^2}{4at}\right) \approx \frac{q}{4\pi\lambda}\ln\left(\frac{4at}{r_w^2 C}\right), \tag{46}$$

where q is the power applied per unit length during the experiment, E_1 is the exponential integral, and $C = \exp(\gamma)$ is the exponential of Euler's constant. For the case of the ramp power-forcing function, the long-time solution is

$$\frac{\Delta T(t)}{t} \approx \frac{\hat{q}}{4\pi\lambda}\ln\left(\frac{4at}{r_w^2 D}\right), \tag{47}$$

where $\hat{q}$ is the slope, or time derivative, of the power applied per unit length during the experiment and $D = \exp(1 + \gamma)$. The long-time approximation in Eqs. (46) and (47) is normally valid for experimental times greater than 50–100 ms. The characteristic dimensionless time for the transient hot-wire experiment is $\tau = at/r_w^2$ with the validity of the long-time approximation extending to shorter real times for fluids with large thermal diffusivities and for cells with small hot wires. The step power-forcing function is most commonly used because of simplicity and a well-developed set of corrections to the ideal heat-transfer model. The ramp power-forcing function is less likely to drive convection in the fluid, since the temperature gradient in the fluid remains smooth and continuous throughout the fluid during an experiment. However, this technique has not been widely used. A key advantage of all the transient techniques is that both thermal conductivity and thermal diffusivity can be obtained.

Effects due to axial thermal conduction can be eliminated through the use of a compensating dual-wire cell. In the dual-wire configuration, the transient temperature rise of a short wire can be subtracted from that of the main long wire using a Wheatstone bridge. The resulting signal represents the response from a finite-length wire with a length that is equal to the difference between the long and short wire lengths. The contribution of the ends, where the axial temperature gradient is significant, is eliminated using this dual-wire technique. Alternatively, fine voltage-sensing leads, which measure the wire resistance increase due to heating, can be located at points on the hot wire that are at a sufficient distance from the end supports so that there is no axial temperature gradient present. The transient hot-wire techniques readily allow detection of convection during measurements, since a finite length of time is required at any given power to move the fluid in the presence of the temperature gradient. Convection occurs at shorter times as the applied power of the measurement is increased and is apparent because it causes deviations from the ideal conduction heat-transfer model.

Since the hot wires are directly immersed in the fluid of interest, problems arise when the fluid is highly polar and has a significant electrical conductivity. These electrical difficulties can be directly overcome by electrically insulating the hot wire. The electrical insulation should be thin to minimize corrections to the ideal line-source model. The most common systems are platinum wires insulated with polyester, anodized tantalum wires, and liquid metals in quartz capillaries. The thermal conductivity of polar fluids such as alternative refrigerants, alcohols, water, and even aqueous salt solutions can be measured using electrically insulated wires or capillaries. Additional details are available in the references at the end of this article.

2.4 Periodic Methods

Periodic methods such as forcing the heat flux using sinusoidal power (or temperature) measure the thermal diffusivity of the fluid, since the penetration distance into the fluid is a function of the period or frequency of the temperature cycle. If the average applied power is known during a periodic heating experiment, then it is possible to obtain the fluid thermal conductivity directly. The most common periodic heating method uses a wire that is driven with a low-frequency power cycle such that $Q = Q_0[1 + 2 \times \cos(\omega t)]$. The third harmonic of the heating current is proportional to the wire temperature cycling amplitude:

$$\Theta_3 = \frac{Q_0}{2\pi\lambda L} \ln\left[\frac{2}{\gamma r_w}\left(\frac{a}{2\omega}\right)^{1/2}\right], \tag{48}$$

where $\omega = 2\pi f$ is the angular frequency of the heating current and L is the wire length. This equation holds for low frequencies and fine wire diameter where

$$r_w^2\omega \leq 4\lambda/\pi C_w \rho_w \tag{49}$$

and C_w and ρ_w are the heat capacity and density of the wire. Equation (48) shows that both the thermal conductivity and the thermal diffusivity can be found if a range of frequencies is studied. A detailed discussion of periodically heated wires can be found in Shpilrain *et al.* (1975) and the monograph by Vargaftik *et al.* (1994).

Recently, Peltier drivers have been used to produce sinusoidally varying temperatures to measure the thermal diffusivity of fluids. Peltier drivers allow the fluid surfaces to be periodically cooled and warmed relative to the bulk fluid temperature. Czarnetzki and Roetzel (1994) describe periodic temperature experiments for several geometries including a circular cylinder, a sphere, a semi-infinite body, and a slab. They determined from this work that the cylinder and slab geometries produce thermal diffusivity data with the least uncertainty. No attempt was made to quantify the heat that was input and removed during these experiments, so only thermal diffusivity was determined. However, the thermal conductivity of the fluid can be obtained from these measured thermal diffusivities using Eq. (6) if the fluid density and isobaric heat capacity are available or can be estimated using an accurate equation of state.

2.5 Optical Methods

Optical methods are attractive for measuring the thermal diffusivity of transparent liquids. As with the periodic methods, the thermal conductivity of the fluid can be obtained from the measured thermal diffusivity using Eq. (6) if the fluid density and isobaric heat capacity are available or can be estimated using an accurate equation of state. Photon-correlation spectroscopy does not require a temperature gradient, and so it is particularly useful in the critical region, where the susceptibility of the fluid to convection is greatly enhanced. In Rayleigh scattering, the spectrum of the scattered light has three peaks, the Rayleigh line and the symmetric pair of Brillouin lines. In the light-scattering technique, the Rayleigh spectrum, due to fluctuations of the fluid's refractive index (or dielectric constant), is measured at a known angle relative to the incident laser beam. For a pure fluid, these entropy fluctuations are directly related to the thermal diffusivity of the fluid,

$$a = 1/q^2\tau_s, \tag{50}$$

where $q = 2k\sin(\theta/2)$, k is the incident wave number, q is the scattered wave number, θ is the scattering angle, and τ_s is the intensity autocorrelation decay time for entropy fluctuations. For a mixture, there are contributions from both entropy and concentration fluctuations. The concentration fluctuations become significant if there is a significant difference in the refractive index of the components in the mixture and provide a measure of the mass diffusion coefficient

$$D = 1/q^2\tau_c, \tag{51}$$

where τ_c is the intensity autocorrelation decay time for concentration fluctuations. Fortunately, the decay time of the concentration fluctuations is usually much longer than that for the entropy fluctuations, so that both the thermal diffusivity and the mass diffusion coefficient can be resolved in many situations.

In forced Rayleigh scattering, the thermal diffusivity of a sample is found by observing the decay time of light diffracted from a periodically heated area in the fluid. The heating is provided by an excitation laser and is localized by the interference pattern from two crossed laser beams in the fluid. The localized heating of the fluid at the antinodes of the interference pattern generates a sinusoidally periodic temperature pattern during the heating cycle. The periodic temperature pattern affects the refractive index of the fluid and acts like a diffraction grating on the probe laser beam. The excitation beam is then turned off, and the decay of the temperature pattern is monitored through the diffraction of the low-powered probe beam. The thermal diffusivity is given by

$$a = -\tfrac{1}{2}\left(\frac{P}{2\pi}\right)^2\left(\frac{d\ln I_1}{dt}\right), \tag{52}$$

where I_1 is the first-order diffracted beam intensity and P is the grating spacing. This method has been applied to extremely corrosive materials such as molten salts. A more detailed description is provided by Shaumeyer *et al.* (1991).

2.6 Reference Materials and Data

A variety of absolute and relative experimental techniques are available to measure the thermal conductivity and thermal diffusivity of liquids. There are uncertainties associated with each of these techniques, which are increased under certain conditions. For instance, thermal radiation errors in techniques that require a temperature gradient are larger at high temperatures and for fluids that moderately absorb infrared radiation. Photon-correlation spectroscopy has large uncertainty at low temperatures relative to the gas–liquid critical point, but it has significant advantages near the gas–liquid critical point since it does not require a macroscopic temperature gradient. Thus, light-scattering measurements of thermal diffusivity are complementary to transient and steady-state measurements of thermal conductivity. It is desirable to use data from a variety of absolute techniques to develop standard reference data for the thermal conductivity of liquids. These standard reference data can be used both to verify the performance of new absolute measurement techniques and to calibrate relative thermal-conductivity and thermal-diffusivity instruments. A number of reference liquids have been proposed by IUPAC collectively spanning a temperature region from 180 to 575 K at saturation pressure. These materials can be obtained in high purity and do not decompose easily at elevated temperatures.

A number of criteria are used by IUPAC to select standard reference materials for the thermal conductivity of liquids:

1. The temperature interval between the freezing point and the normal boiling point, i.e., the extent of the normal liquid range, must be large and include some thermometric fixed point.
2. The liquid should be nontoxic and noncorrosive with respect to the usual engineering materials.
3. The liquid should be obtainable at low cost and guaranteed high purity.
4. Several fluids are required to cover as wide a range of thermal conductivity as possible.
5. Reliable values of liquid densities for the saturated and compressed liquid should be available in the literature, allowing reliable extrapolation of high-pressure data to the saturation line. Additionally, it is desirable for the reference fluids to have a high viscosity to minimize uncertainty due to fluid convection and to be either totally transparent or totally opaque to thermal radiation, to minimize uncertainty due to thermal radiation.

Water and toluene are two of the most widely studied and best characterized liquids. Their thermal conductivities are very different, so they are useful for calibrations of relative instruments. However, water is a very good solvent and picks up ionic impurities, air, and carbon dioxide. The electrical conductivity of water and other highly polar liquids increases as these impurities are dissolved and can be a significant problem for many measurement techniques. Water should not be used to calibrate instruments, such as bare transient hot-wire cells, that are sensitive to electrical conduction in the sample. Likewise, care must be taken when handling hydrocarbon reference fluids such as toluene, dimethylphthalate, and *n*-heptane, since they have a tendency to absorb water from the air in open containers, particularly at lower temperatures. Dimethylphthalate has the highest viscosity of these hydrocarbon reference fluids, which makes it the least sensitive to temperature gradients that might induce convection errors.

Water has been widely studied because of its industrial importance and its significance in natural and geological phenomena. A widely accepted standard surface correlation for the thermal conductivity of water and steam was developed by the International Association for the Properties of Water and Steam (IAPWS) over the temperature range of 273–1073 K at pressures at least to 100 MPa (Sengers and Watson, 1986). IAPWS provides recommended values for the thermal conductivity of saturated liquid water from 273 to 646 K. IUPAC has recommended several reference correlations for saturated liquid water that have a smaller uncertainty but that cover a more limited temperature range. These correlations have evolved through the years as more accurate data have been reported. An early reference correlation was proposed by Nieto de Castro *et al.* (1986) and covered the temperature range from 274 to 370 K with an estimated uncertainty of 1%, and subsequently by Le Neindre (1987). A new IUPAC correlation was presented by Ramires *et al.* (1995) over the same temperature range, which reduces the estimated uncertainty to 0.7% using new data from transient hot-wire experiments using electrically insulated wires. Agreement between the IAPWS and IUPAC recommendations is within 1%, and these correlations will evolve as new data are obtained.

Toluene is also very well characterized near the saturated-liquid line using steady-state, transient, and light-scattering techniques. Two IUPAC reference correlations were proposed by Nieto de Castro *et al.* (1986) from 230 to 360 K (1%) and 189 to 360 K (1.5%) and subsequently by Le Neindre (1987). A new correlation has recently been described by Ramires *et al.* (1996) that covers the range from 189 to 553 K. The estimated uncertainty of this reference data correlation is 1% from 189 to 440 K, 1.5% from 440 to 480 K, and 2% above 480 K.

An IUPAC reference data correlation is described by Nieto de Castro *et al.* (1986) and Le Neindre (1987) for saturated liquid *n*-heptane. This correlation covers the temperature region from 191 to 365 K with an estimated uncertainty of 1.5%. This correlation was based on a limited number of data sets that had significant discrepancies between them but remains the best available recommendation for the thermal conductivity of saturated liquid *n*-heptane.

A good discussion of the advantages of dimethylphthalate as a thermal-conductivity reference fluid is provided by Poltz and Jugel (1982) along with a demonstration of the contribution of thermal radiation on thermal-conductivity measurements. An IUPAC standard reference data correlation is described by Le Neindre (1987) for saturated liquid dimethylphthalate from 273 to 493 K. No estimated uncertainty is provided for the dimethylphthalate correlation.

3. PURE FLUIDS

The thermal-conductivity surface for argon is shown in Fig. 6 as a function of temperature and density. These data were reported by Perkins *et al.* (1991b) using the transient hot-wire technique. Argon is a spherical, nonpolar, monatomic molecule and hence is a nearly ideal fluid, yet it is representative of a wide range of fluids as will be shown. The gas–liquid critical point for argon is about T_c = 150.66 K, ρ_c = 13.29 mol/L, and P_c = 4.906 MPa, and the triple point is T_t = 83.80 K, ρ_t = 35.40 mol/L, and P_t = 0.0689 MPa. The compressed-liquid region exists at pressures above the saturation pressure from the triple point to the critical-point temperature. Argon is supercritical at temperatures above T_c, but the smooth behavior along the supercritical isotherms relative to both the subcritical gas and liquid phases illustrates the need to consider all three of these regions in order to understand the liquid-phase thermal conductivity. An increase in the thermal conductivity is apparent in the supercritical isotherm nearest to the critical point. This bump is due to the thermal-conductivity critical enhancement, which is significant in an extended region around the critical point and thus affects the subcritical liquid and vapor isotherms. Even a material such as argon "gas" has a liquid phase at a low enough temperature. The reduced parameters of temperature ($T_r = T/T_c$) and density ($\rho_r = \rho/\rho_c$) relative to the gas–liquid critical point are important in the context of the phase behavior and the thermophysical properties of fluids.

The thermal conductivity of water, calculated from the IAPWS correlation (Sengers and Watson, 1986), is shown in Fig. 7. Although water is a fluid that is liquid at ambient conditions, the thermal conductivity, when it is plotted in terms of reduced temperature and density, appears to be very similar to that of argon. The gas–liquid criti-

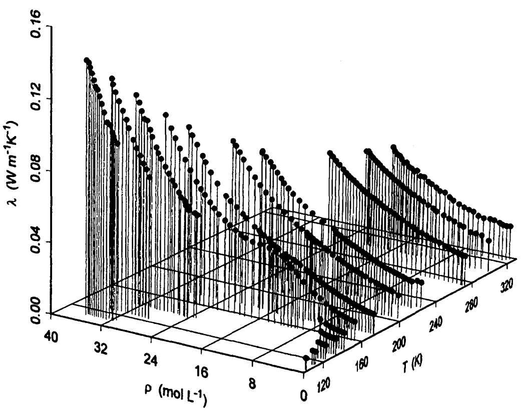

FIG. 6. Thermal-conductivity measurements for argon, reported by Perkins *et al.* (1991b).

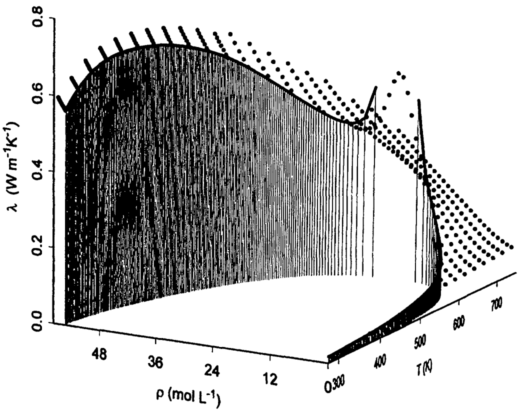

FIG. 7. Thermal-conductivity surface for water from IAPWS model (Sengers and Watson, 1986).

cal point for water is at T_c = 647.096 K, ρ_c = 17.87 mol/L, and P_c = 22.064 MPa, and the triple point is at about T_t = 273.16 K, ρ_t = 55.50 mol/L, and P_t = 611.657 Pa. The compressed-liquid region again exists at pressures above the saturation pressure between T_t and T_c. Water is very polar, with a dipole moment of about 6.14×10^{-24} C·m (1.84 debyes) and is very unusual since the solid line has a negative slope at pressures from the triple point to 209.9 MPa. This unusual behavior can also be seen in the thermal conductivity of saturated liquid water. Figure 7 shows that the thermal conductivity of saturated liquid water increases from the triple point to a maximum of about 0.68 W/(m K) near 400 K. The thermal conductivity of most liquids at saturation is a monotonically decreasing function of temperature as seen in argon. However, in water, we have a competing mechanism related to the association phenomenon; at low temperatures, the effective diameter of the fluid constituents is increased, so that the thermal conductivity is decreased, according to the structure of Eq. (11). The effect of the critical enhancement of thermal conductivity is apparent in the saturated-liquid and vapor lines as they approach the critical point in Fig. 7.

3.1 Saturated Liquid

At saturation, a liquid is in equilibrium with vapor. For a given temperature between the triple point and the critical point, this occurs at the saturation vapor pressure. The properties at saturation are a unique function of temperature for any given pure fluid. Properties such as the saturated-liquid density, saturated-vapor density, and thermal conductivity of the liquid or vapor at saturation are specified by one variable, normally either temperature or pressure. The thermal conductivity of most liquids decreases as a function of temperature at saturation. Figure 8 shows the thermal conductivity of several liquid alkanes at saturation as calculated with the NIST computer databases for thermophysical properties of Friend and Huber (1994). An upturn is present as the gas–liquid critical point is approached since the thermal conductivity is divergent at the critical point. The critical temperatures of methane, ethane, propane, and *n*-butane are near 190, 305, 370, and 425 K, respectively. The lowest temperatures shown in Fig. 8 correspond to the highest fluid densities and hence have the highest thermal conductivity for any given fluid. The curves in Fig. 8 cross each other in the temperature coordinate system, but would not if plotted in terms of saturated-liquid density. This reflects the weak dependence of liquid thermal conductivity on temperature. Measurement of the thermal conductivity directly along the saturated-liquid line is not possible since a temperature gradient is normally required during the measurement process so that the phase equilibrium will be disturbed. Normally measurements are made in the vicinity of the saturation line and extrapolated to the saturation boundary to obtain the true saturated-liquid thermal conductivities. It is possible to cross over the phase boundary into the two-phase region during a measurement when very clean surfaces or rapid experi-

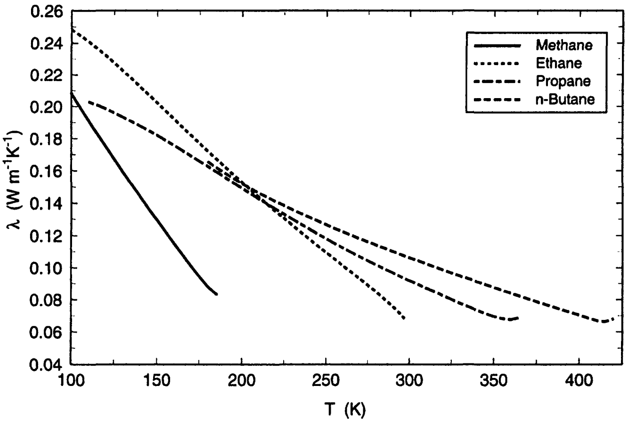

FIG. 8. Family plot of methane, ethane, propane, *n*-butane thermal conductivity calculated using the NIST database correlations.

ments suppress the nucleation of bubbles in the liquid during the measurement process. Under these conditions the fluid is not in equilibrium but is instead in a metastable state. Such data for metastable thermal conductivity have significance in industrial heat-transfer equipment.

3.2 Compressed Liquid

The thermal conductivity of a liquid that is compressed to a pressure and density greater that its saturation value is generally larger than its saturation value. Figure 9 illustrates this effect using the hard-sphere correlation of Assael *et al.* (1992b) for liquid propane at pressures to 70 MPa. This figure shows that the thermal conductivity of liquid propane is a strong function of density with a much weaker dependence on temperature. It is the temperature dependence that keeps the isotherms at different temperatures from falling on a single density-dependent curve. To study this temperature dependence it is necessary to have data over a wide range of pressure from saturation to 50 MPa or more. The curvature of the isotherms becomes more pronounced as the temperature is increased since the fluid becomes more compressible. The figure further illustrates how data along isotherms can be used to extrapolate to the thermal conductivity of the saturated liquid.

3.3 Critical-Region Behavior

Application of simple models, such as the hard-sphere theory, for the thermal conductivity of liquids must be limited to temperatures where the critical enhancement is negligible. Thus, hard-sphere theories work best at lower reduced temperatures. Figure 5 showed the behavior of the thermal conductivity of carbon dioxide in the critical region for liquid, vapor, and supercritical isotherms. Figure 10 shows the relative magnitude of the critical enhancement that is calculated for 1,1,1,2-tetrafluoroethane (R134a) along its vapor pressure locus using the correlation surface of Krauss *et al.* (1993). The critical temperature of R134a is about 374.2 K. The critical enhancement contributes more than 2% to the saturated-liquid thermal conductivity for temperatures above 300 K and exceeds 15% at temperatures above 360 K. Correlations and theories for thermal conductivity of liquids that do not consider the critical enhancement should be limited to temperatures below about $0.85T_c$. The contribution of the critical enhancement is even more significant in the vapor phase where the critical enhancement adds to a smaller background thermal conductivity as shown in Fig. 10. A discontinuity is present in the correlation of Krauss *et al.* (1993) for the saturated vapor near 360 K where the equation of state switches from a classical form ($T <$ 360 K) to a crossover form for the near-critical region.

4. MIXTURES

The topology of the phase behavior for mixtures can be very complex, because multiple liquid phases may be present, the sim-

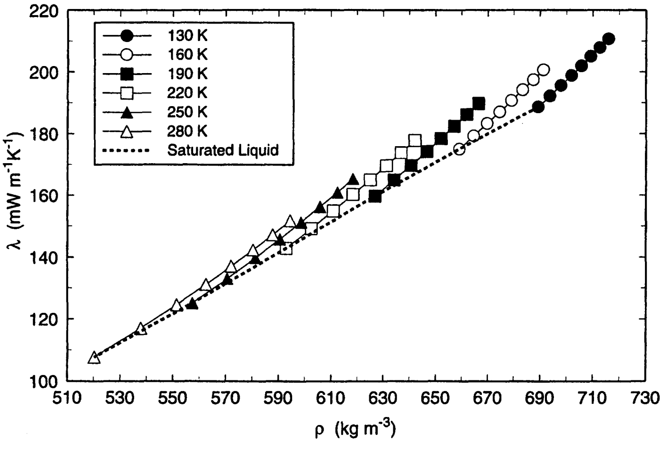

FIG. 9. Thermal conductivity of compressed liquid propane at low reduced temperatures from the hard-sphere correlation of Assael *et al.* (1992b).

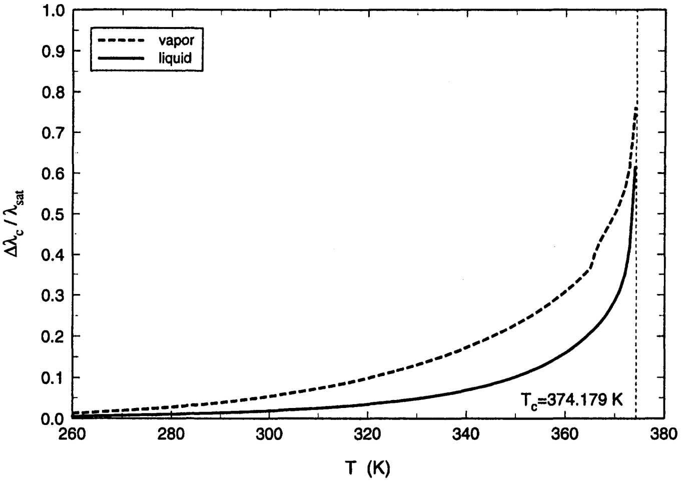

FIG. 10. Fraction of the thermal conductivity of 1,1,1,2-tetrafluoroethane (R134a) due to critical enhancement along the saturation boundaries. Calculated from Krauss *et al.* (1993) correlation.

ple melting line can be complicated by eutectic points and multiple solid phases, and the liquid–vapor critical locus can have a variety of behaviors. Nonetheless, the general behavior of the thermal conductivity of liquid mixtures is similar to that of pure liquids. As an example, Fig. 11 shows thermal conductivity data for a standard dry air, which contains 78.12% nitrogen, 20.96% oxygen, and 0.92% argon, where the composition is expressed as mole fractions. These data were obtained using the transient hot-wire technique (Perkins and Cieszkiewicz, 1991), and the thermal conductivity of air looks very similar to the thermal conductivity of argon that was shown in Fig. 6. For this standard composition, there is a triple point near 59.75 K (although the coexisting solid and vapor phases have different compositions), and the liquid–vapor coexistence boundary extends to its maximum temperature near 132.62 K (which is slightly above the critical temperature near 132.52 K).

In Fig. 12, we have shown the extensive data (and correlating surface) for the methane–ethane binary system, which was illustrated in reduced units in Fig. 4. Again, the density dependence dominates for the compressed fluid, and the mixture values of thermal conductivity interpolate smoothly between the pure-fluid values. The data for each mixture composition exhibit the char-

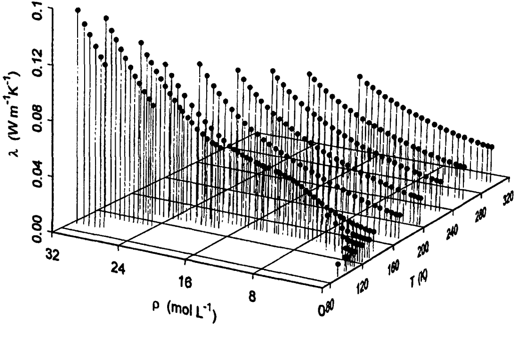

FIG. 11. Thermal-conductivity data surface for air reported by Perkins and Cieszkiewicz (1991).

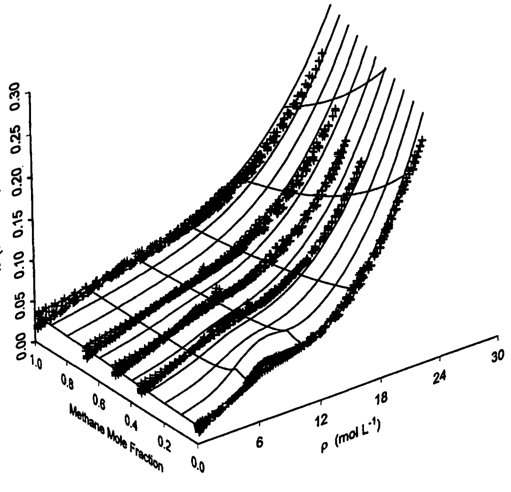

FIG. 12. Thermal-conductivity surface for methane–ethane binary mixtures reported by Friend and Roder (1987).

acteristics that have been described for pure fluids. At a fixed density, the thermal conductivity generally increases with increasing temperature. The thermal-conductivity critical enhancement is responsible for isotherms at lower temperatures crossing higher-temperature isotherms and the bumps that are centered near the composition-dependent critical density in Fig. 12.

For mixtures, such as air or methane + ethane, the liquid–vapor phase boundary for a fixed composition is defined by the dew-point locus and the bubble-point locus rather than a simple vapor-pressure curve. The bubble point gives the state at which the first bubble of vapor will form when a compressed liquid of fixed composition is brought to a lower pressure along an isotherm. Generally, the vapor will have a different composition than the liquid with which it coexists. The dew-point locus lies at lower pressures and gives the temperature and pressure where the first condensation occurs when a vapor at fixed composition is isothermally compressed. Again, the liquid composition generally differs from the composition of the original vapor. The dew-point locus and bubble-point locus can meet at the critical point, which represents the limiting state at which the vapor-phase and liquid-phase properties are identical. However, the critical point does not necessarily coincide with the maximum temperature for phase separation, which is often called the maxcondentherm temperature. When we discuss the thermal conductivity of a saturated-liquid mixture, we mean that the temperatures and pressures are along the bubble-point locus. Measurements of the thermal conductivity at the bubble point are complicated because some of the heat input can generate bubbles of gas. In Fig. 13, we show calculated values of the thermal conductivity for three binary mixtures of nitrogen and oxygen along their bubble-point curves and the analogous values for the saturated liquid of the pure components. Again, the similarity of these curves is readily apparent.

The behavior of the thermal conductivity of mixtures in the region of the critical point remains a subject of experimental and theoretical interest. In binary systems such as methane + ethane (Roder and Friend, 1985), helium-3 + helium-4 (Meyer, 1984), and carbon dioxide + ethane (Leuttmer-Strathmann and Sengers, 1996), this behavior looks similar to that seen in pure fluids. However, in contrast to pure fluids, theoretical calculations of the critical enhancement term indicate that it should have a finite value as the critical point is approached; this maximum is difficult to observe experimentally because of its close proximity (several millikelvins) to the critical point.

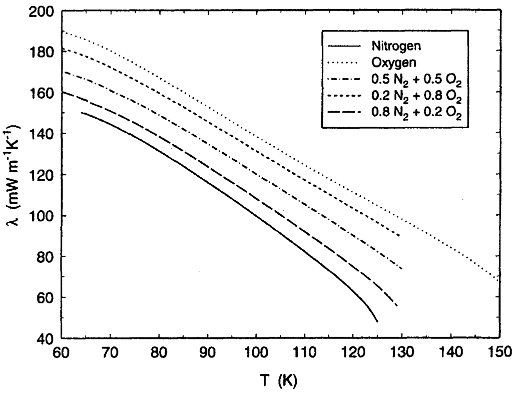

FIG. 13. Thermal conductivity of mixtures of nitrogen and oxygen along bubble-point locus.

5. MISCELLANEOUS ADDITIONAL TOPICS

The previous sections have provided the basis for approaching the wide range of literature that is available on the thermal conductivity of liquids. It is now apparent that there are difficulties in separating other modes of heat transfer from pure thermal conduction during experimental measurements. This is important to consider when assessing work in the literature where widely different values for thermal conductivity are reported for the same fluid. The need for thermal-conductivity data in engineering heat-transfer calculations has also been discussed. Theoretical tools that are available for the correlation of liquid thermal-conductivity data have been summarized. The fact that liquid thermal conductivity cannot be considered in isolation from the thermal conductivity of the vapor and supercritical gas has also been illustrated. It remains to consider some interesting cases that are important but that did not fit well in the context of the previous discussion.

5.1 Cryogenic Fluids

The discussions above have assumed that classical descriptions are adequate, and this is true for normal liquid systems. However, quantum mechanics represents a more fundamental approach to the understanding of physical phenomena, and we will very briefly discuss situations in which this may become important. For a theoretical understanding of the internal modes of energy storage in a molecular system, the quantization of available states may be useful; see, e.g., Eq. (15). From the point of view of statistical physics, quantum effects become important when the thermal de Broglie wavelength $[= h/(2\pi \times mkT)^{1/2}]$ becomes comparable to the interparticle spacing in the fluid system. From this we can obtain a dimensionless parameter Λ defined by

$$\Lambda \approx 1.474\rho^{1/3}/M^{1/2}T^{1/2},$$

where M is the usual molar mass (in g/mol), T is in kelvins, and ρ is in moles per cubic decimeter. When Λ is comparable to or greater than 1, quantum effects must be considered. For water at ambient conditions, $\Lambda \approx 0.08$, and the system is essentially classical. On the other hand, for light molecules at low temperatures, quantum effects are important. Thus, for liquid helium near 2 K, $\Lambda \approx 1.7$, and the system is, in fact, in the He II superfluid state at temperatures below the lower lambda point near 2.18 K. Heat transfer in this system is not well defined by Fourier's law, Eq. (1), and for some flows the heat-flux vector is proportional to the cube root of the temperature gradient (Srinivasan and Hofmann, 1985). Molecular hydrogen is another system in which quantum effects play an important role. In this fluid, the relative spins of the nucleon can be parallel (orthohydrogen) or antiparallel (parahydrogen), and these modifications have distinct energy states available. The "normal" population of a system of fluid hydrogen contains a 3:1 ratio of ortho-to-para modifications, but the parahydrogen molecule dominates for equilibrium systems at very low temperatures. Because the conversion rate between the two modifications is slow in the absence of a catalyst, measurements of the thermal conductivity of hydrogen can give different results depending on the history of the system. We can calculate and observe different dilute-gas values for the thermal conductivity of the two modifications, and in fact the fluid can be considered a mixture with each component having a different value for the thermal conductivity. Empirically, we can describe the thermal conductivity of the "normal" population, the equilibrium population, or the value for each pure modification (Roder, 1984). However, for the liquid phase, which exists below the critical temperature of about 33 K, these differences in thermal conductivity are small.

5.2 Refrigeration Fluids

Concerns with the environmental problems associated with chlorofluorocarbon (CFC) refrigerants have led to very active research on the thermophysical properties, including thermal conductivity, of alternative fluids such as the hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), propane, butanes, and their mixtures. There is a rich collection of recent data and correlations for the thermal conductivity of these alternative refrigerants. For the thermal conductivity of a wide variety of alternative refrigerants and their mixtures in the liquid phase, there are two notable correlation packages. First, the hard-sphere model of Assael *et al.* (1995) provides estimates for the density, viscosity, and thermal conductivity of nine refrigerants; the model is embodied in a computer package called TRANSP. Second, there is the extended corresponding-states model of Friend and Huber (1994), which is available in REFPROP from NIST. The current NIST REFPROP computer program provides estimates or correlations for density, entropy, enthalpy, specific heat, sound speed, compressibility, phase equilibria, viscosity, and thermal conductivity of 43 fluids and mixtures of these fluids with up to five components. Both of these correlation schemes have been compared extensively to the most reliable data that are available.

5.3 Liquid Fuels and Petrochemicals

There has been a long-term interest and extensive literature on the thermal conductivity of liquids that are used as fuels or as feedstocks in petrochemical processes. These materials can range in complexity from pure fluids such as hydrogen and methane to mixtures of numerous components, where it is only possible to characterize the boiling-point range of the liquid. Other nonpolar liquids such as nitrogen, oxygen, argon, carbon monoxide, carbon dioxide, and hydrogen sulfide can be considered in this group. These materials can all be treated well with extended corresponding-states correlations or with hard-sphere correlations. Assael *et al.* (1992b) describe their hard-sphere model for the self-diffusion, viscosity, and thermal conductivity of *n*-alkanes from methane to hexadecane. This work has been extended to include mixtures of *n*-alkanes (Assael *et al.*, 1992c), of aromatic hydrocarbons (Assael *et al.*, 1992d), and of alcohols (Assael *et al.*, 1994). All of these materials, and the refrigerants described above, are included in the computer package called TRANSP developed by Assael, Dymond, and co-workers. Hard-sphere correlations for the thermal conductivity and viscosity of a wide range of polar liquids are also provided by Bleazard and Teja (1996). A total of 58 polar liquids, including alcohols, diols, disulfides, amines, carboxylic acids, alcohol-ethers, pyridines, ethanol-amines, ethanoates, and poly(ethylene glycol)s are represented by this correlation at temperatures from 293 to 493 K.

Thermal-conductivity correlations for many of these materials are contained in three NIST databases: NIST12, NIST14, and NIST SUPERTRAPP (Friend and Huber, 1994). NIST12 contains detailed information on a wide range of thermophysical properties, including liquid thermal conductivity, for pure light gases, including *n*-alkanes up to butane. NIST14 is a mixture correlation that contains many of the materials in NIST12 plus *n*-alkanes to hexane, and hydrogen sulfide. The extended corresponding-states technique used in NIST14 uses propane as a reference fluid, and exact shape factors are computed from the pure-fluid correlations for each of the components in this database. NIST14 also uses the pure-fluid correlation directly when a pure fluid is selected. The NIST SUPERTRAPP database currently has information on 116 fluids for which there is much less reliable data available. The NIST SUPERTRAPP program can estimate the properties of pure fluids and mixtures containing up to 20 components using extended corresponding states. The package does not currently contain information on alcohols but does include normal and branched alkanes to *n*-tetracosane, cyclic and aromatic hydrocarbons, alkenes, and di-alkenes. The extended corresponding-states model of NIST SUPERTRAPP has recently been extended to undefined liquid mixtures by Baltatu *et al.* (1995), and requires only the specific gravity and the mean average boiling point as input parameters to obtain estimates of the liquid thermal conductivity. A collection of liquid thermal-conductivity data and correlations can also be found in the American Institute of Chemical Engineers DIPPR Data Compilation of Pure Compound Properties.

5.4 Aqueous Systems

The thermal conductivity of water is best described by the water model of the International Association for the Properties of Water and Steam (IAPWS) and can be used as the basis of property calculations associated with processes using steam as the working fluid, such as electric power generation (Sengers and Watson, 1986). Many measurements have been reported for the thermal conductivity of aqueous salt solutions, but no global correlation scheme has been reported as for the case of refrigerants, fuels, and petrochemicals largely because of theoretical difficulties. The maximum in the saturated-liquid thermal conductivity of water near 400 K, shown in Fig. 7, provides some insight into the difficulties in predicting the thermal conductivity of mixtures containing water as a component. There is certain to be new development in the description of the thermal conductivity of aqueous mixtures because of their industrial and environmental importance.

GLOSSARY

Bubble-Point Locus: The locus of state points, characterized by temperature, pressure, etc., where the first bubble of gas begins to form in a liquid mixture of defined composition at equilibrium.

Corresponding States: When the intermolecular potentials of two fluids are conformal, such that characteristic energy (temperature) and distance (density) parameters can be properly scaled, the thermophysical properties of one fluid can be mapped to those of another.

Critical Point: In a pure fluid the gas–liquid critical point is where the vapor-pressure curve terminates. In a mixture the gas–liquid critical point is the point where the dew-point locus meets the bubble-point locus.

Dilute-Gas Thermal Conductivity: The dilute-gas thermal conductivity is defined in the limit of zero density. This is not physically attainable since heat transfer at zero density is due to molecular conduction (collisions of molecules with enclosure surfaces rather than collisions between molecules themselves), so that extrapolation from higher densities is necessary.

Excess Thermal Conductivity: The contribution to total thermal conductivity from increasing the density (pressure) of the fluid.

Hard-Sphere Model: A liquid-phase theory that accounts for properties based on collisions between hard-sphere molecules.

Heat-Transfer Coefficient: A lumped parameter that is used by engineers to account for complex heat-transfer situations with thermal conduction, fluid convection, thermal radiation, and phase changes. Temperature differences are system specific, usually between a surface and the bulk fluid.

Thermal Conductivity: A linear coefficient that is defined by Fourier's law for heat conduction. This property characterizes heat transfer through a medium that is stationary, opaque to thermal radiation, and at steady state.

Thermal-Conductivity Critical Enhancement: The thermal conductivity of a pure fluid diverges at the gas–liquid critical point with a characteristic critical exponent. The thermal conductivity is enhanced in a region of temperature and density in the vicinity of the critical point and makes a smooth transition from divergent to background values in this crossover region.

Thermal Diffusivity: A linear coefficient that characterizes the transient diffusion of heat through a medium that is stationary and opaque to thermal radiation.

Vapor-Pressure Locus: The locus of points (temperature, pressure, and densities) where vapor and liquid coexist for a pure fluid. The vapor-pressure locus terminates in the gas–liquid critical point.

INTRODUCTION

The thermal conductivities of various solids show differences in both magnitude and temperature dependence. These result from different mechanisms of heat transport: lattice waves, free electrons, and sometimes internal electromagnetic radiation. The interaction and scattering processes that limit the contributions of these carriers have been studied not only to understand basic processes in solids, but also to understand thermal conductivity better, so that the available data can be interpolated and extended for technical purposes beyond the measured values.

1. BASIC CONCEPTS

A temperature difference within a solid causes heat flow. At any place the local value of the heat current per unit area **Q** is proportional to the local temperature gradient grad *T*. This linear relation or Fourier's law

$$\mathbf{Q} = -\boldsymbol{\lambda}\cdot \mathrm{grad}\, T \qquad (1)$$

defines the thermal conductivity $\boldsymbol{\lambda}$. In anisotropic solids it is a symmetric tensor. In isotropic materials, such as a polycrystalline aggregate without preferred orientation, $\boldsymbol{\lambda}$ becomes a scalar. In crystals of cubic symmetry, $\boldsymbol{\lambda}$ has only diagonal components equal to each other, and the conductivity acts like a scalar. For scalar λ the heat current is parallel to grad *T*. Polycrystalline cubic solids will be isotropic more readily than other polycrystalline materials.

In the definition of thermal conductivity it is implied that there is no transport of matter and no electric current. Hence a temperature gradient is generally accompanied by a thermoelectric field. Convection can be disregarded in solids, but infrared radiative heat transfer can occur within dielectric solids at high temperatures, provided they do not first become conducting and thus opaque.

The SI unit of thermal conductivity is the $\mathrm{W \cdot m^{-1} \cdot K^{-1}}$, though the $\mathrm{W \cdot cm^{-1} \cdot K^{-1}}$ is still frequently used. Conversion between various thermal conductivity units is given in the article Heat Transfer.

The principal carriers of heat in solids are lattice vibrations, free electrons, and electromagnetic radiation. The first is a mechanical transfer of energy between atoms, and this lattice thermal conductivity is present in all solids. It can often be regarded as energy flow carried by lattice waves, i.e., high-frequency elastic waves. In electrically conducting solids, thermal energy is also transferred by mobile electrons, and this electronic component of thermal conduction is related to the electrical conductivity. In transparent or translucent solids there can be transport by electromagnetic radiation, which is often size dependent.

Thus the thermal conductivity of solids shows a variety of behavior that depends on which component is dominant. The range of variation is not as wide as that of electrical conductivity, since the lattice component provides a lower limit to the thermal conductivity.

One can express the thermal conductivity as a sum of contributions by different carriers (a), i.e.,

$$\lambda = \sum_a \lambda_a = \sum_a \tfrac{1}{3} C_a v_a l_a, \tag{2}$$

where C_a is the contribution of carrier a to the specific heat per unit volume, v_a its speed, and l_a its mean free path. For each carrier, λ_a can be similarly divided into contributions from subgroups (bands and energy ranges for electrons, polarization, and frequency ranges for lattice waves). The mean free path of each carrier is limited by interactions with lattice vibrations and with the other carriers, and also by scattering at crystal imperfections, such as impurities and solutes, vacancies, dislocations, and boundaries. The lower the temperature, the greater is the relative importance of imperfections.

Table 1 gives thermal conductivities of a few solids, ranging from metals and alloys to semiconductors and insulators. This illustrates differences in behavior and ranges of variability.

2. MEASUREMENTS

The thermal conductivity λ of solids can be measured by steady-state methods or can be deduced by transient measurements that yield the thermal diffusivity α, which is defined by

$$\lambda = \alpha C, \tag{3}$$

where C is the specific heat *per unit volume.* To obtain λ from α requires a knowledge of the specific heat, but this property is not nearly as sensitive to crystal imperfections as are the thermal conductivity and diffusivity. Therefore, one can use specific-heat data obtained separately, except for ceramics at high temperatures, where an electronic contribution may depend on impurities.

Thermal-diffusivity measurements have the advantage that they do not require measuring quantities of heat; only precise knowl-

Table 1. Thermal conductivity of some solids ($\mathrm{W \cdot cm^{-1} \cdot K^{-1}}$).

T (K)	20	90	300	600	1200	1500

edge of distance and time are needed. If heat input and temperature excursions are also measured, one can obtain specific heat and thermal conductivity as well. However, in the widely used flash diffusivity technique, which measures relative temperature excursions at well-defined distances and times, one only obtains diffusivities but avoids heat measurements.

2.1 Steady-State Methods

Thermal conductivity is measured using a steady heat current, produced by a heater of known power. The current is made to flow through a specimen of regular shape. The resulting temperature gradient either is uniform or has a variation depending on the geometrical symmetry of the arrangement. It is determined by two or more thermometers at defined locations. The specimens can be rods, linking a heater and a heat sink, or plates of large area, with the heat input uniformly distributed on one side, or again they may be long cylinders with a uniform axial heat source. The problem is to ensure that all the heat that is supposed to flow through the specimen actually does so, and in a uniform manner, which is not always easy. Thermometer connections and other leads can divert heat flow. Radiation and gas conduction cause leakage from the heater and, in the case of rods, also from the side walls. Gas conduction can be reduced by evacuating the surroundings.

Radiation increases rapidly with temperature. It can be disregarded only at low temperatures, below 50 K and sometimes below 100 K or even somewhat higher, depending on the conductivity and the shape of the specimen. At higher temperatures, the specimen should be shorter, but this makes it harder to define thermometer positions. Sideways radiation can be reduced by fine powder packed around the specimen. Guard cylinders, matching the temperature drop, reduce the problem but do not eliminate it.

Comparative methods have been used with success: the same heat current is made to flow through a standard and the unknown specimen; the temperature gradients in each are compared. Each conductivity range requires a separate standard.

Since thermal conductivities vary with temperature, the temperature difference between thermometers should be small compared to the absolute temperature; this requires accurate thermometry. One must also ensure that a steady-state temperature distribution and heat flow have been reached. This requires patience and judgment. Automatic data acquisition can be of great help.

There is no quick and easy way to measure thermal conductivities. Difficulties increase with increasing temperature and decreasing conductivity. Different ranges of these values require different geometries.

2.2 Dynamic Methods

The time-dependent Fourier equation for heat conduction is

$$\frac{\partial T}{\partial t} + \alpha \operatorname{div} \operatorname{grad} T = 0, \tag{4}$$

where T is temperature, t is time, and α is the thermal diffusivity. This equation governs the temperature field for a time-dependent heat input, and the decay of temperature inhomogeneities in the absence of heat input. General methods of solving Eq. (4) and special cases are given by Carslaw and Jaeger (1959). The diffusivity is found by measuring the temperature response at times well defined compared to L^2/α, where L is the distance from a heat source to the temperature sensor.

In the Ångström method, with sinusoidal heat input at one point and a sensor at another, one measures the phase difference. The characteristic time is usually of the order of 10 s, and the heating frequency is well below 1 Hz for bar-shaped specimens. For low-conductivity materials one can use long cylinders with a central heater wire, either pulsed or sinusoidally heated. If only response times and distances are measured, the diffusivity is obtained. If heat input and temperature changes are measured as well, the thermal conductivity and the specific heat are also measured.

In the flash diffusivity method, heat is deposited on one side of a specimen disc. The temperature rise on the other side is monitored as function of time. Heat may be generated by a current pulse in a thin-film resistor or deposited by a pulse of radiative energy. An absorbing layer is used for translucent specimens. An accurate measure of specimen thickness is needed, with corrections for absorption depth or for the heat conversion layer. Corrections are required for sideways conduction. On the back face, the sensor can be a contact thermometer, such as a thermocouple, or may be an infrared detector. Modern techniques of timing and rapid data acquisition have made this method feasible, and it is now widely used.

Special techniques have been developed for fibers and thin films. Oriented bundles of fibers have been used, while for single fibers one can use the deflection of an optical beam by the heated air at a point along the fiber to measure its thermal diffusivity.

For low-conductivity materials and thin films, a powerful method has been developed recently (Cahill, 1990). A thin metal strip deposited on the surface is heated by an alternating current, and its temperature is measured. The amplitude of the third harmonic of temperature, studied as function of ac frequency, yields the thermal conductivity.

Thermal-conductivity measurements have been discussed by Parrott and Stuckes (1975), by several contributors in Tye (1969), and by Ho in Touloukian *et al.* (1970). Transient techniques are treated by Kubičar (1990).

3. LATTICE WAVES

In a regular lattice of atoms linked to each other by harmonic forces, the normal modes of vibration are progressive displacement waves. The displacement $\mathbf{u}$ of the atom at site $\mathbf{x}$ at time t is, for each such wave, of the form

$$\mathbf{u}(\mathbf{x},t) = A(\mathbf{q},j)\boldsymbol{\epsilon}_j \exp(i\mathbf{q}\cdot\mathbf{x} - i2\pi ft), \qquad (5)$$

where $\mathbf{q}$ is the wave vector, f the frequency, $\boldsymbol{\epsilon}_j$ a unit vector in the direction of displacement or polarization, and A the amplitude. Each normal mode or lattice wave is specified by $\mathbf{q}$ and by the polarization, denoted by the index j. In an isotropic medium, the three polarization directions $\boldsymbol{\epsilon}$ are longitudinal (one) and transverse (two). In a crystal, these three directions are still mutually perpendicular but not simply related to the direction of $\mathbf{q}$ except for propagation in a principal direction. At low frequencies or long wavelengths these waves are the same as elastic waves in the corresponding continuum, where for any direction, frequency and wave vector are proportional to each other. Thus the phase velocity $2\pi f/q$ depends on direction of $\mathbf{q}$ but not its magnitude.

At high frequencies, when wavelengths are comparable to interatomic distances, f does not vary linearly with $\mathbf{q}$, and the three polarization directions, still mutually perpendicular, depend also on the magnitude of $\mathbf{q}$. The periodicity of the lattice limits the number of physically distinct values of $\mathbf{q}$; this number equals the number of unit cells in the crystal, while the number of polarizations for each $\mathbf{q}$ is three times the number of atoms per unit cell, so that there are three normal modes for each atom. There are three polarization branches for which $f \to 0$ as $q \to 0$; these are acoustic branches. For the others, the optical branches, there are no corresponding waves in the elastic continuum.

The vibrational energy of each mode is

$$E(\mathbf{q},j) = (2\pi f)^2 M|A(\mathbf{q},j)|^2, \qquad (6)$$

where M is the average atomic mass. The thermal energy of vibration is the sum of E over all normal modes.

According to quantum mechanics, the energy of each normal mode is not continuously variable but consists of an integral number N of quanta, each of energy hf, where h is the Planck constant. There is, in each mode, also an irreducible zero-point energy $hf/2$, which is part of the energy of formation of the crystal, and not regarded as thermal energy. The quanta of energy, hf, are the phonons; there are $N(\mathbf{q})$ phonons in each mode $\mathbf{q}$ (the polarization index j will now be implied).

Because real lattice forces have anharmonic (nonlinear) components, and because real crystals are not structurally perfect and also have external boundaries, the lattice waves are not true normal modes, so that energy is exchanged between them continuously. This interaction establishes thermal equilibrium. The average number of phonons and the average energy content of a mode of frequency f at temperature T in thermal equilibrium is

$$N^0 = [\exp(hf/kT) - 1]^{-1}, E^0 = hfN^0, \qquad (7)$$

where k is the Boltzmann constant. In the classical limit (when $T > hf/k$), E^0 approaches kT.

For thermodynamic properties, it suffices that interactions exist and establish equilibrium. To understand transport properties such as thermal conductivity one must also know the strength of these interactions.

The specific heat (per unit volume) due to lattice waves is

$$C = \int C(f)df = \int g(f)hf\frac{dN^0(f)}{dT}df, \qquad (8)$$

where $g(f)$ is the number of modes per unit volume in the frequency interval df. The lattice vibrations can be regarded as a gas of phonons, each carrying energy hf with a velocity equal to the group velocity of the wave, $\mathbf{v} = 2\pi\partial f/\partial \mathbf{q}$.

4. THERMAL CONDUCTIVITY OF INSULATORS

Except at very high temperatures, where electronic conduction or radiation may become appreciable, the thermal conductivity is due to phonons. Equation (2) can be generalized to a sum over polarizations and an integration over frequencies, so that

$$\lambda_p = \tfrac{1}{3}\sum_j \int C_j(f)v_j(f)l_j(f)df. \qquad (9)$$

Here $C_j(f)$ is the spectral contribution to the specific heat per unit volume due to the jth polarization branch, v the magnitude of the group velocity, and l the mean free path, a function of frequency and polarization. The factor $\frac{1}{3}$ applies to isotropic or cubic solids. The equation must be modified for highly anisotropic solids. Note that $l = v\tau$, where τ is a relaxation time, which describes the return to equilibrium of a perturbed distribution. The integrand thus contains the group velocity as a factor v^2; even modes of negative group velocity make a positive contribution to the conductivity. The major contribution to λ_p comes usually from the three acoustic-mode branches. Optical modes contribute significantly when two sublattices have nearly equal masses, so that the optical branch is almost a continuation of the acoustic one.

The mean free path $l(f)$ depends on the temperature and crystal perfection. It is limited by the following processes:

1. interaction between lattice modes, or phonon–phonon interactions, due to departures of the interatomic potential energies from a quadratic (harmonic) dependence on relative displacements;
2. scattering of phonons by lattice imperfections (e.g., solute atoms, other point defects, dislocations, extended defects, and inclusions), similar to scattering of elastic waves by irregularities; and
3. scattering of phonons by external boundaries, or by grain boundaries in polycrystalline aggregates.

4.1 Intrinsic Thermal Conductivity

This is governed by the anharmonic or nonlinear components of the interatomic force constants, that is, components of the potential energy of cubic or higher power in the relative displacements or strains. The cubic terms cause energy interchange between groups of three modes at a time. In the quantum mechanical description, two modes lose one phonon each, and one mode gains one phonon, or vice versa. For three interacting modes, of wave vectors $\mathbf{q}$ and $\mathbf{q}'$, transferring energy into mode $\mathbf{q}''$, there is a condition of energy or frequency conservation

$$f + f' = f''; \qquad (10)$$

and since the anharmonic linkages form a regular lattice, there is a wave-vector selection condition

$$\mathbf{q} + \mathbf{q}' = \mathbf{q}'' + \mathbf{b}. \qquad (11)$$

Here $\mathbf{b}$ is a reciprocal lattice vector of the crystal lattice. The case $\mathbf{b} = 0$ is a normal or N-process. When $\mathbf{b} \neq 0$, one speaks of a U-process (Umklapp or flip-over process), a combined three-phonon interaction and Bragg reflection. U-processes cannot occur in an elastic continuum. N-processes cannot, by themselves, restore equilibrium if the phonon distribution is biased in direction, as it is in the presence of a temperature gradient. However, they can enhance the relaxation rate in combination with other processes, by transferring energy from modes that are weakly scattered to those that experience stronger scattering.

At temperatures at or above the Debye temperature, i.e., in the equipartition regime when $E^0 = kT$ for all modes, the intrinsic mean free path becomes

$$l_i(f,T) = (16\pi)^{-1}v(\mu a^3/kT)f_m/f^2, \qquad (12)$$

where f_m is the highest frequency of the acoustic branch, a^3 the volume per atom, and μ the shear modulus. The numerical constant is somewhat uncertain and depends on the approximations made. If one uses a Debye-type approximation for $C(f)$, i.e., $C(f) \propto f^2$, and integrates Eq. (9) from 0 to f_m, the intrinsic thermal conductivity becomes

$$\lambda_i = (3/16\pi)\mu v^2 T^{-1} f_{\mathrm{D}}^{-1} N^{-2/3}, \qquad (13)$$

where f_{D} is the Debye frequency and N the number of atoms per unit cell. This expression is similar to the one first derived by Leibfried and Schlömann, which has been compared to the conductivity of many dielectric crystals by Slack (1979).

It is interesting that, since $C(f) \propto f^2$ and $l_i \propto f^{-2}$, the integrand in Eq. (9) containing $C(f)l_i(f)$ is independent of f, so that equal frequency intervals make equal contributions to the intrinsic conductivity. This contrasts with the vibrational energy content, which is dominated by the highest frequencies.

At low temperatures heat is carried mainly by low-frequency waves ($f \sim kT/h$). Intrinsic thermal resistivity is then due to U-processes, which require the prior presence of phonons near the zone boundary. As a result, the intrinsic mean free path has the form

$$1/l_i \propto f \exp(-T_c/T), \qquad (14)$$

where kT_c/h is comparable to the frequency of zone boundary modes, but may change with temperature and defect content. Typically T_c is around half the Debye temperature. The intrinsic thermal conductivity increases rapidly with decreasing temperature, until at very low temperatures the mean free path is limited by boundary scattering. Near that transition, thermal conductivities go through a pronounced maximum.

4.2 Boundary Scattering

Both external boundaries and grain boundaries limit the phonon mean free path to a value L, which is of the order of the smallest linear dimension of the crystal, or, in the case of polycrystalline aggregates, of the order of the average grain diameter. However, L is not quite independent of frequency but increases slowly with decreasing frequency. In the case of external boundaries, the diffuse component of scattering depends on roughness and increases with frequency. Thus, below the maximum, the thermal conductivity increases with crystal size, and $\lambda(T)$ increases with T, but not as rapidly as the specific heat.

Polycrystalline solids have a conductivity at low temperatures much lower than single crystals. Grain-boundary scattering is probably due to thin intergranular regions, rather than due to misorientation of grains. The thermal conductivity increases with temperature, but significantly more slowly than the specific heat. At ordinary and high temperatures, the effects of grain-boundary scattering persist, affecting phonons of lowest frequencies. For micron-sized grains the conductivity reduction is of the order of 1% to 3%, which is comparable to the precision of measurements.

4.3 Defects

Point defects (solute atoms, isotopic mixtures, vacancies, and interstitials) scatter as f^4 and affect mainly the high-frequency modes. Extended defects scatter with weaker frequency dependence. Sheetlike defects (inclusion plates and stacking faults) scatter as f^2. Sessile dislocations scatter as f, in virtue of their long-range strain field. Mobile dislocations show resonance scattering as well. Thus point defects are important at ordinary temperatures but may also be significant at temperatures near the conductivity maximum at lower temperatures, while extended defects are important at low temperatures. Three-phonon N-processes often enhance the effect of point defects; they conserve phonon momentum $h\mathbf{q}/2\pi$, but transfer excess momentum of the phonon gas from low frequencies, where point-defect scattering is weak, to modes of high frequencies, where scattering is strong. The role of N-processes has been well discussed by Berman (1976).

Point-defect scattering cross sections can be estimated if the nature of the defects is known, and with confidence for substitutional atoms differing from normal atoms in regard to mass only. In some crystals the naturally occurring isotopic mass fluctuations reduce the low-temperature thermal conductivity below its intrinsic value, the value it would have if limited only by anharmonic processes. Measurements on crystals with artificially controlled isotopic compositions have been made on germanium, lithium fluoride, diamond, and solid helium.

At ordinary and high temperatures, solute atoms of large mass difference and vacancies cause observable decreases in thermal conductivity if their concentration exceeds a few percent. The conductivity of mixed crystals has a minimum around 50% concentrations. At low concentrations c, if point-defect scattering is strong, $\lambda \propto (Tc)^{-1/2}$. Point defects reduce the contributions to the conductivity by high-frequency phonons. Additional reductions are caused by extended defects and grain boundaries, as well as by conduction electrons. These reduce the contribution of the low frequencies. The thermal conductivity of Si-Ge alloys has been extensively studied and conforms to this picture.

5. ELECTRONIC THERMAL CONDUCTIVITY

This is the dominant component in pure metals and dilute alloys, the most important component in alloys, and significant in semimetals and in semiconductors with large electron or hole concentration. In principle it is given by Eq. (2), so that

$$\lambda_e = \tfrac{1}{3} C_e v_e l_e, \tag{15}$$

where l_e is the electron mean free path and v_e an electron velocity. However, the electronic contribution to the specific heat is usually only a small part of the total, so that Eq. (15) is not useful. Also the mean free path l_e occurs as a factor in the electrical conductivity, and it is more useful to relate λ_e to the electrical conductivity σ. The Wiedemann–Franz law, extended by Lorenz, expresses λ_e as

$$\lambda_e = L\sigma T, \tag{16}$$

where T is the absolute temperature and L, the Lorenz ratio, is $L = n(k/e)^2$, where k is the Boltzmann constant, e the electronic charge, and n a numerical parameter whose value, given by theory, is discussed below. It usually ranges from 2 to 4, but can exceed that value substantially in intrinsic semiconductors. In pure metals at low temperatures, n can be smaller.

The electric current caused by a field is made up of contributions from electrons of different energies E, so that the electrical conductivity can be expressed as

$$\sigma = \int \left(-\frac{df^0}{dE}\right) s(E)dE, \tag{17}$$

where $s(E)$ is the product of the density of electron states and the mobility. The latter contains the electron mean free path $l_e(E)$. The other factor in the integrand is the derivative of the Fermi–Dirac electron distribution function in equilibrium,

$$f^0(E,\zeta,T) = \{\exp[(E - \zeta)/kT] + 1\}^{-1}, \tag{18}$$

where ζ, the Fermi energy, depends on temperature and electron density.

A temperature gradient perturbs the electron distribution, making electrons flowing down the temperature gradient slightly warmer. This produces both an electric and a heat current. The definition of thermal conductivity requires zero electric current; hence there is a thermoelectric field to oppose that current. Defining moments of the integrand of Eq. (17) by

$$M_m = \int - \left(\frac{df^0}{dE}\right) s(E) \left[\frac{E - \zeta}{kT}\right]^m dE, \tag{19}$$

one can show the Seebeck coefficient to be $S = (k/e)M_1/M_0$, and the Lorenz ratio to be

$$L = n(k/e)^2 = (k/e)^2[M_2/M_0 - (M_1/M_0)^2]. \tag{20}$$

This expression applies generally, from cases of high electron densities in metals to low densities in semiconductors, including when both electron and hole bands contribute (ambipolar diffusion). The Lorenz ratio is proportional to the second moment of the partial electrical conductivity about the mean energy of conduction (Klemens, 1969). However, this result assumes that the electron mean free path is the same for thermal as for electrical conduction.

6. METALS

In metals the electron density is high and the electron gas is highly degenerate—that is, at the Fermi energy the density of free-electron states is high—and both the density of states and the partial conductivity $s(E)$ in Eq. (19) are almost constant over an energy interval of order kT above and below ζ, which is the important energy range for electrical and thermal conduction. If $s(E)$ is constant, the ratio M_2/M_0 is determined by the width of the bell-shaped function $-df^0/dE$ in units of kT, and $M_2/M_0 = -\pi^2/3$, while $(M_1/M_0)^2$ is negligible (or S is small compared to $k/e = 86\ \mu\text{V/deg}$). This leads to the Sommerfeld (1933) value of L:

$$L_0 = (\pi^2/3)(k/e)^2 = 2.45 \times 10^{-8}\ \text{V}^2/\text{deg}^2. \tag{21}$$

Any asymmetry of $s(E)$ about ζ causes a small Seebeck coefficient S; L is below L_0 by S^2. Curvature of $s(E)$ causes a further deviation from L_0. This may be of either sign, but positive deviations are more common at high temperatures (White, 1991). The reason may be a tendency, for reasons of crystal stability, for ζ to lie preferably at a minimum in the density of states and avoid a maximum. The higher the temperature, the larger the deviations of L from L_0. Deviations up to about 15% occur above 1000 K in transition metals, where the subbands of the d electrons give structure to the density of states of the required scale. See Klemens and Williams (1986).

The thermal conductivity of metals can be understood in terms of the electrical conduction. The mean free path of electrons is limited by scattering processes, both by thermal vibrations or phonons, and also by impurities, solutes, and other lattice defects. The corresponding electrical resistivities are the temperature-dependent intrinsic resistivity $\rho_i(T)$, which tends to zero at very low temperatures, and the residual resistivity ρ_0, independent of T but depending on defect content or solutes. According to Matthiessen's rule the resistivity is additively composed of these two components, but there are deviations $\Delta\rho$, so that

$$\rho = \rho_0 + \rho_i(T) + \Delta\rho, \tag{22}$$

where $\Delta\rho$ vanishes as ρ_0 or T goes to zero.

The electronic thermal resistivity $W_e = 1/\lambda_e$ can be similarly expressed as

$$W_e = W_0 + W_i + \Delta W. \tag{23}$$

Now one expects that ρ_0 and W_0 are related by the Sommerfeld Lorenz ratio, i.e., $W_0 = \rho_0/L_0T$. The relation between ΔW and $\Delta\rho$ is not well known, since when $\Delta\rho$ is large, there is usually an appreciable lattice component of thermal conductivity. However, theoretically one expects ΔW to equal $\Delta\rho/L_0T$, at least approximately. Only at low temperatures in pure metals ($W_i > W_0$) does one find that ΔW is much larger than $\Delta\rho/L_0T$. This is expected from the transport equations.

At ordinary and moderately high temperatures, one also expects that $W_i(T) = \rho_i(T)/L_0T$, so that $\lambda_e = L_0T/\rho$ for metals, except for departures of L from L_0 at very high temperatures because $s(E)$ is not quite constant, as mentioned above. Since for most metals $\rho_i \propto T$, λ_e is only weakly temperature dependent.

However, at low temperatures $W_i(T)$ does not decrease as rapidly as $\rho_i(T)/T$ with decreasing T, and the Lorenz ratio ρ_i/TW_i is not constant for pure metals but is proportional to T^2, until a temperature is reached where W_0 is comparable to W_i. This follows from the formal solution of the Boltzmann equation (Wilson, 1952). It can also be physically explained in terms of a shorter electron mean free path for thermal conduction than for electrical conduction; see, e.g., Klemens (1956). Electrons are brought into equilibrium by electron–phonon interactions. In each interaction the energy of an electron is altered by an amount of order kT, and the direction by an angle of order T/θ, where θ is the Debye temperature. At low temperatures it takes many such interactions (of order θ^2/T^2) to reverse the direction of an electron, but only one interaction to change its energy significantly, so that the mean free path for electrical conduction exceeds that for thermal conduction by that same factor. In metals of simple band structure $\rho_i \propto T^5$ while $W_i \propto T^2$.

For a more detailed discussion of the Lorenz ratio see Klemens and Williams (1986), and for low-temperature conduction properties, Klemens (1956).

At ordinary and high temperatures the electrical and thermal conductivities of metals are not very sensitive to solute impurities. A rough but general rule states that it takes around 1 at.% of solutes to double the electrical and thermal resistivities at room temperature, with correspondingly smaller changes at higher temperatures. Impurities that are not dissolved in the matrix have little effect. At low temperatures the effect of solutes is more pronounced.

Figure 1 shows the thermal conductivity of pure copper. From room temperatures up, it is practically constant. At low temperatures it increases, consistent with $W_i \propto T^2$. Finally, depending on specimen perfection, a temperature is reached where W_0 and W_i are equal and the conductivity is a maximum. At still lower temperature, $\lambda = L_0T/\rho_0$ and varies from sample to sample. In copper and in other metals of high electrical conductivity, the lattice component is negligible.

7. ALLOYS

There is a gradual transition in the thermal conductivity from pure metals, with impurity content up to 0.1 at.%, to alloys with solute content exceeding 1%. The term W_0 in Eq. (23), which dominates only at low temperatures in metals, now becomes comparable with or larger than W_i at room temperatures, and with increasing solute content at even higher temperatures. The electronic component λ_e increases linearly with T and continues to increase, even though more slowly, at highest temperatures. Since λ_e is now smaller, the lattice component λ_p is no longer insignificant, particularly at low temperatures.

The lattice thermal conductivity at ordinary and high temperatures of metals and dilute alloys is similar to that of dielectric solids of comparable elastic properties, limited also by anharmonic interactions, so that $\lambda_p \propto T^{-1}$. However, in concentrated alloys it is reduced by the solute atoms, which scatter the high-frequency phonons, especially by solute atoms of substantial mass difference. This also reduces the temperature dependence until it approaches $\lambda_p \propto T^{-1/2}$, just as for mixed dielectric crystals. Solutes that dif-

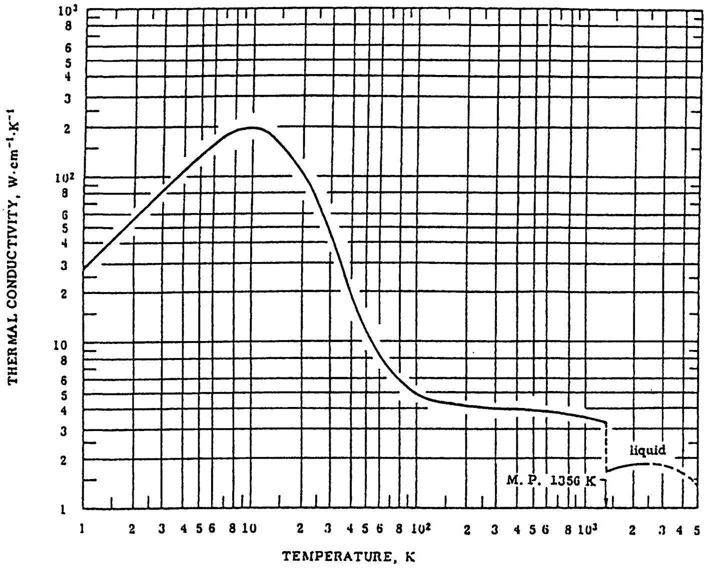

FIG. 1. Thermal conductivity of copper, "recommended" values derived from several reliable measurements for a hypothetical specimen of residual resistivity $\rho_0 = 1 \times 10^{-3}\ \mu\Omega\cdot\text{cm}$ by Touloukian *et al.* (1970).

fer substantially in size from the host have limited solubility and thus a smaller effect.

The phonon mean free path at low frequencies is limited by interactions with electrons, so that the lattice component is decreased. At low temperatures λ_p varies with T between T and T^2 and attains a maximum around 30 K. In some transition metals this maximum can be very broad. Thus λ_p is considerably lower than in dielectric solids at low temperatures and does not depend on external specimen size or grain size in polycrystalline specimens.

The thermal conductivity is thus composed of two components: λ_e varying as T at low temperatures and gradually less rapidly at higher temperatures, and λ_p, which has a maximum somewhere between 20 and 40 K. Therefore λ has a hump near that temperature. Figure 2 shows the thermal conductivity of a Cu-Zn alloy after plastic deformation and after various stages of annealing. Since $\lambda_e = L_0T/\rho$, it can be calculated from the measured electrical resistivity, and λ_p can be deduced. The lattice conductivity is reduced by plastic deformation, because phonons are scattered by dislocations. Dislocations are removed by annealing, so that λ_p increases and the "hump" becomes more pronounced. The low-temperature thermal conductivity of alloys can be more sensitive to cold work than the electrical resistivity.

While copper, silver, and gold alloys can have significant lattice components even close to room temperature, this component is smaller for aluminum alloys and negligible near room temperatures and above. For aluminum alloys the simple Wiedemann–Franz law $\lambda = L_0T/\rho(T)$ can be used to estimate the thermal conductivity, except below 70 K. Transition-metal alloys, where λ_e is smaller, sometimes have significant lattice components even at room temperatures. At low temperatures λ_p is smaller because the interaction of phonons with d-band electrons is stronger than in the simple metals (Klemens and Williams, 1986).

So far only single-phase alloys have been discussed. If two or more phases are present, the overall conductivity is an average of that of the phases, as discussed in Sec. 9. Similar considerations also govern their electrical conductivity. If all the phases are metallic, one can assume, as a first approximation, that the overall thermal and electrical conductivities are related by the Wiedemann–

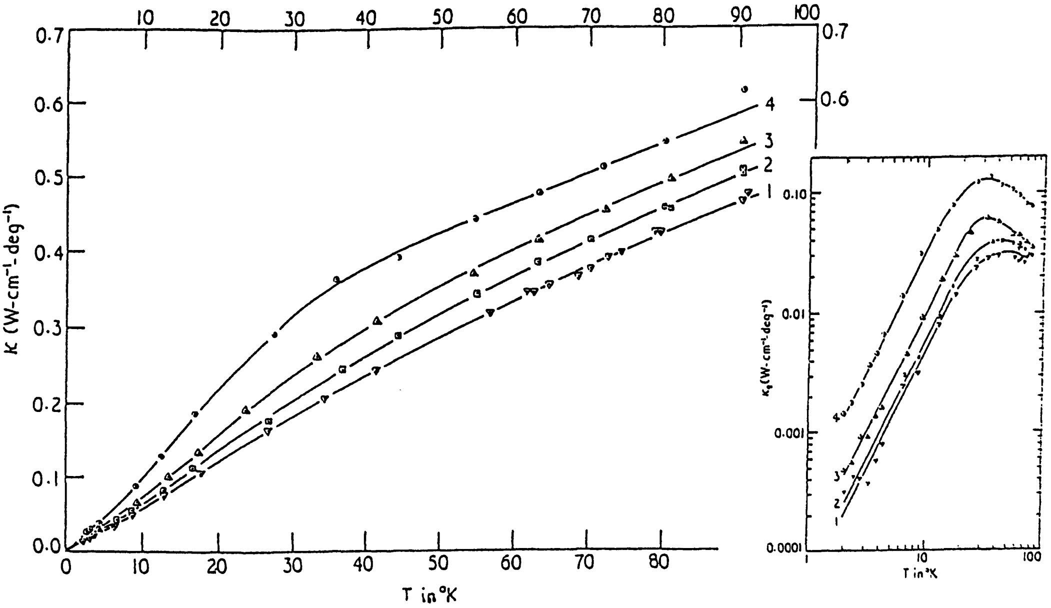

FIG. 2. Thermal conductivity of Cu-30% Zn after severe plastic deformation (curve 1), and subsequent annealings to 250 °C (curve 2), 290 °C (curve 3), and to 450 °C (curve 4). Insert shows calculated lattice components. From Kemp *et al.* (1959).

Franz law. However, if one phase is metallic and the other electrically insulating, this is no longer the case.

8. SEMIMETALS AND SEMICONDUCTORS

In semimetals the density of free electrons is less than in metals, and the electron gas is not highly degenerate at ordinary temperatures: the density of states and $s(E)$ vary over energies of order kT near ζ. Furthermore, λ_e is lower, so that λ_p is more important and, in some cases, the dominant component. At the Fermi energy the density of electron states is finite, so that there are free electrons and a finite electrical conductivity even at very low temperatures.

In semiconductors there are two bands separated by an energy gap, with the Fermi energy lying within the gap. The electron and the hole bands each contain a small number of carriers with Maxwell–Boltzmann distributions. The concentration of carriers is readily changed by donor or acceptor solute atoms. However, when these donors or acceptors provide a sufficiently large carrier concentration, either electrons or holes, the carrier concentration becomes somewhat degenerate, λ_e becomes appreciable, and the semiconductor approaches the behavior of a semimetal.

The lattice component of thermal conductivity is, in both cases, similar to that of a dielectric crystal of comparable elastic properties and size, except that phonons can also be scattered by electrons or holes. However, unlike the case in metals, only phonons of low frequency can interact with the carriers, because the partially occupied electron or hole states occupy only limited regions in wave-vector space. In semimetals this limits the wave vectors of the interacting phonons to the diameter of the Fermi surfaces, with a corresponding upper bound to their frequencies. In semiconductors this upper bound depends on temperature, and varies as $T^{1/2}$ for electron–phonon interactions within a valley. Some semiconductors contain more than one valley. Intervalley scattering reduces the mean free path of phonons in narrow frequency bands at high frequencies.

In arsenic and antimony the thermal conductivity is mainly electronic, but L departs from L_0 because $s(E)$ is not constant about ζ. The lattice conductivity shows up as a hump around 20 K in As and around 10 K in Sb. The separation into λ_e and λ_p has been made by magnetothermal conductivity measurements. Bismuth, on the other hand, has a relatively small electronic component. The thermal conductivity is essentially due to λ_p except below about 3 K, where $\lambda_e \propto T$ becomes larger than $\lambda_p \propto T^3$. At higher temperatures bismuth has the thermal conductivity of a dielectric crystal.

Graphite, with an electron and a hole band that overlap slightly, has a dominant electronic component at very low temperatures with $L = L_0$, and again at very high temperatures with $L \approx 2L_0$. Except at these extreme temperature ranges, the lattice component dominates. It also differs from other solids because of its layer structure that makes both the electrical conductivity and the thermal conductivity, including the lattice component, very anisotropic. The phonon gas has a two-dimensional character at all but low temperatures. This enhances contributions from low frequencies, and thus increases the sensitivity of the lattice thermal conductivity to extended defects (see Sec. 11.4).

The thermal conductivity of semimetals has been reviewed by Uher (1991).

In semiconductors of large band gap, such as germanium and silicon, the intrinsic electrical conductivity is small and λ_e is not important, except at high temperatures in Si. Donors and acceptors increase the electrical conductivity, so that λ_e becomes comparable to λ_p at high temperatures and carrier concentrations. The Lorenz ratio $\lambda_e/\sigma T$ depends somewhat on the energy dependence of the electron mean free path, and for single-band conduction it is related to the thermoelectric power.

In the intrinsic regime, L is increased by ambipolar diffusion. Both the electron and hole bands contribute to the conduction. This enhances M_2/M_0 in Eq. (20). Thus L increases with increasing band gap, but σ decreases, so that the ambipolar enhancement of λ_e is most important for moderately large band gaps, such as in InSb. Graphite, as mentioned above, can be regarded as an intrinsic semiconductor with zero band gap, and $L \simeq 2L_0$, though λ_e is only appreciable at very high temperatures.

The thermal conductivity of semiconductors has been reviewed by Steigmeier (1969).

9. SUPERCONDUCTORS

In the normal state, either above the transition temperature or in a sufficiently high magnetic field, the thermal conductivity is like that of a metal or alloy, with electronic and lattice components, and λ_p is usually small in pure metals. In the superconducting state, the thermal conductivity changes and may be either smaller or larger than in the normal state. This can be understood as follows: The electron gas can be divided into Cooper pairs, responsible for superconductivity, and normal electrons, reduced in number. Only the latter are disordered. Therefore:

1. The electronic component λ_e is smaller in the superconducting state than in the normal one, particularly well below the transition temperature, because Cooper pairs carry no entropy.
2. The lattice component λ_p is often increased. While the scattering of phonons by imperfections does not change, the interactions of phonons with electrons is decreased, since Cooper pairs do not scatter phonons. Those lattice waves whose phonon mean free path is normally limited significantly by the phonon–electron interactions have, in the superconducting state, a larger mean free path. At sufficiently low temperatures it is limited only by grain boundaries or by other imperfections.
3. In a mixed state, where flux is trapped in the form of flux tubes or vortices within the material and forms normal regions, the phonon mean free path within the superconducting regions can be limited by the interaction with these vortices. This additional scattering mechanism reduces λ_p in the superconducting regions. The overall thermal conductivity is that of an inhomogeneous solid composed of regions of two different conductivities. Inhomogeneous solids will be discussed in Sec. 10.

In conventional pure-metal superconductors below the transition temperature, the thermal conductivity is therefore lower than in the normal state, where the conductivity is mainly electronic. Well below the transition temperature, λ_e decreases exponentially with decreasing T, because the electronic specific heat C_e behaves likewise. At very low temperatures λ_e is so small that λ_p dominates and varies as T^3, since the mean free path is boundary limited. However, λ_p can be reduced by plastic deformation, because of dislocation scattering; the material thus behaves like an insulator, but with the plastic properties and dislocation density of a metal.

In alloys, depending on the ratio of λ_e to λ_p in the normal state, the conductivity can be either larger or smaller in the superconducting state. At very low temperatures, λ_p will again dominate in the superconducting state. Scattering of phonons by solute atoms is then rarely important.

In the high–transition-temperature superconductors, often called cuprate superconductors, the change in thermal conductivity is usually smaller. The lattice component is a significant fraction of the total in the normal state, but since the transition occurs at higher temperature, the role of electrons in limiting λ_p is smaller; thus the removal of the phonon–electron interaction has a smaller effect on λ_p. Also, the lattice conductivity is often limited by imperfections. There is, however, a possibility that λ_e increases in the superconducting state. Even though C_e decreases, it is possible that the mean free path of the electronic quasiparticles increases. This may give rise to an increase in the thermal conductivity just below the transition temperature.

Thermal conductivities of superconductors were reviewed by Klemens (1956) and Berman (1976), and that of high-T_c superconductors, by Uher (1992).

10. INHOMOGENEOUS CONDUCTORS

Many technically important solids are composites of different materials, each with a different thermal conductivity. Solids containing nonconducting inclusions or pores form a special case, as do solids with highly conducting inclusions in a low-conductivity matrix. The problem of estimating the overall thermal conductivity is mathematically the same as that of calculating the electrical conductivity and the dielectric constant of composites. In addition to composites with sharp boundaries between components, one can also have continuous variations with position of the local conductivity. These problems have not been solved in general, but there are various approximations, applicable to different cases. The literature of these mathematical treatments is widely scattered according to different applications. A useful review is by Landauer (1978).

A related problem is that of averaging elastic moduli of composites, and also thermal expansivity, though in these problems one deals with more parameters. Both of these problems can be formulated in terms of minimizing strain energy, while the conduction problem can be expressed in terms of minimizing the rate of entropy production.

An upper bound to the effective conductivity is provided by the volume average of the conductivities, while an upper bound to the effective resistivity, or a lower bound to the conductivity, is given by the volume average of the resistivities. If there is not too much contrast between local conductivities, these two bounds can be very useful. In other cases one of these bounds may be useful, while the other bound is far removed and thus useless.

A perturbation method, first given by Herring and subsequently extended (Klemens, 1991), expresses the space variations of the conductivity, or those of resistivity, in terms of Fourier components. The effective conductivity λ_{eff} can be expressed as

$$\lambda_{\mathrm{eff}} = \lambda_0 - \langle\cos^2\theta\rangle\langle\Delta\lambda^2\rangle/\lambda_0, \tag{24}$$

where λ_0 is the volume average of the conductivity, $\langle\Delta\lambda^2\rangle$ the mean square departure from that average, and $\langle\cos^2\theta\rangle$ the average square of the direction cosine of the Fourier components with respect to the direction of the temperature gradient. In the absence of a preferred direction, $\langle\cos^2\theta\rangle = \frac{1}{3}$. Similarly the effective resistivity W_{eff} can be expressed in terms of the volume average W_0, the mean square fluctuations $\langle\Delta W^2\rangle$, and the mean square of the sine of the Fourier components with respect to the heat flow direction, by means of

$$W_{\mathrm{eff}} = W_0 - \langle\sin^2\theta\rangle\langle\Delta W^2\rangle/W_0. \tag{25}$$

Without preferred direction, $\langle\sin^2\theta\rangle = \frac{2}{3}$. Depending on which fluctuation is smaller, $\langle\Delta\lambda^2\rangle/\lambda_0^2$ or $\langle\Delta W^2\rangle/W_0^2$, one or the other of the two approximations is preferable. For large contrasts and in the middle of the concentration range, perturbation methods break down.

A different approach is that of the mean-field approximation. To obtain the effective conductivity, the field pattern is calculated around and in an inclusion in a matrix of different conductivity, but the conductivity of the matrix is not that of the matrix material itself, but that of the matrix that contains inclusions—that is, the effective conductivity. This is a good approximation, provided inclusions do not interact. An extension of this approach is to consider three regions: the inclusion, the pure matrix surrounding the inclusion, and the average material. This and other approximations are discussed by Parrott and Stuckes (1975) and also by Grimvall (1986).

While there are many theories that are used to interpret conductivity measurements, there are only a few controlled experiments to test them. No approximation appears to hold over the entire composition range for large conductivity differences of the components. Percolation theories may be applicable in such cases.

11. SPECIAL TOPICS

11.1 Heat-Conducting Substrates

Solid-state electronic components are mounted on insulating substrates, which in turn are mounted on a metallic base. Increasing miniaturization, needed for fast processing and compactness, makes special demands on the ability of the substrate to remove heat by conduction. To achieve a high thermal conductivity, the substrate should be a crystalline dielectric solid of simple atomic structure, of low atomic weight, and free of defects. It need not be a single crystal: at ordinary temperatures the conductivity of a fully densified polycrystalline solid is usually within a few percent of the corresponding single crystal.

The advantage of low atomic weight and simple structure (small unit cell) follows from Eq. (13): one notes that elastic moduli do not vary as much as does the mean atomic mass, which enters into the factor v^2/f_D. The highest conductivity is that of diamond, which can now also be grown as reasonably defect-free thin films. Aluminum nitride, silicon carbide, and beryllia also have good thermal conductivities, and these may be even higher than observed so far, if they can be made free of defects and large grained.

Of course, high thermal conductivity is not the only requirement. Good heat transfer at the interface between the semiconductor circuit element and the substrate is also important, so that thermal expansion differences and acoustic impedance mismatch should be minimized.

11.2 Amorphous Solids

Thermal conduction in amorphous solids is due to phonons, except that in glass at high temperature there is also a contribution by internal radiative heat transfer. The average phonon mean free path $\langle l \rangle = 3\lambda/Cv$ [see Eq. (2)] is quite short, only of the order of a few ångströms. The high-frequency modes, which make the major contribution to the energy content, are thus not progressive waves but vibrations localized at atomic sites, with mechanical energy transfer between sites. Alternatively one can regard these modes as waves with very short mean free path, comparable to their wavelength. This mean free path is referred to as minimum mean free path: increasing the perturbation or the strength of the interaction cannot reduce it further. However, modes of lower frequency are wavelike, since for longer waves the solid approaches an elastic continuum. These waves contribute to the thermal conductivity even at ordinary temperatures. At low temperatures they make the major contribution to the thermal conductivity, so that the average mean free path increases with decreasing temperature.

At low temperatures one can understand the conductivity in terms of Eq. (9), using a Debye model for simplicity. Thus $C(f) \propto f^2$ for f of order kT/h. The disorder of the solid can be described by strong point-defect scattering. However, the mean free path for point defects l_p varies as f^{-4}, and an additional scattering process is required to prevent the integrand $C(f)l(f)df$ from diverging at low frequencies. If this process has a mean free path $l'(f) \propto f^{-n}$, then at very low temperatures $\lambda \propto T^{3-n}$, provided $n < 3$. Combining the scattering rates, so that $1/l = 1/l' + 1/l_p$, leads to a thermal-conductivity curve that increases at low temperatures with increasing T but reaches a constant value or "plateau" at higher temperatures. If now one adjusts this model so that $l(f)$ cannot decrease below a minimum value l_0, the plateau does not extend to high temperatures, but $\lambda(T)$ increases again, still in the low-temperature regime. Eventually, with increasing temperature, it approaches $\frac{1}{3}C(T)vl_0$, where $C(T)$ is the Debye specific heat per unit volume.

The low-frequency scattering mechanism that dominates at low temperatures makes $\lambda(T)$ vary as T^2, so that $l'(f) \propto 1/f$. This can be explained by a model in which an assembly of localized defects can be in two atomic configurations. In silica glasses these could be two configurations of the Si-O-Si chain. Phonon-assisted tunneling allows transitions between these configurations. The energy spacing between them defines the frequency of the phonon that is either absorbed or emitted. Because of the general disorder each defect has a different level spacing or frequency, and these frequencies are widely distributed. A Gaussian distribution much wider than kT/h would then lead to the observed frequency dependence $l' \propto 1/f$.

This model is well supported by other properties, including an excess specific heat at very low temperatures (Phillips, 1981). The nature of these two-level defect sites is not yet fully understood, nor the factors determining their concentration and frequency distribution.

11.3 Thermal-Barrier Coatings

Thermal-barrier coatings are used in aircraft and other gas-turbine engines to insulate metal components from the hot gas stream, improving component durability and engine efficiency. In aircraft engines such coatings can reduce metal temperatures by as much as 170 °C. Current research aims to reduce the thermal conductivity of the coating material, thus allowing a larger temperature drop across the coating. The material of current interest is stabilized cubic zirconia, which, in the fully dense form and without cracks, has a thermal conductivity of about 2 $W \cdot m^{-1} \cdot K^{-1}$ over a wide range of elevated temperatures. Chemical stability is, of course, equally important, and the high oxygen diffusivity of zirconia requires barrier layers, but further improvements demand a better understanding of the thermal-conduction mechanism. Thermal conduction is mainly by lattice waves; above 1000 K a radiative contribution cannot be ruled out.

The suitability of zirconia seems to depend on the fact that the cubic form is stabilized by the addition of solutes (Ca, Mg, Y, Ce), though Ca and Mg tend to migrate at high temperatures. Except perhaps for Ce, the solutes introduce vacancies in the oxygen sublattice; these make the major contribution to the scattering of high-frequency phonons. At the very highest frequencies the phonon mean free path reaches a minimum value of the order of the interatomic spacing and cannot be decreased by additional solutes, but at intermediate frequencies, increasing solute content is still effective. At lower frequencies, where point-defect scattering is weak, one must look for other processes.

Processes scattering low-frequency phonons are grain-boundary scattering, scattering at the interfaces of thin layers, and phonon interactions by two-level systems, as in amorphous solids. At low temperatures the thermal conductivity of stabilized zirconia does show similarity to that of vitreous solids, even though zirconia is crystalline. It has been suggested that some oxygen atoms that are next to vacancies can tunnel between different configurations. This limits the phonon mean free path to about 0.5 μm. If the grain size is comparable or smaller, there would be an additional reduction in thermal conductivity. A similar reduction should be obtained if the coating is deposited as a series of thin films of comparable thickness, separated by layers of different phonon velocity. These layers could also serve as oxygen-diffusion barriers. If the layer thickness or the grain size L is small enough, and the solute concentration c large enough, anharmonic interactions would not be important over the entire frequency range. The conductivity, independent of temperature, would then vary as $c^{3/4}L^{1/4}$. The required grain size or film thickness would probably have to be a few tens of nanometers.

11.4 Layered Crystals: Graphite

Some crystals are composed of atomic layers, with strong atomic bonds within each layer but much weaker bonds between atoms in adjacent layers. As a result, the phonon velocity is very anisotropic, much larger for propagation in the layer plane than normal to it. Also the layer spacing may then be larger, reducing the Brillouin zone in the normal direction. Thus energy is propagated mainly in the layer plane for all frequencies above a critical frequency f_c, which is well below the maximum frequency of the acoustic branch. For $f < f_c$, propagation is in three dimensions. In graphite, which is very anisotropic, $f_c = 4$ THz while the in-layer acoustic branches extend to 25 and 37 THz respectively. Thus above f_c the phonon gas is two-dimensional, $C(f) \propto f$, while in three dimensions $C(f) \propto f^2$. Other layered crystals may have a relatively smaller range of two-dimensional behavior. The frequency dependence of the intrinsic mean free path is not affected by the dimensionality and varies as f^{-2}. The spectral thermal conductivity is proportional to $C(f)l(f)$ and varies as $1/f$ above f_c. In contrast to three dimensions, where the intrinsic heat current is due to modes of all frequencies, now the heat is carried mainly by modes near and just above f_c. The thermal conductivity of layered crystals is thus less sensitive to point defects and more sensitive to extended defects than in isotropic crystals. At low temperatures, if grain-boundary scattering dominates, the T dependence of $\lambda(T)$ varies between T^2 and T^3.

The lattice thermal conductivity normal to the layer plane is much smaller than within it. In a polycrystalline aggregate, the thermal conductivity is isotropic if the crystal platelets are randomly oriented but very anisotropic if they lie parallel in a common plane, as in the case of pyrolytic graphite. The overall thermal conductivity is sensitive to the shape of the platelets and their arrangement, and graphite shows a wide range of thermal conductivities.

Other layered materials are not as strongly anisotropic as graphite, but similar considerations may well apply. They have not been investigated as fully as graphite has been.

11.5 Radiation Damage

Fast-particle irradiation causes atomic displacements and lattice imperfections, which reduce the thermal conductivity of insulators. Depending on the nature and energy of irradiating particles, the damage consists of individual displaced atoms and small regions of disorder. The displaced atoms cause interstitials and vacancies. Both of these point defects can move and recombine, but some of them form larger aggregates, leaving behind a residue of individual point defects.

In the case of metals and alloys, the change in the electronic thermal conductivity parallels the change in electrical resistivity through the Lorenz ratio L_0 of Eq. (21). Radiation damage in these materials can be studied more conveniently in terms of changes in electrical resistivity. There have been some studies of changes in the lattice component of thermal conductivity of alloys, but there have been many more studies of changes in the lattice thermal conductivity of insulators and of graphite.

Early studies of the thermal conductivity of irradiated quartz and sapphire at low temperatures showed reductions at temperatures below that of the maximum, which were attributed to phonon scattering by extended imperfections, while reductions above that temperature were interpreted as due to point defects. Extended imperfections have since been seen by electron microscopy in alumina and other dielectrics. The reductions at ordinary and high temperatures in alumina were not inconsistent with low-frequency phonon scattering by such extended imperfections, together with point defects, which are not seen by electron microscopy and which scatter high-frequency phonons. The required concentration of point defects roughly matches the total volume fraction of the extended imperfections.

As the nuclear fuel UO_2 is consumed or "burnt up" in a reactor, various fission products build up as solutes in the matrix, while some that have a larger size mismatch form metallic colloids. Inert-gas bubbles are also formed. The solute ions reduce the thermal conductivity of the matrix, as does increased porosity. Metallic colloids cause a smaller increase; the net effect is a decrease. The thermal conductivity of UO_2 containing solutes that match those produced by fission has been studied in Symfuel (see Glossary) without the difficulties of radioactivity. Nonstoichiometry has also been studied. It appears that oxygen reduction does not cause oxygen vacancies but metal colloids, increasing the conductivity. Excess oxygen, in the form of oxygen interstitials, scatters phonons strongly and reduces the conductivity.

There has been much work on the reduction of thermal conductivity in neutron-irradiated graphite. Probably both point defects and extended defects contribute to the decrease. Extended defects should be relatively more effective than in other solids, because the layer structure enhances the role of the low-frequency modes, as discussed in Sec. 11.4. However, the grain structure also changes, as indicated by density changes, and this makes the interpretation more difficult.

GLOSSARY

Anharmonicity: Terms in the potential energy of a lattice as function of strain or displacement beyond the quadratic or harmonic terms. The cubic anharmonic terms are the most important, being responsible for interactions exchanging energy among triplets of normal modes. They are also responsible for thermal expansion.

Boltzmann Equation: The equation that balances the rate of change of the occupation number of particles in phase space due to forces and concentration gradients against the change due to collisions or other interaction processes. In the present context it applies not to gas atoms but to electrons and to phonons.

Boundary Scattering: Scattering of carriers, either electrons or phonons, by boundaries, which may be the external boundaries of the specimen, or internal boundaries such as grain boundaries or boundaries of a thin film. These processes may limit the carrier mean free path.

Cooper Pairs: A pair of electrons of the same momentum but opposite spin, held together by an interaction force and effectively forming a particle obeying Bose–Einstein statistics and able to form a Bose–Einstein condensate responsible for superconductivity.

Electronic Component: The contribution λ_e to the thermal conductivity from the heat flow carried by free electrons.

Intrinsic Conductivity: The conductivity, electrical or thermal, of a structurally perfect solid, limited only by carrier interaction with the vibrations of the lattice. Intrinsic lattice thermal conductivity refers to the lattice component. Intrinsic resistivity is the reciprocal of that conductivity.

Lattice Component: The contribution λ_p to the thermal conductivity from the heat flow carried by lattice waves or phonons.

Lorenz Ratio: The ratio $L = \lambda_e/\sigma T$, where λ_e is the electronic component of thermal conductivity, σ is the electrical conductivity, and T is the absolute temperature. In well-conducting metals when the lattice thermal conductivity is negligible, λ_e is sometimes replaced by the total thermal conductivity λ.

Phonon: The energy content of all waves and other harmonic oscillators is quantized, being an integral number of quanta of energy hf, where f is the wave or oscillator frequency and h is the Planck constant. In the case of elastic waves or lattice waves such quanta are called phonons.

Quasiparticle: A particle moving in a medium, such as a crystal lattice, interacting strongly with that medium. The interaction changes the relation between energy and momentum, but in other respects the particle behaves like a free particle.

Residual Resistivity: The electrical resistivity of a metal or alloy at the absolute zero of temperature, where all the resistivity is due to impurities, solute atoms, or other lattice imperfections, and thermal vibrations do not contribute.

Semimetals: Metals with a smaller electron density than ordinary metals having a density of electron states per unit energy interval that varies sufficiently rapidly about the Fermi energy that this density changes appreciably over an energy interval of the order of kT. The electron gas is then no longer highly degenerate. While this definition would depend on the temperature T, the designation of semimetal is made usually at room temperature.

Symfuel: A mixture of uranium dioxide and a series of other oxides to simulate the composition of uranium dioxide nuclear fuels after a specified fraction of the uranium atoms have undergone fission, and the fission products have formed solute cations in the oxide lattice.

Thermal Diffusivity: The ratio of the thermal conductivity divided by the specific heat per unit volume. This is the quantity usually measured by transient methods.

Two-Dimensional Phonon Gas: In crystals consisting of atomic layers that are only weakly bonded to each other, the phonon gas, or the lattice vibrations, can be regarded as approximating the vibrational spectrum of a two-dimensional system over a wide range of frequencies. The most widely studied solid of this kind is graphite.

INTRODUCTION

Thermal insulation materials help to keep buildings warm when outdoor temperatures are cold and cool when outdoor temperatures are warm. They are also useful in keeping temperatures low in commercial warehouses that store cold or frozen foods, and in trucks, trains, and ships that transport cold and frozen food products. Additionally, thermal insulation is used in the process industries for fire protection, product conservation, temperature control, and energy conservation. There are no fewer than seven different types of insulation materials. Each has its own advantages and disadvantages that are dependent upon the structure in which the materials are used and the climate where they are employed. This article is a survey of information about the properties

and benefits of thermal insulation. Discussion will focus on the material composition of various types of thermal insulation available, how to select the best thermal insulation for a particular purpose, the advantages and disadvantages of using each kind of insulation material, international standards, and the environmental and safety ramifications of thermal insulation manufacturing and handling. Additional information on insulation materials is available from several sources listed under Further Reading. Specific facts from some references are cited throughout this article.

It should be noted that all calculations in this article are in British units only. Because the author did not have the original thickness used for the components of the walls described in this article, an accurate conversion to SI units was not possible.

1. BENEFITS OF THERMAL INSULATION

Although there are many applications of thermal insulation, the most familiar is in building construction. The initial construction of a building offers a one-time opportunity to use high-performance building materials that can maximize the structure's thermal efficiency and help reduce its overall energy consumption. Air leakage and moisture infiltration are the leading causes of energy waste within most residential and commercial facilities. High-performance, energy-efficient insulation creates a well-sealed building envelope that can cut utility costs. It can also help the owner maintain a higher market value of the building by allowing for smaller heating and cooling systems and, in some cases, qualify for rebates from utility companies and preferred interest rates from mortgage companies.

Besides energy savings, improving the thermal efficiencies of a building has environmental benefits. Reducing demand for heated or cooled air reduces the need for burning fossil fuels, which produces carbon dioxide and sulfur dioxide, the latter a recognized element in acid rain.

2. TYPES OF THERMAL INSULATION

Insulation is dead air space or a dead gas space sometimes combined with a reflective surface. The insulation materials used to maintain a particular temperature are like the clothing that allows our body temperatures to remain comfortable in every kind of weather. The characteristics of thermal insulation are determined mainly by its composition. Although there are five major types of thermal insulation, some insulations are hybrids of these types. They are flake, fibrous, granular, cellular, and reflective. Among these types of thermal insulation, there are seven major materials from which insulation is made: polyurethane and polyisocyanurate, styrenic foams, urea formaldehyde, fiberglass, minerals, cellulose fiber loose fill, and vermiculite. All forms of insulation consist of thousands of tiny pockets where dead air is encased, protected, and preserved to maintain the desired temperature within a building, vehicle, or storage vessel.

Thermal insulation is produced in several forms:

1. *Blanket thermal insulation*—a flat, flexible thermal insulation that can be placed over flat, curved, or irregular surfaces. May or may not be faced, coated, or reinforced on one or both sides.
2. *Block thermal insulation*—rigid thermal insulation preformed into rectangular units.
3. *Board thermal insulation*—rigid and semirigid thermal insulation preformed into relatively large-area rectangular units.
4. *Cement thermal insulation*—a prepared composition, in dry form, composed of granular, flaky, fibrous, or powdery materials, which when mixed with the correct proportion of water develops into a mix of plastic consistency. The mixture is then applied by pouring or blowing it into a confined area. It can also be applied by hand.
5. *Foamed thermal insulation*—liquids sprayed on or mixed together, which foam and set into cellular or semicellular organic rigid or semirigid insulation.
6. *Pipe thermal insulation*—rigid or semirigid insulation preformed for application to pipe or tubing.
7. *Reflective thermal insulation*—sheets or preformed shapes to provide spaces, in-

corporating reflective sheets that obtain their insulating resistance from their ability to reflect a large part of the radiant energy incident on them.

2.1 Heat Transfer

Heat is energy in a transient form. It is the result of molecular motion and an interacting form. Heat transfer occurs through conduction, convection, and radiation. *Conduction* is the migration of energy through matter from one atom to another, such as in the metal burner of a stove. *Convection* is the transmission of heat by movement of matter, such as air above the surface of a stove. *Radiation* is heat transfer by electromagnetic waves that does not require an intervening medium. It is often called radiant energy because it manifests itself in rays.

Insulation manages the conduction, convection, and radiation of heat. The effectiveness of an insulating material in resisting heat flow is expressed in its R-value. The higher the R-value, the more resistant a material is to heat flow. The R-value is established in laboratory tests, and is the reciprocal of the numerical value of the heat flow through a material in British thermal units (BTUs) per hour, per square foot of material, per degree Fahrenheit of temperature difference between the heat source and "cool" side of the insulation material. For example, the R-value of 1 in. of fiberglass is 3.2 h-ft^2-°F/BTU. Therefore, the R-value of a $3\frac{1}{2}$-in. blanket of fiberglass is R-11. Table 1 gives the R-values of some commonly used insulation materials.

Table 1. Thermal resistance of common insulations. Source: Society of the Plastics Industry, Inc.; Polyurethane Division.

Insulation type	Thermal resistance, R-value per inch thickness
Rigid polyurethane foam	
With impermeable facers	7.1–8.7
With permeable facers	5.6–6.2
Extruded polystyrene	5.0
Expanded polystyrene	3.85–4.35
Phenolic foam	
Closed cell	8.2
Open cell	4.4
Dry glass fiber batts	3.0
Dry mineral wool batts	3.0
Dry mineral wool loose fill	3.0
Dry cellulose fiber loose fill	3.13–3.70
Vermiculite	2.13–2.27

2.2 Foam Insulation

2.2.1 Polyurethane and Polyisocyanurate These materials can be expanded into a cellular structure of very low density. Their R-values, or ability to resist heat flow, are excellent because the blowing agent, a gas of low thermal conductivity, remains trapped in the foam. The kind of gas used varies. For years, the industry used chlorofluorocarbons (CFCs) as the blowing agents to create the foams' cellular structure and to contribute to the products' insulating efficiencies. Blowing agents commonly used today include hydrochlorofluorocarbons, hydrocarbons, and carbon dioxide.

2.2.2 Styrenic Foams These materials are made from polymerized styrene through the extrusion or expansion of polystyrene beads. In expansion, the starting material is small, dense beads containing butane, pentane, or some other volatile gas. When the beads are heated by steam, the gas expands, puffing up the beads. Additional steam heating in a mold fuses the beads into a large block of beadboard that is cut into slabs by pushing it through an array of parallel hot wires.

2.2.3 Urea Formaldehyde (U-F) Foam Generated at the installation site by mixing the U-F resin with a catalyst and detergent and, using compressed air, blowing the frothy product into a wall, U-F sets quickly. Over a period of months, air replaces the water vapor and formaldehyde in the foam's open cell structure.

2.3 Fiberglass Insulation

Fiberglass is a silicate manufactured by melting glass and then extruding it through a whirling hollow cylinder with peripheral perforations to form fibers. Steam jets then impinge on these fibers and attenuate them to a diameter as low as 0.001 in. The resulting wad of glass wool is passed through a spray of thermosetting resin to bind the fibers together and compress it to the desired density. Next, it is baked to set the binder and sliced into batts, blankets, or rigid panels. A relatively new kind of fiberglass is being used in refrigerators as well as in ovens, water heaters, and advanced car batteries. It is composed of a vacuum panel of fiberglass that is thermally crafted inside a steel foil container. Its R-value is more than six times the R-value of polyurethane foam insulations of the same thickness. Its high-temperature resistance can approach 1000 °F. Fiberglass is resilient and has little tendency to mat together unless it is saturated with water.

2.4 Mineral Insulation

Rock wool is similar to fiberglass, except that it is made by melting steel, copper, or lead slag and then spinning it. Slag wool is made from by-product slag produced in the manufacture of steel and other metals. "Rock wool" is, in fact, usually slag wool. Often, the term "mineral wool" is applied to slag wool, although mineral wool is really a generic term covering this group of insulation materials. The properties of rock wool and slag wool are identical to those of fiberglass. In the form of loose fill, they can be blown into walls and attics.

Asbestos is the only natural mineral fiber known. It has been replaced by other insulants because of the severe health threat associated with breathing asbestos fibers. Consequently, it is unusual to find asbestos in structures built during the past 30 years.

2.5 Other Common Insulation Materials

2.5.1 Cellulose Fiber Loose Fill The most common form of cellulose building insulation today is loose fill, which contains recycled paper that is shredded, then pulverized in hammer mills, and treated with a dry fire retardant such as boric acid or ammonium sulfate. In walls, cellulose may settle with time. Under no circumstances, however, should cellulose be allowed to get wet, since exposure to water washes out the fire retardant and compresses the fibers into a small mass not much different from papier-mâché. Other cellulosic insulants include cotton waste from the clothing industry, eel grass, shredded coconut shells, and shredded sugar cane.

2.5.2 Vermiculite This material is expanded mica. Chemically, it is a layered silicate rock containing about 12% water by weight. The rock is crushed and then heated quickly to about 1600 °F. This process causes the water to expand rapidly into steam and forces the layers apart into accordion-like flaky granules. Perlite is made using a nearly identical process. The difference is that the raw material is volcanic rock, which has a different crystal structure than the silicate rock used to manufacture vermiculite. Perlite's finished product is in the form of puffy white granules.

2.6 Methods of Manufacture

2.6.1 Polyurethane and Polyisocyanurate Insulation The isocyanate and blowing agent are mixed and then extruded into a laminator where the resulting slurry foams until it reaches the height where the aluminum or other facer is located. This restricts the thickness of the foam, which adheres itself to the facers. Finished foam boards are then cut to the desired length. These materials have a closed-cell foam structure. They are available as boardstock, laminated panels, or structural insulated panels with a variety of facers. Polyurethane foam can be fabricated and installed on-site by spraying, pouring, and frothing. Polyurethane foams can also be made with metal-faced panels, primarily for use in curtain wall applications.

2.6.2 Styrenic Foams These materials are made into sheets by extrusion and by molding. The extruded product has a higher R-value than the molded one. Extruded polystyrene is made by forcing a hot mixture of polystyrene, a solvent, and a gas at high pressure into a cavity at atmospheric pressure where, because pressure is abruptly reduced, the mixture expands into a foam with fine, tiny closed cells. In making molded sheets, polystyrene beads are placed in a mold and exposed to heat. This process expands the beads and fuses them into a larger block. Blocks and extruded foam are later cut into sheets for use.

2.6.3 Fiberglass This material is made by subjecting molten glass to blasts of air that blow the material into thin threads. Additional details of the manufacture of fiberglass insulation were included in Sec. 2.2.

2.6.4 Mineral Insulation Vermiculite is made from a micalike mineral consisting of aluminum-iron-magnesium silicates that, heated to high temperatures, expand and provide a wide range of densities. Rock wool is manufactured by melting steel, copper, or lead slag and spinning it. Perlite is made from natural glass, siliceous and volcanic in origin. Through rapid heating, the crushed ore particles are expanded from 4 to 20 times their original volume.

2.6.5 Cellulose Fiber Loose Fill Cellulose is manufactured from newsprint, paperboard stock, or virgin wood fiber and is treated with a fire retardant. Additional details of the manufacture of cellulose insulation were given in Sec. 2.4.1.

3. APPLICATIONS

3.1 Construction

3.1.1 Residential Insulation is an important factor in building a home and in reducing the cost of energy used in existing homes. Regardless of the situation, the amount and placement of insulation in a home helps to determine heating and cooling costs, as well as the comfort level of the house. For two reasons, sufficient attic insulation is very important for residential construction. One, heat rises and can escape in large quantities through the attic; and two, attics are easy to insulate because they are usually unfinished. Insulation in walls and floors is also effective in reducing energy costs. Modern doors and windows are designed to reduce interior energy loss or gain during heating and air conditioning seasons, respectively. In a well-insulated home, the insulation acts as a blanket that covers surfaces adjoining areas at different temperatures, such as floors over cold areas, perimeter joists, crawl spaces, and basements.

3.1.2 Commercial Like residential buildings, commercial structures need to be insulated from the elements. The process for determining which areas need to be insulated is the same as that for deciding which parts of a home must be protected from extreme heat and cold. Although many commercial structures lack attics, wood frames, and basements, careful attention must be given to using the best material for insulating the ceiling. Failure to use the right kind of insulation in the right locations of a commercial building can be more costly than failing to insulate a home properly. Depending upon the specific building design and construction site, performance needs for specific insulating systems will vary. Today, the largest contributor to energy waste in buildings is heat loss or gain through walls, roofs, and windows.

3.2 Walls and Ceilings

Most insulation materials can be used over plywood or as sheathing when the framing is adequately installed and supported. Special nailing procedures allow exterior foam sheathing and siding to accommodate thicker composite boards. Insulation boards can also be used to fill cavities between studs, as can fiberglass. Loose materials can be blown into place between studs. Foam core panels can be used for curtain wall applications. These panels are made in a variety of thicknesses and are sandwiched between facers such as steel or aluminum for maximum effectiveness.

When properly applied, polyurethane spray foams have no seams or joints, and so they can eliminate drafts and heat leaks when applied on the interior or exterior of structural walls. Such foams will adhere to most substrates that are clean and free of grease, oil, or loose scale. On the interior, these foams can be used to fill cavities between studs or can be sprayed on block walls or other wall surfaces. Rigid polyurethane foams can be poured or frothed in place on the job site. These foams can be used to fill cavities in concrete or cinder blocks, or in spaces between masonry walls. Within minutes, the foam sets to a strong, closed-cell material that fills voids and does not shrink or settle.

Polyurethane and polyisocyanurate foams are easy to install when used for roof applications. An important advantage of polyisocyanurate roofing boards and spray polyurethane foam is that they can be installed directly on metal decks, provided their fire performance meets applicable building codes. Rigid polyisocyanurate roofing boards are lightweight and can be manufactured with a variety of flexible facers, including aluminum foil, asphalt, saturated felt, organic/inorganic felts, or multilayered composites. Rigid facers such as plywood, wafer board, or gypsum board can also be used. These composite boards have exceptional structural strength.

Lightweight rigid polyurethane spray foam roofing is applied on the job site, creating a seamless insulated surface. Spray polyurethane foams adhere to almost any substrate that is sound, clean, dry, and free of loose material. They conform easily to complex surface configurations and, therefore, are particularly effective for domed roofs and for sealing around projections such as pipes, conduit, air conditioning equipment, and bracing. Polyurethane foam also adheres to itself, allowing layers to be built up to required thicknesses and to create positive drainage pitches.

3.3 Appliance Insulation

3.3.1 Water Heaters Wrapping a water tank with a 4-in. fiberglass or foam blanket is one of the easiest ways to reduce heat loss. For the typical 40-gal tank, a thermal blanket can save hundreds of dollars per year in electricity or gas bills (Gay, 1980). Such a blanket is necessary because manufacturers cannot increase tank thickness significantly, as tanks must often pass through doorways and down basement stairs during installation. Applying a 1-in. blanket of fiberglass or urethane pipe insulation to water lines close to the hot water tank can cut energy loss from those sources by up to 50%.

3.3.2 Refrigerators Next to water heaters, refrigerators are the second-highest energy users in the home. A typical 16-cubic-foot refrigerator uses about 1800 kWh/yr compared to more than 4000 kWh/yr for a 40- or 50-gal water heater. The best refrigerators are filled with about 2.5 in. of polyurethane between the inner liner and cabinet. Urethane-filled appliances use about 20% fewer kilowatt hours per year than fiberglass-insulated refrigerators manufactured before the availability of urethane.

3.3.3 Ovens A relatively new kind of fiberglass insulation has an R-value more than six times the R-value of polyurethane foam insulations. It is a vacuum panel of thermally crafted fiberglass inside a steel foil container, and it can be used in refrigerators, water heaters, and advanced automotive batteries, as well as in ovens. This type of insulation is suitable for applications where the inside temperature approaches 1000 °F (Anon., 1993).

3.4 Commercial Refrigeration

3.4.1 Transportation The frozen food industry depends on insulation for its very existence. At the processing plant, low-temperature freezers consisting of insulated enclosures make it possible for food to be frozen immediately after it is processed. Foods are then transported in refrigerated railroad cars, trucks, and ships to wholesalers and dealers. Insulation used in refrigerated vehicles usually consists of reinforced fiberglass panels with polyurethane insulation that is 5–6 in. thick and foamed in-place (Anon., 1977–1981, p. 153). Some vehicles refrigerated by carbon dioxide use polyurethane boards to minimize heat loss. Generally, the liquid carbon dioxide changes into a vapor as it reaches piping nozzles. The vapor, which is heavier than air, moves down through vents around the lading.

3.4.2 Warehousing For the past 30 years, panels made from polystyrene and polyurethane protected by metal skins have been the most efficient materials to insulate refrigerated warehouses. Panels help to ensure that high-quality products are installed at a job site because they are produced under ideal conditions in a manufacturing plant, can be erected quickly, and last a long time. In contrast, many variables can affect the quality of materials foamed in-place on a job site. Panelized construction also provides a superior vapor barrier and can be moved from one location to another if the user's needs change. Panel bow due to skin temperature variation is desirable to prevent delamination. White-colored panels reflect more heat and have subsequently lower surface temperatures than natural aluminum or galvanized or stainless steel. The lighter the color, the less the panel tends to bow and the lower the exterior surface temperature. Prior to the introduction of polystyrene and polyurethane panels, insulation consisted largely of fiberglass sandwiched between two layers of plywood. The insulation properties of these materials are inferior to those of polystyrene and polyurethane. Consequently, they are no longer used in commercial refrigeration applications.

3.5 Process Industries

In the process industries, semirigid pipe insulation is used to protect buildings and pipes from fires, as well as to minimize the heat transfer from a material in transit or in storage vessels and in pipes. Using insulation to minimize a product's heat loss is becoming more widespread as materials are loaded into tank cars and hauled to users, arriving at their destinations within 5–15 °F of their temperature at loading (Anon., 1977–81, p. 213). Using standard heat-transfer formulas, one can calculate the required insulation thickness required for specific applications.

4. MATERIAL SELECTION CRITERIA

4.1 Thermal Insulation Values

When choosing insulation materials, the most important criterion is thermal efficiency, or a material's ability to block heat flow. Thermal insulation values are expressed as R-values, or a measure of the material's resistance to heat transfer. Pockets of air slow down the flow of heat because still air is a poor heat conductor and because convection is suppressed in small pockets of air. The closed-cell foam structure of polyurethane and polyisocyanurate foams offer very effective air infiltration resistance, minimal moisture pickup, no harboring of fungi and mildew, excellent dimensional stability, no shrinkage and settling, and resistance to organic solvents.

4.1.1 Increasing R-Values The R-values of polyurethane and polyisocyanurate foams more than double as the thickness doubles. For example, if a 1-in. piece of rigid polyisocyanurate foam insulation with a permeable facer has an R-value range of 5.6 to 6.2, a 2-in.-thick piece of the same material has an R-value range of 12.1 to 13.6. These higher R-values can reduce the thickness of the insulation required.

In contrast, styrenic foams, whether extruded or expanded, have R-values of about 4.0 to 5.0, fiberglass batts around 3.0, and cellulose fiber, mineral wool, and vermiculite still lower. The R-values of all these materials increase arithmetically relative to their thicknesses. Two inches of styrenic foams, for example, has an R-value of 8.0 to 10.0, and 2 in. of fiberglass batt insulation has an R-value of 6.0.

4.1.2 Efficiency The R-values of various layers in a thermal shell can be used to calculate the total R-value, or R(tot). The total R-value is the sum of all the R-values comprising the insulating shell. In the case of a 2 × 4-in. stud wall that is fiberglass-insulated and a double-pane window, R(tot) for each would be as follows:

Wall, between the studs	R-Value
Air film (outside, in 7.5 mph wind)	0.25
1/2-in. gypsum board	0.45
3.5-in. fiberglass	11.00
5/8-in. plywood	0.80
Air film (inside)	0.70
R(tot) =	13.20

Window	R-Value
Air film (outside, in 15 mph wind)	0.15
Two 1/8-in. glass panes	0.05
4-in. air space	1.00
Air film (inside)	0.70
R(tot) =	1.90

The total R-value of a section of the thermal shell and temperatures on each side of the section can be used to estimate the amount of heat flowing through the section. This calculation does not account for transient behavior (variations with time) or for defects or inclusions in the materials of construction, which may alter the heat flow. The basic heat-flow equation is

$$q = \frac{A(t_1 - t_2)}{\mathrm{R(tot)}}$$

where q = rate of heat flow, BTU/h, A = the area of the section (ft^2), t_1 = warmer temperature (°F), t_2 = colder temperature (°F), and R(tot) = total thermal resistance [(ft^2-°F-h)/BTU].

That equation may be used to calculate the rate at which heat is flowing into the house through *one square foot* of the wall by rewriting it as $q/A = (t_1 - t_2)/R$. The following example assumes an outside temperature of 90 °F and an inside temperature of 75 °F, and uses the R-value given previously for the wall between the studs of a 2 × 4-in. stud wall with a typical fiberglass.

$$\begin{aligned} q &= \frac{1 \times (90 - 75)}{13.2}\ \text{BTU/h} \\ &= \frac{1 \times 15}{13.2}\ \text{BTU/h} \\ &= 1.14\ \text{BTU/h per square foot of wall area.} \end{aligned}$$

The same equation can also be used to calculate the rate at which heat is flowing through the window. This example assumes an outside temperature of 15 °F, an inside temperature of 70 °F, and a window that is 3 × 5 ft.

$$\begin{aligned} A &= 3\ \text{ft} \times 5\ \text{ft} = 15\ \text{ft}^2 \\ q &= \frac{15(70 - 15)}{1.9} = \frac{15 \times 55}{1.9}\ \text{BTU/h} \\ q &= 434\ \text{BTU/h or } q/A = 28.93\ \text{BTU/h per square foot of window area.} \end{aligned}$$

A similar calculation can be done for the portion of the wall that includes the stud. To complete the calculation of the total heat loss, the known areas of each section of the composite wall structure are multiplied by the heat loss per square foot of each part of the section. To calculate the total and effective R-values of an insulated 2 × 6-ft^2 stud wall with a high–R-value interior sheathing of polyisocyanurate foam, separate calculations must be performed for the framed section and the insulated section; see Table 2.

4.2 Advantages and Disadvantages of Various Insulation Materials

All insulation materials may require a vapor barrier between the material and the interior of the building. They also make it necessary for buildings to have a mechanical fresh-air exchange system that compensates for the loss of natural air flow.

4.2.1 Polyurethane and Polyisocyanurate Foams These materials provide a high strength-to-weight ratio and resist shrinkage and settling in cavities. Additionally, they resist moisture pickup, many organic solvents, fungus, and mildew. These foam insulation materials adhere to most common building materials, adapt to mold configurations for the production of complicated shapes and intricate surface detail, require no special tools for shaping, and produce seamless surfaces when applied by spray.

Disadvantages include the need for thermal protection from fire on the interior, such as a 1/2-in. gypsum wallboard, unless fire testing demonstrates that such thermal barriers are unnecessary. Polyurethane and

Table 2. Calculation of effective R-value for composite section.

	R-values in framed section	R-values in insulated section
Outside air film (7.5 mph wind)	0.25	0.25
Wooden shingles	0.85	0.85
1/2-in. plywood (R = 1.25/in.)	0.60	0.60
5-5/8-in. studs (R = 1.25/in.)	7.05	—
Fiberglass batts, R-19	—	19.00
1-in. polyisocyanurate foam	7.50	7.50
1/2-in. gypsum board	0.45	0.45
Inside air film	0.70	0.70
R(tot) =	17.40	29.35

If the framing constitutes 15% of the total wall area, then the effective R-value of the wall is

$$R(\text{eff}) = \frac{1}{0.15/17.40 + 0.85/29.35} = 27.03$$

polyisocyanurate foams also require proper precautions during foaming and spraying operations to prevent accidental ignition of the foam. When used for exterior applications, these materials need weatherproof protection from sunlight and other weather conditions. If the insulation materials are exposed continually to temperatures greater than 175 °F, physical property deterioration may occur.

4.2.2 Styrenic Foams Polystyrenes of the expanded and extruded varieties are dense products that are hard to ignite, and their strength makes them especially suitable for use on top of roofs or to face exterior basement walls. The disadvantage of these materials is that they degrade in sunlight. They should be covered in most applications to prevent degradation.

4.2.3 Fiberglass With a relatively high R-value, fiberglass is easy to work with, does not readily absorb water, is nonflammable (although its resinous binder is flammable), and does not rot. If the paper backing on fiberglass batts and blankets is impregnated with asphalt, however, the flammability is greater. Although the R-value for fiberglass batts and blankets is usually high, its R-value *per inch* is lower than that of some foams. Working with fiberglass can irritate skin, eyes, and lungs. Studies on whether fiberglass is a carcinogen are inconclusive, and precautions to prevent exposure are desirable. Individuals installing batts or loose fill should wear a hat, pants and a long-sleeved shirt, safety goggles or glasses, and a disposable dust mask to guard against any potential harm.

4.2.4 Mineral Insulation The properties, advantages, and disadvantages of rock wool and slag wool are virtually identical to those of fiberglass, and one should take similar precautions when installing such materials.

4.2.5 Other Materials Cellulose is economical and environmentally safe, and provides nearly the same insulating performance as fiberglass. Additionally, the major cost of its manufacture is paid for when cellulosic insulant materials are used for their initial purposes. The disadvantages of cellulose include its tendency to settle over time, flammability, and high rate of moisture absorption. If the insulated area of the building is accessible, however, settling can be overcome by "topping," or adding additional material to, the insulation periodically.

Urea formaldehyde (U-F) is a relatively inexpensive material that can be injected evenly into any wall cavity. Its disadvantages are that it may shrink after injection and give off lingering formaldehyde vapors. Because it is blown in on the job site, the quality of U-F foam can vary from one installation to another. Whether the foam is effective also depends upon numerous variables, including temperature and humidity on injection day, how the ingredients are mixed, age of the ingredients, and the type of injection apparatus used. Some U-F foams can experience shrinkage or break down at temperatures and moisture levels only slightly above those found in a typical house or commercial building. U-F is generally not applied to attics because direct exposure to the atmosphere and high attic temperatures accelerates drying and causes excessive shrinkage and cracking. Since formaldehyde gas is heavier than air, it can settle into the rooms below.

Vermiculite and perlite are both noncombustible and can be used in high-temperature applications, such as industrial furnaces. They can be mixed with concrete and poured into voids in cement block walls to reinforce home insulation. Vermiculite and perlite, however, have relatively low R-values.

Reflective insulation, such as aluminum foil, can serve as an insulant between a steam or hot-water radiator and an adjacent wall. In such a narrow space, there is generally insufficient room for fiberglass or another bulky insulant, but a single layer of foil reduces heat loss through that part of the wall directly behind the radiator. Similarly, a wall may be protected from the radiant energy of a wood stove by using a protective layer of shiny aluminum. The aluminum should be positioned an inch away from the wall so that it may be cooled by air currents on both sides, and it should not be paper-backed. Aluminum foil is not effective in walls because several layers of it can trap moisture and negate its intended purpose.

4.3 Geographic Demands

4.3.1 Climatic Structures in the harshest climates, such as Scandinavia and the northeast and midwest regions of the United States, require insulation with an R-value of around 50, regardless of whether they are heated by electricity, gas, oil, or a heat pump. Buildings in moderate climates such as those of Japan, the Mediterranean Sea region, and the southern and southwestern United States should use insulation with R-values between 30 and 40. Regardless of climate, thermal insulation used should have the ability to resist moisture and to withstand the effects of broad temperature variations and humidity.

The cost of thermal insulation materials *per R-value per square foot* ranges from around $US 0.01 for fiberglass batts and loose fill to $US 0.077 for polyisocyanurate and extruded styrenic foam, both in rigid board form. In between those two extremes are cellulose at $US 0.014, loose-fill mineral wool at $US 0.019, and expanded styrenic foam at $US 0.046 (Council of American Building Officials, 1992).

4.4 Construction Codes

4.4.1 Model Energy Code The Model Energy Code (MEC) was developed by the Council of American Building Officials. The MEC governs the design and construction of new buildings that are heated and cooled. It also requires that plans and specifications show in sufficient detail pertinent data about and features of the building and its systems, including design criteria, construction materials and their heat transmission rates, and the efficiency of the insulating materials. The MEC energy-efficiency performance standards are based on several criteria, including R-values of the various components and heating degree days (HDDs). Reflecting local climate, HDDs are determined by totaling over a year the temperature differences above or below 65 °F each day, and they are used in estimating fuel consumption.

4.4.2 ASHRAE Standard 90.2 Developed by the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE), Standard 90.2 establishes specific design parameters governing the transmission of heat and cooled air through building components for the purpose of maximizing thermal efficiency in residential construction, including single-family houses, multiple-family structures of three stories or fewer above grade, mobile homes, and modular houses. ASHRAE Standard 90.2 is similar to the MEC. It tends to predict thermal performance for buildings in warm climates more accurately than for structures in colder environments.

4.4.3 Good Cents Program An energy conservation initiative developed by Southern Electric International, a division of The Southern Company, which is headquartered in Atlanta, Georgia, U.S.A., the Good Cents Program provides energy standard guidelines for builders, owners, and operators to construct energy-efficient homes and buildings. Building contractors who participate in the Good Cents Program are committed to using high levels of insulation that allows for the downsizing of heating, ventilation, and air conditioning systems, among other energy-efficient building practices. Nearly 300 utilities in 30 states participate in the Good Cents Program. If the MEC, ASHRAE Standard 90.2, and the Good Cents Program were incorporated into new residential construction only, the United States could save more than 7.2 trillion BTUs of energy each year. Similar savings would be available worldwide if all building contractors adopted these or similar approaches to energy conservation (Council of American Building Officials, 1992).

5. ENVIRONMENTAL CONSIDERATIONS

5.1 Energy

The single largest contributor to energy waste in commercial and residential construction is heat loss or gain through walls, roofs, and windows. Rigid polyurethane and polyisocyanurate foam are the most effective materials for keeping indoor temperatures at their desired levels and minimizing the use of energy to heat or cool to a comfortable temperature. All insulation materials, however, reduce heat loss or gain. To determine which ones are best for a particular application, all of the variable factors must be considered and the projected savings relative to the investment in insulation calculated.

5.1.1 Conservation More than one-third of the energy consumed in the United States is used to heat and cool residential and commercial buildings. The Model Energy Code (MEC), American Society of Heating Refrigerating and Air Conditioning Engineers (ASHRAE) Standard 90.2, and the Good Cents Program are U.S.-based efforts to help conserve energy by promoting construction that is appropriate to specific climate zones.

As mentioned in Sec. 4.4.3, if new residential construction were built to the stipulations of the MEC, the United States would reduce its energy consumption by more than 7×10^{12} BTUs in a single year. That amount of energy saved would be enough to power New York City for several years. Over a 50-yr period, emissions of carbon dioxide could be reduced by 280 million tons (Council of American Building Officials, 1992).

5.1.2 Efficiency As discussed in Secs. 2.5 and 4.1.2, polyurethane and polyisocyanurate foam insulation have the highest R-values, followed by extruded polystyrene, fiberglass, mineral wool batts and loose fill, cellulose, and vermiculite.

5.2 CFC Elimination

Chlorofluorocarbons (CFCs), a family of fluids that are extremely stable, fully halogenated, and nontoxic, have been at the center of the ozone depletion and global warming debate. CFCs had been used as blowing agents to create the cellular structure of foam insulation and contribute to the products' R-values. Regarded by many scientists and policymakers as a key weapon in the war against energy waste in the 1970s, they are now considered a major contributor to the problem of ozone depletion in the upper atmosphere.

In 1987, 30 countries and the European Community signed the Montreal Protocol, which called for a 50% reduction in CFCs by mid-1998 and a complete ban on CFCs by the year 2000. A 1993 agreement reset the complete ban to 1 January 1996 (Anon., 1994a). Manufacturers of foam insulation board have eliminated CFCs ahead of schedule, developing safer products. As of 31 December 1993, members of the Polyurethane Insulation Manufacturers Association (U.S.A.) had stopped using halogenated CFCs in the manufacture of their products.

Some of the most promising replacements for CFCs are hydrochlorofluorocarbons (HCFCs). They pose less threat to the ozone layer than CFCs because they break down before they reach the upper portions of the atmosphere. However, they still are ozone-depleting substances, and they too will be phased out. To reduce the amount of CFCs used in the manufacture of polyurethane and polyisocyanurate products, some manufacturers have mixed water into their formulations. The R-values for these products, however, go down accordingly, and these materials could lose their R-values in applications faster than their predecessors did. This phenomenon is known as *thermal drift.*

CFC-11 and CFC-12, two commonly used blowing agents in the manufacture of rigid foam and polyurethane insulation, have been replaced by HCFC-141b and HCFC 142b. These replacement blowing agents are made using pentane, a solvent that contributes to localized smog, and are about 11% as damaging to the ozone as CFC-11 (Anon., 1994b). Manufacturers of rigid foam and polyurethane insulation continue to work on a third generation of blowing agents.

Through a public–private research project involving the United States Department of Energy, Oak Ridge National Laboratory, the United States Environmental Protection Agency, Polyurethane Insulation Manufacturers Association, the National Roofing Contractors Association, and the Society of the Plastics Industry, manufacturers are working on CFC substitutes that will not harm the atmosphere. The cost, structural soundness, fire resistance, and toxicity of these new materials are remarkably similar, if not identical, to those of the substances they replaced (Brown, 1994).

GLOSSARY

Batt: A piece of insulation, of the flexible type, cut into easily handlable sizes, square or rectangular in shape, with a vapor barrier on one side, and with or without a container sheet on the other side.

British Thermal Unit (BTU): The amount of heat that will raise the temperature of 1 lb of water by 1 °F.

Chlorofluorocarbons (CFCs): A family of fluids that is stable, hydrogen free, and nontoxic, widely used until recently as blowing agents to expand the cells in the manufacture of rigid foam boards.

Conduction: The migration of heat through matter from atom to atom.

Convection: The transmission of heat by movement of bulk matter.

Heat: Energy in transient form. The result of molecular motion and interacting forces.

Polystyrene: A resin made by polymerization of styrene as the sole monomer.

R-value: The effectiveness of an insulation material in resisting heat flow. R-value is established through laboratory testing that measures the heat flow through a material in BTUs per hour, per square foot of material, and per degree of temperature difference between the heat source side and the "cool side" of a structure.

Radiation: The transmission of heat without the benefit of a medium.

Thermal Drift: The tendency of insulation to lose R-value over time. This change in R-value stems from slow leakage of the gas trapped within the material's cells.

Thermal Insulation: Material having air- or gas-filled pockets, void spaces, or heat-reflective surfaces, which, when properly applied, will retard the transfer of heat with reasonable effectiveness under ordinary conditions.

INTRODUCTION TO THERMAL PLASMAS

Plasmas are partially or fully ionized gases consisting of electrons, ions, and neutral atoms and possibly molecules. Plasmas are abundant in the universe; as a matter of fact, more than 99% of the universe is plasma, making it the most abundant state of matter. But also on Earth, plasmas appear in nature in the form of lightning, or as aurora borealis in the upper atmosphere. But only in the beginning of the 19th century did investigations on laboratory plasmas begin, after electricity had become available in the laboratory through the use of galvanic cells.

The characteristics of a plasma are described by the electron density n_e and the electron temperature T_e, and these two properties can vary over a wide range, giving plasmas a wide variety of characteristic features. Thermal plasmas occupy a relatively small region in n_e-T_e space, as shown in Fig. 1. Typical ranges for n_e in thermal plasmas are 10^{22} to 10^{25} m^{-3}, and ranges for T_e are 5000 to 50 000 K. What distinguishes "thermal plasmas" from other types of plasmas is that

1. all species have a Maxwellian velocity distribution according to the same temperature, i.e., the temperatures of the electrons, ions, and atoms and/or molecules are identical;
2. the excited energy states are populated according to a Boltzmann energy distribution; and
3. the composition of the plasma can be derived from chemical equilibrium relations, including the Saha equation for the determination of the degree of ionization (see Sec. 1.4.2).

The term "thermal plasma" is derived from the fact that these types of plasmas are closer to thermodynamic equilibrium than any other type of plasma. The listed requirements for thermal plasmas are met in a state of complete thermodynamic equilibrium; however, this state requires in addition a blackbody radiation field in the plasma, a condition that is generally not met in terrestrial plasmas. But the conditions still are met when a state of "local thermodynamic equilibrium" (LTE) prevails, i.e., when the energy transfer from one particle to another takes place over a distance that is small compared to variations in the plasma properties. This is the reason why minimum values for the electron density and the electron temperature are needed for a thermal plasma, because there must be a sufficient number of collisions with electrons having energies above the threshold energies for excitation, dissociation, and ionization.

These requirements for existence of a thermal plasma lead to the following characteristics:

1. high energy densities, typically on the order of 10^7 to 10^9 $\mathrm{J/m^3}$, largely because of the availability of ionization and frequently also dissociation energies;
2. high luminosity because of the high population densities of excited states; and
3. high electrical and thermal conductivities because of the presence of highly mobile electrons.

These characteristics present the attractions for the use of plasmas as well as the difficulties in controlling them:

- The high energy densities make plasmas useful for material treatment—any material can be melted, vaporized, dissociated

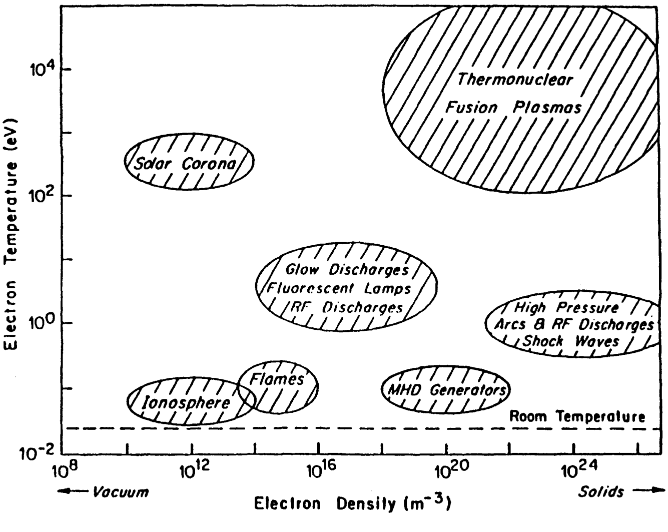

FIG. 1. Electron temperatures and electron densities for different types of plasmas (Fauchais *et al.*, 1987, with kind permission of the authors).

and even ionized with the aid of a thermal plasma, and numerous applications have evolved in the area of materials treatment starting with the establishment of the arc furnace for steel melting in the second half of the 19th century. Today, thermal-plasma technology is an indispensable and growing part in the materials-processing industry.

- The high luminosity of the thermal plasma has led to the development of plasma light sources as early as 1850, and plasma light sources have taken over illumination of the majority of the larger illuminated places.
- The high electrical and thermal conductivities and their variability with temperature as well as the high energy densities of the thermal plasma have resulted in a naturally evolving application. When an electric circuit is opened while a current is flowing in it, the circuit voltage across the opening gap results in the formation of a plasma. Cooling the plasma reduces the electrical conductivity and will result in the interruption of the circuit current.

The high energy densities of thermal plasmas require that any solid surface exposed to the plasma has to be cooled to insure its integrity. This cooling results in an energy loss from the plasma, and steady-state plasmas need an energy source for continuous generation of the plasma. The design of appropriate cooling mechanisms is a central task for the designer of thermal-plasma devices. The steep temperature gradients between the plasma and the cooled surface also result usually in nonequilibrium conditions in the boundary layer between the plasma and the surface, which have to be considered when the performance of the specific plasma device is to be predicted. On the other hand, the fact that a plasma is electrically conducting offers the use of electrical discharges as a convenient means to generate plasmas: a current flowing through the plasma dissipates sufficient energy to make up for the energy losses to the cooled environment.

This survey of thermal-plasma devices first reviews the generation and characterization of thermal plasmas. Then the three application areas in which specific characteristics of the thermal plasma are used are discussed: thermal-plasma devices for treatment of materials, for serving as light sources, and for interrupting the current in an electric circuit.

1. GENERATION AND CHARACTERIZATION OF THERMAL PLASMAS

For steady-state operation, thermal plasmas are in general generated by electric discharges, i.e., by Joule heating of a gas by the current flowing through this gas. Transient thermal plasmas can be generated by pulsed discharges (spark or arc discharges) but also by shock waves and laser pulses. Since most thermal-plasma devices operate in steady state or quasisteady state (i.e., thermal equilibrium is obtained), more emphasis is placed on the description of discharge-generated thermal plasmas. Among those, the electric arc is most frequently used for generation of thermal plasmas, with high-frequency induction discharges the second most frequently encountered method.

1.1 Electric-Arc Discharge

Among all electrical discharges, electric arcs have characteristically the highest current densities (10^3 to 10^5 A/cm^2) and the lowest electric fields (typically 5 to 50 V/cm), and among thermal plasmas they possess the highest energy density (10^7 to 10^9 J/m^3) (see SPARKS, ARCS, AND OTHER ELECTRIC DISCHARGES). Photographs of an electric-arc discharge are shown in Plate 1. The arc discharge is usually divided into three regions, in which different physical effects dominate: the cathode region, the arc column, and the anode region. Figure 2 illustrates the different regions of the arc and the potential distribution along the discharge. Each thermal-plasma device using an arc for plasma generation is characterized by the design of its cathode, its anode, and the column region.

1.1.1 Cathode Region The cathode is at a negative potential with respect to the arc discharge. It therefore attracts positive ions. Since most of the electric current is carried by electrons, the cathode must emit electrons that allow the current to flow

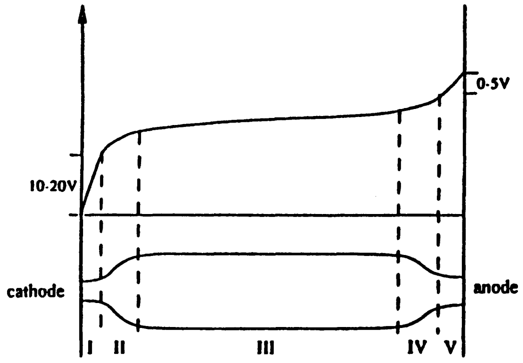

FIG. 2. Schematic of the different regions of an electric arc and the potential distribution along the arc axis. I, cathode-fall region; II, cathode boundary layer; III, arc column; IV, anode boundary layer; V, anode-fall region. Distances are not to scale.

through the sheath region in front of the cathode to the arc column. Electrons can be released from the solid cathode surface by different physical mechanisms: thermionic emission, field emission, or a hybrid of these mechanisms, TF emission, and a mechanism sometimes called explosive emission with evaporation from microscopic spots.

1.1.1.1 Thermionic Emission. This type of electron emission takes place when a material can be heated to sufficiently high temperatures (2500 to 4000 K) that enough energetic electrons exist in the solid that can escape the bonding imposed by the lattice. Usually refractory metals are required for thermionic cathodes, and the arc attachment is usually a stationary high-temperature spot on the cathode. The materials property controlling the performance of a thermionic cathode is the work function, the average energy required to extract one electron from the metal surface. The relation between the electron current density j_e, the cathode surface temperature T, and the work function Φ is given by the Richardson–Dushman equation,

$$j_e = \frac{4\pi k^2 e m_e}{h^3} T^2 \exp\left(-\frac{e\phi}{kT}\right), \tag{1}$$

where e and m_e are the electron charge and mass, respectively, h is Planck's constant, and k is the Boltzmann constant. Thermionic cathodes are characterized by relatively low erosion rates for nonoxidizing plasma gases. Tungsten and graphite are the most frequently used thermionic cathode materials, and additions of rare-earth oxides, alkaline-earth oxides, or thorium oxide are frequently used to lower the value of the work function. A lower work function leads to emission of the required number of electrons for the chosen operating current at lower cathode surface temperatures, thus reducing cathode erosion. For most operating conditions, the dominant heat input into the cathode is through the ion flux hitting the surface, and the dominant cooling mechanism is the release of electrons. Thermionic cathodes can be found in devices ranging from discharge lamps at one or a few amperes and with power dissipation of 100 to 1000 W to arc furnaces for steel production using currents of up to 100 kA and power levels up to 100 MW.

1.1.1.2 Field Emission. Emission of electrons from a cold metal surface takes place when a high electric field in front of the surface allows a substantial number of electrons to tunnel through the potential barrier separating the conduction band of the metal lattice from the surface. Fields in excess of 10^9 V/m are usually necessary, and, in general, localized field enhancement through microscopic protrusions from the surface is required. There is probably no thermal-plasma device with a cathode operating purely with field emission.

1.1.1.3 Thermionic–Field or TF Emission. This type of emission covers a wide range of operating conditions, from a reduction of the electric field required for field emission when the surface is heated or even molten, to the reduction in temperature required for thermionic emission from a refractory metal when a high electric field is present in front of the surface. Sometimes, the term TF emission is used to describe all emission mechanisms other than thermionic and field emission.

1.1.1.4 Explosive Emission. When a local surface inhomogeneity results in very high current densities, high localized heat flux or heat dissipation results in rapid evaporation of microscopic portions of the cathode metal and partial ionization of the metal vapor. This process is inherently unsteady on a very short time scale with a continuous random motion of the arc attachment spot. Application of a magnetic field can influence the motion and is used to control the arc attachment. The material evaporation can be significant at high currents, but in oxidizing atmospheres there may be less material loss than with thermionic cathodes. This type of cathode is used with plasma generators at current levels between 50 A and 10 kA and with most circuit-interruption devices.

Between the cathode surface and the arc column there is a region in which no LTE conditions exist. Immediately in front of the surface is the cathode sheath region in which over an extent of one to ten Debye lengths (i.e., the distance over which a positive charge is shielded by an electron cloud, typically a few micrometers) strong space charges exist, leading to high potential gradients. These potential gradients accelerate the ions toward the cathode surface and the electrons toward the arc column. Between the sheath region and the arc column is a thermalization region or ionization region in which the directed velocity of the electrons is randomized through collisions. While the sheath region can be described by using relations for a collisionless plasma, the conditions in the thermalization region are largely determined by diffusion fluxes. The extent of this region can be up to several millimeters; beyond this distance, LTE conditions are approached and the arc column region is reached.

1.1.2 Anode Region Since the current is mostly carried by electrons, the anode is a passive collector of the electrons and does not need to provide charge carriers. However, the arc attachment is associated with high heat fluxes, requiring cooling of the anode surface for steady-state operation. The energy transfer to the anode strongly depends on the fluid dynamic configuration of the arc. In general, heat losses from the arc to a cooled surface result in a constriction of the arc and higher electric fields and current densities that are needed to pass the current through the cooled region. This configuration is associated with high heat fluxes to the anode surface and a potential increase from the arc column to the anode (constricted attachment). If, however, a superimposed flow compresses the thermal boundary layer between the arc column and the anode leading to steep temperature and electron density gradients over a larger fluid-dynamic stagnation area, the electron-diffusion fluxes resulting from the density gradients can carry the current, and no constriction or increase in potential gradient is needed (Dinulescu and Pfender, 1980; Sanders *et al.*, 1982; Leveroni *et al.*, 1991). Plate 1 illustrates the two different situations. It should be pointed out that such an effect where blowing the hot plasma toward a surface reduces the heat flux to the surface is one of the counterintuitive features associated with electric arcs.

1.1.3 Arc Column The arc column is the region between the cathode and the anode regions and is inherently unstable. The interaction of the arc current with its own magnetic field leads to a magnification of any force interrupting the current path (magnetohydrodynamic or MHD instabilities). The consequence is that any arc operating in steady state requires stabilization. Any stabilization method is based on the fact that the thermodynamically preferred operating condition for the arc is that for which the arc voltage is a minimum (Steenbeck minimum principle) (Peters, 1956). Consequently, stabilization involves creating a condition where the arc voltage increases before the instabilities lead to arc interruption. Unstable arcs in a high-voltage circuit will of course reignite, but a steady-state condition is not possible.

The most frequently used method to stabilize the column is thermal stabilization, where any excursion of the arc from a straight path leads to strong cooling of the column and an associated voltage increase. Thermal stabilization can be obtained

1. through wall stabilization, where conduction heat flux from the arc column to a cooled wall increases strongly for an asymmetric position of the column, or
2. through convective stabilization, where a cold gas flow surrounds the arc and an asymmetric position of the column requires more gas heating and higher voltages.

A variant of this convective stabilization is the swirl stabilization where the plasma gas is introduced into the arcing device with a tangential velocity. The resulting vortex introduces centrifugal forces acting more strongly on the higher-density cold gases, creating a cold gas layer surrounding the arc. A natural stabilization mechanism is present with short arcs through the flow induced by the cathode jet action (for currents above about 50 A). A constricted cathode attachment leads to a current-density gradient in the direction from the column to the cathode, and the interaction of this current-density gradient with the self magnetic field of the arc current results in a strong plasma flow away from the cathode (Maecker, 1955). The description of the arc column by various modeling approaches is discussed in Sec. 1.4.2.

1.2 Radio-Frequency Induction Plasmas

In radio-frequency induction (RFI) devices, a high-frequency current (typically 450 kHz to 13.5 MHz) flows through a coil surrounding the plasma vessel. The current variation with time induces a voltage that in turn can sustain a current flow in a ring-shaped path through the plasma, thus generating the plasma through thermal ionization processes (see Fig. 3). As with the arc, discharge initiation requires generation of charge carriers by external means to initiate current flow, and high-frequency sparks or coronas may serve this purpose. RFI discharges do not require electrodes, but a cooled cylindrical wall surrounding the plasma is needed for discharge stabilization. The gas to be heated flows axially through the ring-shaped discharge region. Nonuniformity of the induced electric fields and skin effect lead to nonuniform heating of the plasma, resulting in a plasma region in which the hottest region can assume the shape of a doughnut. However, the temperature and density gradients are considerably smaller than those encountered in arc discharges, and the plasma volume is considerably larger for comparable power levels.

1.3 Alternative Thermal-Plasma Generation Methods

There are several other methods with which thermal plasmas can be generated, but there are no thermal-plasma devices making use of them. They should be mentioned here only for the sake of completion. Rapid compression of a gas in a shock wave can lead to sufficient heating that a plasma is generated. One example for this occurrence is the re-entry of a spacecraft into the Earth's atmosphere. The shock wave generates a plasma surrounding much of the spacecraft, leading to a communication blackout and ablation of protective heat shields. Shock-wave–generated laboratory plasmas have been used for the measurement of plasma properties; however, the inherently transient nature of shock-wave–produced plasmas raises questions about how close to local thermal equilibrium these plasmas are.

Interaction of high-power laser or particle beams with strongly absorbing solid or liquid matter also can generate thermal plasmas. These effects have been investigated in connection with nuclear fusion research and with weapons research. Laser treatment of materials can lead to the evaporation and ionization of some of the material to be treated, leading to an enhancement or a reduction of the desired effects. Again, these effects are transient in nature, and how close the generated plasma is to LTE must be investigated from case to case.

1.4 Thermal-Plasma Characterization

The primary variables that characterize thermal plasmas are the temperature, composition, and velocity. If LTE exists, composition and density are unique functions of the temperature. However, wherever the thermal plasma interacts with solid or liquid matter—e.g., for materials processing—there are nonequilibrium regions between the thermal plasma and the material to be processed, and characterization of these regions is usually of greater interest than those in which LTE prevails. There are many methods available for characterizing well-behaved simple laboratory plasmas through description by models and by diagnostic experiments. It is more difficult to find descriptions of thermal plasmas in actual devices because there are usually three-dimensional effects, complex gas mixtures, variations with time, and nonequilibrium effects present. An exception to this rule is provided by discharge lamps, which have been modeled and diagnosed fairly accurately for quite some time.

1.4.1 Thermal-Plasma Diagnostics

1.4.1.1 Plasma Temperature. The most straightforward way to determine plasma temperatures is absolute line-intensity measurement in emission spectroscopy, since for LTE conditions a unique relationship exists between the line intensity and the temperature at a given pressure (see, for example, Lochte-Holtgreven, 1968). With a calibrated optical system consisting of an imaging system, a spectrometer, and a detection system, the intensity can be measured and the temperature calculated. One difficulty is that the measurement usually consists of a signal obtained from integration over a path along which the temperature varies because the plasma is nonuniform. Knowledge of the intensity variation along this path is needed for temperature determination, which requires multiple measurements. For a cylindrically symmetric plasma, these measurement requirements can be reduced to the measurement of the lateral intensity distribution and transforming it to the radial distribution by solving Abel's integral equation. Other methods using emission spectroscopy include the relative line-intensity method, where the intensity ratio of two or more lines can be used to derive the temperature. Line-emission spectroscopy is the preferred method for temperature determination inside an arc plasma.

An intrusive method but independent of the plasma geometry is offered by the enthalpy probe. In this calorimetric method, a small-diameter tubular probe cooled by high-pressure cooling water is inserted into the plasma stream, and a measured amount of the plasma gas is sucked into the channel and cooled by the cooling-water flow. Knowledge of the gas composition then allows the temperature to be determined (Grey and Jacobs, 1964; Capetti and Pfender, 1989).

Use of Langmuir probes in thermal plasmas is difficult, but they have been successful in determining electron temperatures close to a cooled surface in which the probe is imbedded. A method recently developed for probing thermal plasmas involves pulsing the probe with a potential positive with respect to the plasma potential and recording the probe current during the pulse time. A subsequent negative pulse attracts ions, which bombard the probe surface and clean it from contamination (Leveroni *et al.*, 1991). These measurements are particularly of interest in regions close to a surface where deviations from LTE, especially elevated electron temperatures, are to be expected.

Recent developments in high-power laser diagnostics have opened the door to temperature measurements that are truly local and that do not require the assumption of LTE. One of these methods consists of measuring the line shape of the laser light scattered in a small plasma volume and comparing it with a theoretical line shape (Snyder *et al.*, 1994). Heavy-particle and electron temperatures can be measured independently. Another laser-spectroscopic method for temperature determination, laser-induced fluorescence (LIF), consists of selectively exciting specific upper energy states with the radiation from a tunable laser, and measuring the intensity of the de-excitation emission. The intensities can be related to the lower-state population densities and therefore can yield a value for the temperature.

1.4.1.2 Electron Densities. Measuring electron densities is of interest when deviations from equilibrium values are expected. Since the dominant recombination process in thermal plasmas is three-body recombination, recombination can be relatively slow, and fast-moving or rapidly cooling plasma flows may exhibit higher electron densities than the temperatures would predict. Two emission-spectroscopic methods are used for determination of electron temperatures: the absolute continuum intensity and the Stark line-broadening method. The continuum radiation from a plasma is generated by free electrons in the charge field of ions or other electrons (bremsstrahlung), or by free electrons recombining with ions (free-bound radiation). An expression for the intensity of the continuum radiation has been derived for hydrogenic atoms with correction factors for argon, and the electron density can be derived from it (Griem, 1964). The other emission-spectroscopic method is based on line broadening by the Stark effect, i.e., the removal of degeneracies of excited-state energy levels due to the electric field from free electrons. For hydrogenic atoms, this line broadening can be calculated as a function of the electron density, and comparison of the theoretical line shape with the measured one yields the electron density.

Also laser scattering or microwave interferometry can be used for electron-density determination, and there are several laser-spectroscopic methods available for probing the composition of plasmas with several components. Most of these methods are applicable only for recombining plasma flows, because in the plasma-generation region there is usually too much background radiation from the high-temperature plasma. Also the enthalpy probe can be used to measure the composition of a recombining plasma if the gas sample is channeled to a mass spectrometer. Obviously, only stable species can be measured this way.

1.4.1.3 Plasma Velocity. The plasma velocity is usually of interest in the region outside the plasma-generation region, i.e., in the plasma jet (except for circuit-breaking devices). One of the most prominent methods for measuring velocities is laser Doppler anemometry, which can be used in a variety of different arrangements. In one of these methods, the split beams of a laser generate an interference pattern in the space to be probed, and submicron seed particles in the plasma flow scatter the laser light with a modulation imposed by the interference pattern. With knowledge of the geometry of the pattern, the particle velocity can be derived from the scatter signal.

Also the enthalpy probe can be used to measure the plasma velocity. If the temperature at a certain location in the plasma has been determined, measurement of the stagnation pressure allows derivation of the velocity. A recently developed method uses the propagation of a disturbance of the plasma to determine the plasma velocity. Such a disturbance may be caused by a short-term instability of the arc, which is carried with the plasma flow and can be detected as an intensity fluctuation propagating downstream (Coudert *et al.*, 1993).

There are numerous diagnostics that result in qualitative descriptions of thermal plasmas. Examples are schlieren photography for flow studies and high-speed videography for detection of instabilities. Computerized image analysis of these images can yield some approximate values for the parameters of interest, such as the geometry of the high-temperature core of a discharge. With the continued advances in video technology, one will probably see an increasing amount of these techniques in combination with computer analysis being applied for quantitative characterization of thermal plasmas.

1.4.2 Plasma Characterization by Modeling Of the different regions of the arc, the arc column has been fairly well described by two-dimensional models. In general, the conservation equations are used, with some approximations usually made for boundary-layer flow. Additional terms made necessary by the presence of plasmas are the magnetically induced forces in the momentum equations, and the Joule heating term $\mathbf{j} \cdot \mathbf{E}$ in the energy equation. The equations can be rather complex nonlinear partial differential equations. The nonlinearity appears because of the strong dependence of the thermodynamic and transport properties on temperature and composition, and numerical solutions of the conservation equations are required even for the simplest case of a wall-stabilized arc column where there are no axial velocity and temperature gradients (fully developed flow condition). In this case the momentum and energy conservation equations are decoupled, and the energy equation is reduced to the well-known Elenbaas–Heller equation (Pfender, 1978)

$$\frac{1}{r}\frac{d}{dr}\left(r\kappa\frac{dT}{dr}\right) + \sigma E^2 - P_R = 0, \qquad (2)$$

where κ and σ are the thermal and electrical conductivities of the plasma, respectively, E is the electrical field strength, and P_R is the power loss by radiation per unit volume. Presence of the Joule heating term requires additional equations: Ohm's law providing the relation between current density and electric field, and current conservation for dc arcs or Maxwell equations for rf plasmas. Since plasmas are by definition reacting gases (ionization reactions are always present), the perfect-gas law has to be supplemented by equations giving the composition. For LTE, minimization of Gibbs's free energy or appropriate mass-action laws are used, like the Saha equation for determining electron densities:

$$\frac{n_e n_i}{n} = \frac{2Z_i}{Z_0}\frac{(2\pi m_e kT)^{3/2}}{h^3}\exp\left(-\frac{E_i}{kT}\right), \qquad (3)$$

where n_e, n_i, and n are the densities of electrons, ions, and neutral particles, respectively, Z_i and Z_0 are the partition functions for the ions and the neutral species, k and h are Boltzmann's constant and Planck's constant, and E_i is the ionization energy. In case of nonequilibrium, in particular in recombining plasmas, a set of rate equations for the possible chemical reactions has to be used.

Plasma jets and electrode regions are more difficult to model. Plasma jets are in most plasma devices turbulent, and their behavior is to a large extent determined by entrainment of cold gas into the hot plasma jet. Two-fluid models have been recently successfully used for describing this feature (Huang *et al.*, 1995). The electrode regions are associated with strong deviations from LTE, and different approaches have to be used. In particular for the condition where the anode consists of a ring-shaped nozzle surrounding the plasma jet, the attachment is usually unstable, resulting in a constant motion of the arc root, and a three-dimensional description is necessary (Wutzke *et al.*, 1967; Paik *et al.*, 1993). In case of an arc anode attachment in a fluid-dynamic stagnation region, progress has been made in describing the different attachment modes—diffuse attachment with current flow driven by diffusion and constricted attachment with a positive anode fall (Jenista, 1995; Zhu *et al.*, 1992). Similarly for the arc cathode attachment, models exist describing the attachment with different simplifying assumptions (Hsu and Pfender, 1983; Morrow and Lowke, 1993; Zhou and Heberlein, 1994), but no model has been formulated that is generally valid for the cathode region under all conditions.

2. PLASMA TORCHES AND ARC-GAS HEATERS

2.1 Plasma-Generator Device Purpose and Categorization

The processing of materials requires the controlled change of the physical and/or chemical characteristics of a substance, such as melting or evaporation; reduction or formation of oxides, carbides, or nitrides; or transformation of materials from a bulk material to a powder or from a powder to a coating.

The principal advantages offered by the use of plasmas for the processing of materials are the following:

1. The use of electrical energy for the generation of thermal energy makes the heating of the medium independent of its oxygen potential or its combustion energy—any material can become a plasma; it also gives enhanced control over the environment.
2. The high energy densities associated with a plasma allow the processing of high-temperature materials that are stable under lower flame temperatures, and they make high quench rates possible permitting the generation of metastable compounds.

The advantages of plasmas for materials processing were recognized relatively early, and soon after electricity became widely available, arc furnaces were introduced for bulk melting of metals by W. von Siemens in 1878. In the early 1900s, a thermal-plasma reactor was developed by Birkeland in Norway for the bulk chemical synthesis of calcium nitrate at power levels extending to 250 MW. While this process has been surpassed by low-temperature nitrogen-fixation processes, the plasma process for acetylene synthesis from natural gas developed by Chemische Werke Hüls in Germany during the

1920s and 1930s has been commercial since 1938 and is presently producing acetylene with an installed capacity of 180 MW. Systematic research on stabilizing the plasma in a plasma-generation device during the 1920s and again during the 1950s has resulted in the development of numerous plasma heater designs for a number of specific applications.

Thermal-plasma devices for materials processing are generally referred to as plasma generators, plasma torches, plasma heaters or plasma furnaces, or plasma reactors. While thermal-plasma generators refers to all devices in which a thermal plasma is produced for external or internal use, the distinction between the definitions for the other terms are somewhat less clear. A *plasma torch* (sometimes also called *arc-gas heater* or *induction gas heater*) is in general a device in which a plasma is generated to heat a gas flow, which exits the device in the form of a plasma jet that is then used for various plasma processes. In this device, the function of the electrodes is only to serve as termination of the arc, and the device is frequently called *nontransferred plasma torch.* In a plasma heater or a *plasma furnace,* the flow of the plasma gas is minimized and the plasma, usually an electric arc, heats the material to be processed directly. If one of the electrodes is also the material to be processed, the device is called a *transferred-arc plasma heater.* The *plasma reactor* is the device in which the plasma promotes physical and/or chemical reactions. The plasma generator can be part of the plasma reactor, always in the case of a plasma furnace or transferred-arc plasma device, or it can be separate as in the case of some plasma torches. A further categorization method uses the cathode emission mechanism for arc plasma generators, i.e., hot-cathode (thermionic emission) generators or cold-cathode generators. Lastly, also the arc-stabilization mechanism may serve as a categorization method, such as flow- or swirl-stabilized generators or wall-stabilized plasma heaters. Each of these devices can be designed for a different range of current and voltage levels, as is shown in Fig. 4.

Obviously, there are a number of different design options for plasma-device designs, which have to be matched with the specific materials-processing requirement, such as power level and enthalpy level, oxidizing or reducing environment, amount of off-gas permitted, and length of operation between service periods. In the following, a few specific applications are discussed in detail to illuminate the matching of these requirements.

2.2 Plasma-Spray Torches

Plasma spraying is a coating process in which metallic or ceramic particles are introduced into a high-velocity plasma jet, where they are melted and accelerated toward a

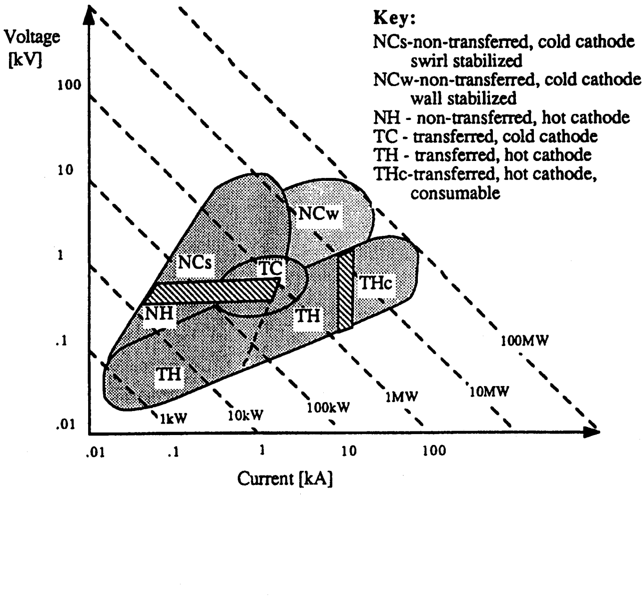

FIG. 4. Schematic of the voltage, current, and power ratings of different types of plasma torches (Heberlein, 1992).

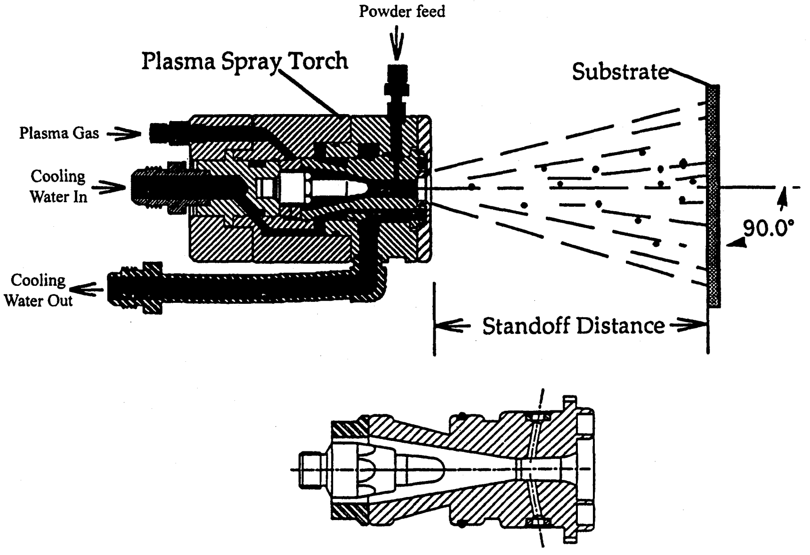

FIG. 5. Plasma-spray torch schematic (Miller SG 100, with kind permission of Praxair Thermal Spray Systems).

substrate on which the desired coating is formed. This technology has found widespread applications in the aerospace industry; e.g., the majority of the parts of a jet engine are coated to protect them against corrosion and excessive temperatures. But also in the medical implant industry and in the petrochemical industry, plasma spraying is used, and the technology is expanding into the automotive industry. Plasma spraying can be performed either in an open atmosphere (atmospheric-pressure plasma spraying or APS) or in a low-pressure chamber of 50 to 200 Torr where the plasma is expanded through a nozzle (low-pressure plasma spraying or vacuum plasma spraying, VPS). Figure 5 shows the cross section of a plasma-spray torch, with a hot cathode, usually of thoriated tungsten, and a cylindrical, water-cooled anode. The powder is injected downstream of the anode attachment point of the arc, i.e., the configuration is a nontransferred plasma heater. The arc is convection stabilized by the arc gas flow, which is frequently introduced with a swirl component at the root of the cathode rod, thus enhancing the stabilization. Typical operating conditions are 350 to 1200 A arc current, 25 to 80 V arc voltage, and 10 to 80 kW arc power. The most frequently used plasma gases are mixtures of argon with helium or hydrogen, or nitrogen. Higher-power torches are available, but their use is not as widespread. In atmospheric-pressure plasma spraying the jet is usually highly turbulent and cold air is entrained into the plasma, resulting in quite nonuniform conditions. Figure 6 shows a high-speed picture of a plasma-spray jet with particles. In this 50-ns exposure the particles have been illuminated by a laser strobe, and the image has been captured with a CCD array with an electronic shutter (Malmberg and Heberlein, 1993).

Because of the commercial importance of the plasma-spray process, the plasma-spray

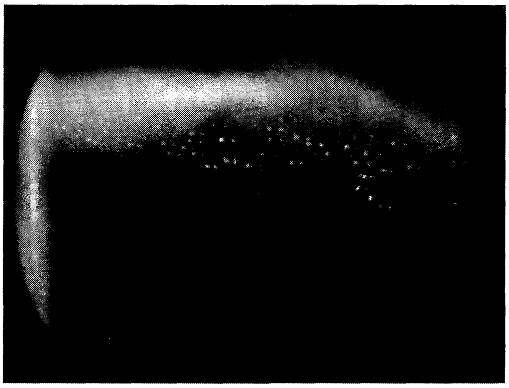

FIG. 6. High-speed videograph of a plasma-spray jet during spraying operation (exposure time 50 ns) (Malmberg and Heberlein, 1993).

jet has been well characterized through various diagnostics and modeling. Figure 7 shows the isotherms and isovelocity contours of a typical plasma-spray jet (Vardelle *et al.*, 1983); however, the values shown are time-averaged values, and significant variations may occur. Near the nozzle exit, peak velocities of 600 to 1000 m/s may be encountered in atmospheric-pressure plasma-spray jets (significantly higher in VPS), and temperatures of 12 000 to 15 000 K. The quality of the coating is predominantly determined by the particle temperature and particle velocity at the moment of impact on the substrate and by the substrate temperature. There have been several methods developed to measure particle velocity and temperature, the most elegant one developed by Fincke *et al.* (1990). In this method, two beams of a laser are used to measure particle velocity using laser anemometry and average size, and at the same time the radiation from the particle at two different wavelengths is measured and used to determine the particle temperature (two-color pyrometry).

The behavior of the arc inside the anode channel is less well characterized, partially because of the difficulty of gaining optical access and partially because of its usually unstable behavior. There is a constant motion of the arc anode attachment spot, which is desirable because it reduces anode erosion. This motion of the attachment spot is caused by the arc restrike phenomenon, in which the cold gas flow surrounding the arc drives the anode attachment downstream until an upstream restrike between the arc column and the anode wall occurs (Wutzke *et al.*, 1967), and by the plasma gas swirl. However, this motion induces fluid-dynamic instabilities in the plasma jet, causing nonuniform conditions. Some recent research efforts have concentrated on the characterization of these arc instabilities and the influences of operating conditions and different anode designs; however, no complete model exists that can describe the three-dimensional, time-dependent nature of the arc in a plasma-spray torch satisfactorily.

There are several variants of the plasma-spray process and of the plasma-spray torch for other applications. In wire-arc spraying, the coating material is introduced in the form of wires, melted by an arc struck between the two wire tips. A high-velocity stream of an atomizing gas blows the molten material in the form of fine droplets toward the substrate (see Fig. 8). In rf plasma spraying, the powder is injected into the plasma through a water-cooled injection probe in the center of the rf plasma torch. rf plasma spraying offers longer residence times of the particles in a region of moderately high temperatures, assuring complete melting of the particles. This feature may in some applications be more important than achieving the high particle velocities that can be obtained in dc plasma spraying.

Torches resembling plasma torches are also used for plasma cutting or some types of arc welding, although in these applications the arc is transferred to the workpiece. In a completely different type of application, the arc-jet thrusters used for space propulsion of

satellites were derived from the same type of torch that served as the origin of the plasma-spray torch.

2.3 Plasma Torches for Gas Heating and Chemical Processing

The principal requirements for arc-gas heaters for bulk chemical processing are the efficient heating of selected gases to specific bulk enthalpy levels, and high reliability and low maintenance. The power levels used are between 0.5 and 8 MW, with most of the applications requiring 1 to 3 MW or multiple heaters at these power levels. The majority of these torches operate in the nontransferred mode, although transferred-arc operation is possible if gas heating is combined with processing of a solid material serving as electrode. These torches have usually high gas heating efficiencies of 70 to 90%, but the average gas temperatures are usually relatively low (less than 7000 K).

The majority of the gas heater designs are based on the concept developed by Hüls for the acetylene generation process. Figure 9 shows, as an example for such an arc-heating device, a plasma torch developed by Westinghouse (Wolf and Fey, 1971; Heberlein *et al.*, 1989). It consists of two tubular electrodes arranged coaxially beside each other. The electrodes are water cooled, and the arc is struck between the inside surface of one electrode and the inside surface of the other. The process gas is introduced between the electrodes with a strong swirl, though part of the process gas can be introduced axially. A current passing through a coil surrounding the electrode tubes generates a magnetic field, which leads to a rotation of the arc electrode attachment, thus increasing electrode life and improving arc heating effi-

ciency and uniformity of the process-gas enthalpy levels.

This torch design is being used in applications ranging from air heating for metal-recovery shaft furnaces to providing process heat in a reactor for processing hazardous liquid wastes. Similar torches have been used for the commercial production of titanium dioxide pigment from arc-heated oxygen and titanium tetrachloride (George and Hare, 1983) and for the recovery of aluminum metal from the dross (Drouet, 1993).

2.4 Transferred-Arc Devices

The highest heat fluxes from an electric arc are to its electrodes. The reason for this fact is that in addition to the heat transfer by conduction, convection, and radiation, the energy transfer associated with current flow is present, i.e., for the anode, the kinetic energy of the electrons as well as the electron condensation energy (work function). In addition, usually the steepest temperature gradients are in front of the electrodes, maximizing the conduction heat flux. Heat fluxes in excess of 10 kW/cm^2 can be obtained. Figure 10 shows a typical temperature distribution in a transferred-arc device (Young *et al.*, 1983). Although this temperature field was measured at relatively low currents (200 A), the major change with increasing current is that the dimensions will increase with little change in peak temperatures.

Transferred-arc furnaces have been used extensively in the metallurgical industry, because the high heat fluxes associated with an arc anode attachment can lead to rapid melting of the anode material. As a matter of fact, the first commercial thermal-plasma device used for materials processing was the arc furnace developed by W. v. Siemens in 1878 for the melting of steel. Figure 11 shows a schematic of this device (Reid and Camacho, 1987). A graphite rod serves as a thermionic cathode while the molten metal serves as the anode. Carbon ablation from the consumable cathode can provide a reducing atmosphere. The majority of arc furnaces have been operated with ac; in particular, three-phase arc furnaces with three

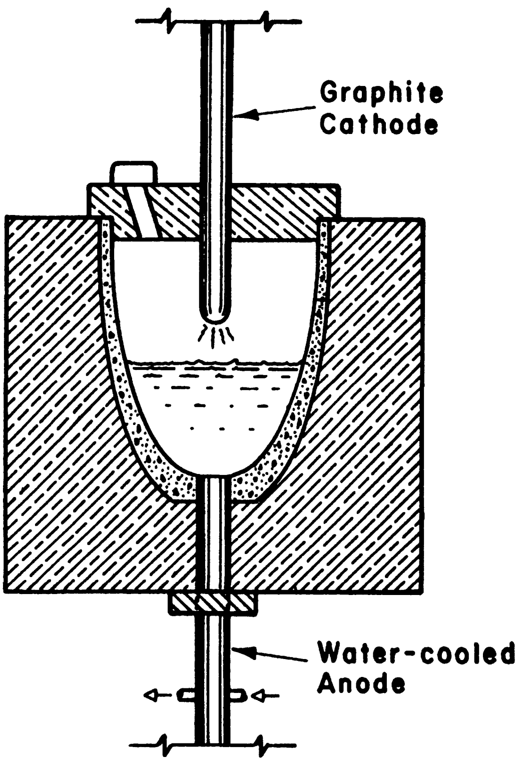

FIG. 11. Schematic of the original Siemens arc furnace (Reid and Camacho, 1987, with kind permission of the author).

electrodes each connected to one phase and the melt serving as ground are widely used. However, more efficient conversion of ac to dc has recently led to preference of dc arc furnaces because ac arc furnaces provide an inductive load with varying power dissipation resulting in very high noise levels and requiring power-factor correction between the load and the grid. In addition, dc arc furnaces allow improved process control and can reduce the graphite loss. One of the most advanced dc transferred-arc installations is the 45-MW furnace in Middleborough, South Africa, for production of ferrochrome. A schematic of this furnace developed by Mintek, S. A., is shown in Fig. 12 (Barcza *et al.*, 1989). The hollow carbon cathode allows introduction of fine raw materials through the cathode into the arc, reducing carryover of the fines with the off-gas.

While the high-power installations usually rely on consumable graphite cathodes, lower-power plasma furnaces operating at current levels below 10 kA use mostly nonconsumable cathodes usually made of tungsten with the addition of a low–work-function material for improved electron emission. Plasma heaters of this type are used increasingly for tundish heating during the continuous-casting process of steel. In this application, the molten metal flows into the tundish—a giant bath tub—from where it is cast. Because of the heat losses in the tundish, reheating of the metal at the location of the exit spout is necessary, if one wants to avoid filling the tundish with a highly superheated metal. Plasma heaters have the advantage that they can be turned on quickly when the temperature drops below a preset value and can provide a sufficient amount of heat with little gas flow. This type of heater operates typically in the power range of 1 to 3 MW, with currents rarely exceeding 3 kA.

On the lower end of transferred-arc power levels are plasma cutting torches. A schematic of such a torch is shown in Fig. 13. The arc is strongly constricted for maximizing current densities, and the metal to be cut serves as the anode. Oxygen is the preferred plasma gas, because the chemical reaction between the oxygen plasma and the metal increases the heat fluxes and therefore the cutting speed. Hafnium cathodes are used to avoid rapid cathode erosion. Torches of this type can be found in almost any sheet-metal shop, and their sizes range from 100 W to a few kilowatts.

For a few applications, transferred-arc plasma torches with cold cathodes have been developed. One example is the torch developed by Retech shown in Fig. 14 (Eschenbach, 1989). This torch, originally widely

used for titanium remelting, has more recently been applied in waste-processing reactors. In this application, the arc is struck between the upper cylindrical electrode and the waste material contained in a rotating tub. The rotation, at approximately 50 rotations per minute, allows continuous exposure to the plasma heat until a slowing down of the rotation results in flow of the molten waste material into a crucible where a nonleachable slag is formed. This torch can operate at power levels of up to 2 MW.

2.5 Plasma Torches for Space Applications

The space program has led to the development of two types of plasma torches:

1. high-power segmented plasma heaters for testing of materials and
2. arcjet thrusters for satellite propulsion.

When a spacecraft returns into the Earth's atmosphere (or ventures into the atmosphere of another planet), the sudden change in density of the surroundings coupled with the very high velocities of the space vehicle generates a plasma surrounding the vehicle and results in extremely high heat fluxes to parts of the vehicle. To simulate these conditions and study the behavior of potential protective materials, high-enthalpy plasma facilities have been developed. Most of these high-power plasma devices are based on segmented-arc heater designs, where insulated water-cooled discs separate anode and cathode and stabilize arcs up to 3 m in length. Figure 15 shows one of these designs (Winovich and Carlson, 1980). In this design, the electrodes consist of several water-cooled rings with separate current attachments allowing for parallel current flow and reduced heat flux to each electrode section. The individual constrictor discs are arranged in modules of 30 segments, each individually cooled with high-pressure deionized water, and 13 modules comprise the entire constrictor.

Typical arc currents range up to 5.4 kA, and arc voltages up to 11 kV can be obtained. The downstream electrode is followed by a nozzle in which the high-enthalpy gas stream is expanded into a low-temperature chamber in which the test specimen is mounted (e.g., a protective tile for the space shuttle). Part of the high gas temperature is transformed into hypersonic gas velocities, thus creating the conditions simulating those the spacecraft encounters during re-entry. It needs to be mentioned that gas heating efficiencies are rather low, so that this type of torch has not found applications in materials processing.

The electric-propulsion application of thermal-plasma devices makes use of the fact that electric energy can produce high-velocity gas flows with much less mass compared to combustion-based propulsion devices since no reactions between different gases are required for producing the heat. The life of a satellite is in part dependent on how long its position can be controlled by periodic propulsion thrusts. These propulsion bursts require low thrusts and last for relatively short times. Chemical propulsion requires transport of fuel and oxidant, while electric propulsion requires only one gas and the power-conditioning equipment transforming the output of the solar arrays into a high-voltage, low-current source. Arcjet thrusters are one of the electric propulsion devices having considerably better specific impulse than conventional chemical rockets, although much lower thrusts because of lower mass flows. These arcjet thrusters were originally developed in the 1960s; however, only recently have they been used in spacecraft partially because of the advances in solar-array technology. Figure 16 shows the schematic of such an arcjet thruster (Sankovic *et al.*, 1991). The design is quite similar to that of the plasma-spray torch, consisting of a thermionic rod cathode and a nozzle anode. One of the differences is that the anode nozzle consists of a tungsten piece and is entirely radiation cooled since no cooling water is available. The gas, hydrazine or hydrogen, enters the device at the root of the cathode rod, is heated by the arc in a cylindrical section of the anode, and then passes through the nozzle where it is expanded to supersonic velocities. Plate 2 shows one arcjet thruster in operation in a laboratory environment.

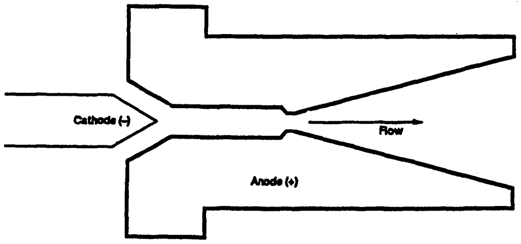

FIG. 16. Schematic of an arcjet thruster for electric space propulsion.

Recently, arcjet thrusters as well as other electric propulsion devices using nonthermal plasmas have been developed for higher-power applications for interplanetary space travel, and they are being adapted for other applications such as thermal-plasma chemical vapor deposition. As an interesting observation one might add that these arcjet thrusters and the plasma-spray torches had a common root, then were adapted by different user communities for different applications, and now start to approach each other again with the development of low-pressure plasma spraying and the use of arcjet thrusters for thermal-plasma CVD. In particular in the modeling of these devices there is a considerable overlap, and input from both user communities can be combined advantageously (George *et al.*, 1996).

3. PLASMA LIGHT SOURCES

3.1 History and Categorization of Discharge Lamps

The importance of plasmas for lighting can be illustrated by a few figures: Approximately 25% of the electrical energy consumed in the United States is used for illumination, and an increasing fraction of this amount for discharge lamps. Practically all street lighting and all lighting of large rooms uses discharge lamps because of their considerably higher efficiencies in converting electricity into light. If we compare the light output of a candle with that of a 40-W fluorescent lamp, we find that the lamp provides 250 times the light for about 1000 times the length of time (Waymouth, 1971). The importance of thermal plasma for lighting is also demonstrated by the fact that discharge lamps are probably the most investigated and most completely characterized of all thermal-plasma devices, and a considerable amount of literature is devoted to this characterization.

The high radiation intensity of the carbon arc not only has stimulated the curiosity of scientists like H. Davy, who is credited with discovering the electric arc, but also has attracted engineers who wanted to utilize this property. Already in the middle of the 19th century carbon arcs were used as light sources. Around the same time, H. Geissler discovered through spectroscopic studies of discharges that different gases emitted light at different characteristic wavelengths, creating the basis for colored discharge lights used for special effects and advertising. In the beginning of the 20th century, P. Cooper-Hewitt experimented with discharges in low-pressure environments containing mercury vapor and discovered that metal-vapor discharges were very efficient light sources. His mercury-vapor lamps were the first commercial discharge lamps, which found widespread use for industrial lighting in the early part of the century. These lamps found successors in fluorescent lamps and in high-pressure mercury lamps. In fluorescent lamps, the mercury discharge takes place in an inert buffer gas (e.g., argon), and by adjustment of the mercury-vapor pressure and the buffer gas pressure, emission of the ultraviolet radiation from the mercury resonance line at 253.7 nm can be optimized to a degree where it contains 60% of the electrical input power (Waymouth, 1971). A phosphor coating on the wall of the discharge tube absorbs this UV radiation and transforms it to light in the visible wavelength region. After the discovery of efficient phosphors in the 1930s and the development of satisfactory processing methods, fluorescent lamps became very widely used. However, the nonequilibrium low-pressure discharges in these fluorescent lamps do not consist of thermal plasmas and will not be further discussed in this article.

Three types of lamps make use of the emission of light from thermal plasmas:

1. high-intensity discharge (HID) lamps,
2. short-arc lamps, and
3. carbon-arc lamps.

The HID lamps are the most widely used illumination sources, and they can again be divided into three different groups: high-pressure mercury lamps, metal-halide lamps, and high-pressure sodium lamps. Each of these lamp types has specific advantages that render them particularly suitable for some specific application.

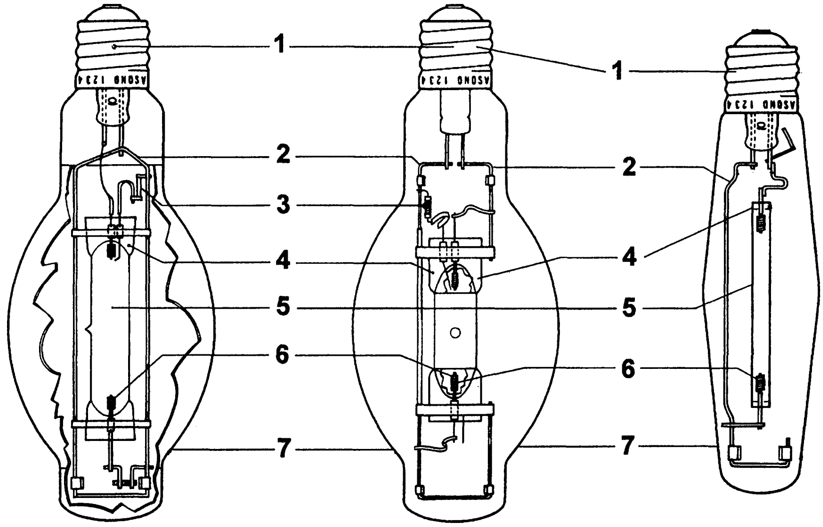
The performance of lamps is given by three characteristics: the efficacy, the color rendition, and the total power or total light output. The efficacy is the efficiency with which the electrical energy is transformed into light that can be detected by the human eye; i.e., the light output is weighted according to the spectral photopic response characteristics of the eye. The unit for measuring efficacy is lumens (abbreviated lm) per watt, and one watt radiated at 555 nm is equivalent to 680 lm. Accordingly, the highest efficacy would be associated with a lamp radiating only in a narrow line around 555 nm, without any loss of heat. For comparison purposes consider that the efficacy of an incandescent lamp is about 20 lm/W, and that of a fluorescent lamp is about 100 lm/W. Color rendition, on the other hand, determines how much energy is radiated in various wavelength bands allowing the light reflected from various objects to be seen in a specific color. Different tasks can require different color renditions, and specific preferences for various color renditions exist depending on people and environment. Discharge lamps exist for a wide range of color renditions. The total power or the total light output is given in watts or in lumens.

3.2 High-Intensity Discharge Lamps

3.2.1 Some Common Characteristics

The basic configuration of all HID lamps is very similar and shown in Fig. 17. The arc is contained in a sealed arc tube, which is mounted in an outer envelope made of borosilicate glass. Electrical connections are made through a brass base similar to those for incandescent lamps. The outer envelope is evacuated or filled with nitrogen at lower than atmospheric pressure. The envelope is designed to fulfill several functions:

1. to protect the arc tube from contamina-



Mercury Vapor Lamp

Metal Halide Lamp

High-Pressure Sodium Lamp

FIG. 17. Construction of high-intensity discharge lamps (with kind permission of North American Philips Lighting Corp.). (1) The brass base, (2) the arc-tube mounting frame, (3) a starting resistor, (4) the arc-tube seal, (5) the arc tube, (6) the double-coiled tungsten electrodes, and (7) the borosilicate glass bulb.

tion, which would influence its operation, and to protect oxidation of the leads;

2. to protect the arc tube from asymmetric cooling during operation, which would change the character of the discharge;
3. to reduce the heat loss from the lamp by absorbing or reflecting infrared radiation from the arc tube; and
4. to absorb the harmful short-wavelength UV radiation emitted by the arc and passing through the arc-tube wall.

The arc tube contains a starting gas, typically argon or, in the case of the high-pressure sodium lamp, xenon, at a pressure of a few Torr, and the metal-containing chemical compound, which is usually in condensed form at room temperature. The choice of arc starting gas is partially determined by the use of the Penning effect: the lowest metastable energy level of a gas is, after the application of a voltage, quickly populated in equilibrium with the electron energies, and transfer of the excitation energy during a collision with an atom of a different gas or vapor with an ionization energy lower than the energy of the metastable energy level leads to efficient ionization and lowering of the breakdown voltage. The energy of the first metastable level of argon is 11.55 eV, and the ionization energy of mercury is 10.43 eV; the first metastable energy level of xenon is at 8.32 eV, and the ionization energy of sodium is 5.14 eV. After arc starting, the arc tube heats up, leading to evaporation of the metal compound accompanied by a significant increase in pressure (100 Torr to 8 atm) and light output. The low ionization energy of most metals results in relatively low power dissipation per unit length of the arc and in relatively low peak temperatures of 5000 to 6000 K.

Most HID lamps operate with alternating current, and the arc extinguishes every half cycle of the 60-Hz supply voltage. A stroboscopic effect or "flicker" is the consequence of this 120-Hz modulation of the light output. However, after initial lamp starting the gas inside the arc tube is sufficiently hot that restriking of the arc during the following half cycle is easily accomplished without special starting aids.

The arc discharge in HID lamps is stabilized by wall stabilization combined with free-convection stabilization. For vertical operation, the arc-heated gas will rise to the top of the arc tube where it will cool down somewhat and return along the arc-tube wall, thus forming free convection cells surrounding the arc column. For operation in other positions, the arc will bow and will be asymmetrically cooled by the proximity to the arc-tube wall resulting in lower efficacies. This effect is not observed with the high-pressure sodium lamp, which has a narrower arc tube and more wall stabilization.

All HID lamps have similar electrodes, shown schematically in Fig. 18. The electrodes consist of a tungsten rod onto which a tungsten coil is wound, which itself is overwound with another tungsten coil. The space between the coils is impregnated with an emission material, a rare-earth or alkaline-earth oxide combination. This emission material reduces the work function for electron emission during the current half cycle when the electrode is a cathode, thus reducing the electrode operating temperature and the material evaporation rate and prolonging lamp life.

Lamp life is usually associated with electrode effects. Evaporation of the emission material and sputtering of the tungsten leads to a darkening of the arc tube with the consequence of higher starting voltages. In particular with the high-pressure sodium lamp, the darkening of the arc-tube walls will increase the operating pressure and voltage to a degree that the voltage will exceed that supplied by the ballast. The lamp will extinguish, cool down, and reignite.

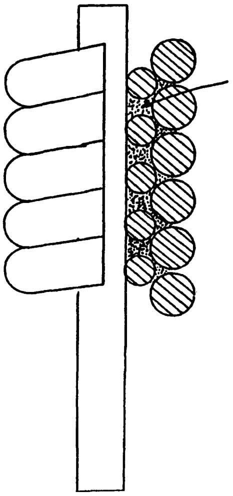


FIG. 18. Electrode design for HID lamp discharges.

Since discharges in lamps have usually falling voltage–current characteristics, i.e., the voltage decreases with increasing current, a stabilizing circuit element has to be introduced, and since most discharge lamps operate on ac, this circuit element is an inductive impedance, which is incorporated into the lamp ballast together with the transformer providing the suitable discharge operating voltage and with the starting circuit. The losses of electrical energy in the ballast have to be taken into account when comparing efficacy values, and they range from 30% for low-wattage HID lamps (50 W or less) to 7% for lamps with power ratings of 1000 W or more.

Although quite sophisticated models have been developed for description of the lamp arcs, in particular with regard to the description of the radiation transport, the Elenbaas–Heller energy equation [Eq. (4) in Sec. 1.4.2] for the fully developed wall-stabilized arc assuming optically thin radiation can give good physical insight into the arc behavior of discharge lamps, such as arc-tube heating for different fill pressures and arc currents. One must, however, bear in mind that the radiation-loss term does not contribute to the energy transport to the wall because most of the radiation penetrates the arc-tube wall. It should be noted that the Elenbaas–Heller equation was derived for describing lamp arcs.

3.2.2 High-Pressure Mercury Lamps

The arc tube of high-pressure mercury lamps consists of a fused silica ("quartz") tube with a circular cross section and pressed end seals. The end seals contain a molybdenum ribbon making the current connection to the electrode stem. A small nipple indicates the location where during the manufacturing process the tube is evacuated and filled with argon at a low pressure and with liquid mercury. The arc is established with the aid of a starting electrode, which is a tungsten rod placed close to one of the arcing electrodes requiring a lower voltage for the initial establishment of a discharge. The starting electrode is electrically connected to the opposite arcing electrode by a resistor, and once a plasma is generated in the arc tube by the initial arc, transfer of the discharge from the starting electrode to the other arcing electrode takes place. The arc results in evaporation of the mercury over a time period of a few minutes, and in a final pressure of 2 to 4 atmospheres depending on the initial amount of mercury in the lamp. During this time the arc voltage drops from approximately 200 to close to 120 V while the arc current increases from less than 1 A to the final value of between 3 and 4 A for a 400-W mercury lamp. After the lamp is turned off, a cooling-down period is necessary to reduce the pressure inside the arc tube and the voltage necessary for lamp starting.

High-pressure mercury lamps cover a wide range of powers and have efficacies of 30 to 65 lm/W. The color rendition is determined by five principal lines in the visible region of the spectrum at 404.7, 435.8, 546.1, 577, and 579 nm, indicating a dominance of green and blue. The majority of the ultraviolet resonance radiation is self-absorbed in the cooler regions near the arc-tube wall. Operation at higher pressures leads to increased broadening of the lines and some shift of the radiation to longer wavelengths; however, there remains a lack of radiation in the red region of the spectrum. To improve color rendition and at the same time make use of the considerable amount of UV radiation from the Hg discharge, the outer envelopes of some mercury lamps are coated with a red-emitting phosphor. Plate 3 shows the spectrum radiated by a high-pressure mercury lamp in comparison with other HID lamp spectra (Kaufman, 1981).

3.2.3 Metal-Halide Lamps The arc tube of the metal-halide lamp is very similar to that of the high-pressure mercury lamp, the major difference being that in addition to mercury, metal-halide compounds provide the metal vapor for the high-luminosity arc. Many metal halides have high vapor pressures at the arc-tube temperatures compared to the metals; thus the halide is readily evaporated. When the halide vapors diffuse into the high-temperature arcing region, the molecules dissociate, providing the metal atoms for the metal-vapor arc, while diffusion of the metal vapor from the high-temperature arcing region leads to recombination with the halide atoms in the cooler regions. As a consequence, one has the metal atoms inside the arc providing the high-intensity radiation, and metal-halide molecules in the colder regions close to the arc-tube wall, reducing the unwanted chemical reactions between the metal and the silica arc-tube material. Mixtures of metal halides are selected to provide a combination of high efficacy and good color rendition. For example, sodium and scandium iodides are used because sodium is one of the most easily excited atoms providing high radiation efficacy, and scandium provides emission lines in many parts of the spectrum. Similarly, a combination of sodium, thallium, and indium iodides in the arc tube provides emission lines in different parts of the visible spectrum, giving good color rendition. Efficacy values range from 75 to 125 lm/W for lamps with power ratings from 175 to 1500 W.

These desirable features have to be obtained through several design modifications compared with the simpler mercury lamp construction. To avoid condensation of the metal halides in the arc-tube ends away from the arc, a reflecting coating is applied to the arc-tube ends to increase the temperature in this region. The halides of some metals, in particular of sodium, experience electrolysis in the silica in the presence of an electric field, leading possibly to sodium diffusion through the arc-tube wall close to the current-carrying wires, as well as to shorting of the starter-electrode wire in the arc-tube end seal. Therefore, the current connections are led farther away from the arc tube, and after arc initiation the starting electrode is either shorted or disconnected from the circuit voltage by a bimetal switch.

Starting of the metal-halide lamp is similar to that of a mercury lamp, only a higher starting voltage is needed. Because the different metal halides have different vapor pressures at the different temperatures the arc tube experiences during starting, the color of the lamp changes during warmup for several minutes. Also, because of the higher arc-tube temperatures compared to that in mercury lamps, cooling down takes considerably longer, and it may take as much as 15 min before a metal-halide lamp can be restarted.

3.2.4 High-Pressure Sodium Lamps In this type of lamp, sodium is the principal light emitter, assuring the highest efficacies (exceeding 140 lm/W with high-power HPS lamps) at the expense of somewhat poorer color rendition. The arc tube contains xenon as the starting gas and sodium amalgam as the compound providing the metal vapor during operation. After warmup, the amalgam is partially evaporated, and both sodium and mercury are in the vapor phase. While the radiation properties are determined mostly by the sodium vapor, the mercury vapor serves as a buffer gas increasing the lamp pressure and with it the arc voltage and the width of the sodium line.

Since silica is attacked by sodium, fine-grained polycrystalline alumina (PCA) is used as arc-tube material. This material is highly translucent, allowing more than 90% of the radiation from the arc to be transmitted. The tube has the shape of a narrow cylinder with metal or cermet endcaps that are attached to the alumina with special frits matching the thermal-expansion characteristics of the alumina.

Even though most of the radiation stems from the resonance doublet of the sodium D lines at 590 nm, the color rendition of these lamps is rather good, because the lines are substantially collision broadened in the high-pressure environment, and a strong "self-reversal" reduces the radiation at the line center. This self-reversal is generated by the absorption of the radiation from the central portions of the arc by the vapor in the cooler outer regions. Plate 3 shows the wavelength distribution of the radiation from such a lamp (Kaufman, 1981).

Because the arc tube of the high-pressure sodium lamp has a rather small diameter, no starting electrode is incorporated, and the lamp is started with a short high-voltage pulse of 4000 to 6000 V. This high-voltage pulse is applied once during every 60-Hz ac voltage cycle until the arc is established. Full operating pressure is reached after approximately 10 min, and since the operating pressure is usually lower than with mercury or metal-halide lamps, restarting after shutoff can occur already after approximately 1 min.

3.3 Specialty Lamps

There are numerous lamps for special applications, but here only two of them are described because of their use of the high energy density of thermal plasmas.

3.3.1 Short-Arc Lamps These types of lamps derive their name from the relatively short distance between the cathode and anode of 0.3–12 mm, which leads to cathode-jet stabilization of the arc. The lamps operate with direct current and use a cathode rod with a conical tip and a slightly larger-diameter anode rod within a spherical or ellipsoidal arc tube made out of fused silica (see Fig. 19). The electrodes are usually water cooled. The most frequently used arcing media are xenon gas at several atmospheres or mercury with xenon added as starting gas. The xenon arcs have the advantage that their spectrum is rather continuous in the visible wavelength region, comparable to that of sunlight.

Short-arc lamps have been designed for power levels of up to 30 kW, and their very high luminosity makes them ideal for applications as search lights or projection lamps. The xenon arc has temperatures higher than the arcs in lamps containing metal vapor, and its appearance can be compared with the cathode region of a free-burning arc. To avoid an excessive amount of short-wavelength UV radiation escaping from the arc and leading to ozone generation around the lamp, a silica is used that cuts off transmission at 210 nm.

3.3.2 Carbon-Arc Lamps A direct-current arc burning between two carbon electrodes has been used for lighting purposes since the middle of the 19th century. Different types of carbon arcs have distinctively different characteristics. The "low-intensity carbon arc" consists of two graphite electrodes, a horizontal anode and a cathode set

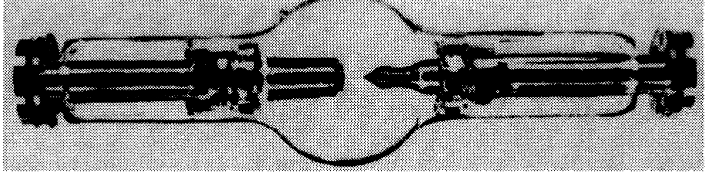

FIG. 19. Schematic of a short-arc lamp (Kaufman 1981, with kind permission of IES).

at an angle to the horizontal, the arc burning in air. The radiation from the crater at the anode tip serves as the light source. Typical currents are less than 10 A for a 9-mm-diameter anode, and typical arc voltages are around 60 V. The anode tip has a temperature of close to 4000 K, and emits essentially blackbody radiation at this temperature. The amount of radiation from the arc itself is small compared to the anode radiation.

If metal compounds are incorporated in the core of the graphite electrode rods, evaporation of these compounds introduces metal vapor into the arc leading to easy excitation of the metal atoms and high luminosity from the arc. Rare-earth metals are frequently used as additions. For increases in the current density, the metal evaporation becomes so strong that a jet from the anode appears similar to the cathode jet, resulting in an enlarged region of radiating gas as shown in Fig. 20 (high-intensity carbon arc, Beck arc).

One of the advantages of the dc carbon-arc lamp is that it provides continuous radiation whereas the lamps operating with alternating current display a 120-Hz flicker because of the periodic extinction and reignition of the arc in every half cycle of the current. Accordingly, the carbon-arc lamp finds its application in movie projection lamps where flicker may lead to elimination of some frames. One of the disadvantages is that the electrodes burn off quite rapidly and have to be continuously fed, comparable to the graphite electrodes in a transferred-arc metallurgical furnace. The carbon arc produces fine soot particles, and usually it burns in a ventilated housing.

4. CURRENT-INTERRUPTION DEVICES

4.1 Fundamentals of Circuit Breakers

Circuit breakers are thermal-plasma devices because current interruption in an electric power grid practically always results in the generation of an electric arc. Formation of the plasma allows the current to be interrupted because, as described in Sec. 1, current flow through a plasma is strongly dependent on the energy losses from the plasma. Strong cooling of the plasma results in a rapid decrease of the electrical conductivity by several orders of magnitude and of the current flow when the circuit voltage approaches a zero value during an ac cycle (current zero).

Current interruption is required in electrical circuits either when switching the power off to parts of the circuit, e.g., an electric installation or a motor, or when as a result of a fault (or a short circuit) a large current can flow from the power grid to the circuit section in which the fault has occurred. Circuit breakers limit the duration of the very high fault currents to a maximum of a few cycles in a 60-Hz power grid, thus minimizing the potential damage by the increased power dissipation. Depending on the location in the power grid, breakers are classified into three voltage categories:

1. low-voltage (110–1000 V) breakers are located close to the end user in the electric power grid,
2. medium-voltage (2500–38 000 V) breakers are in the distribution network, and
3. high-voltage (72–800 kV) breakers are in the transmission portion of the power grid.

During current switching, circuit breakers are used to control the making currents and interrupting currents in electrical circuits. To achieve this operation, breakers have interrupting elements actuated by an electromechanical mechanism. This element consists of a set of contacts (usually one stationary and the other movable) in a medium of gas, oil, or vacuum. For initiating currents (closing operation), assume the breaker contacts are initially separated (open position) with no current flowing through them and the circuit voltage appears across them. As the movable contact closes, the contact separation becomes progressively smaller until a voltage breakdown occurs initiating an electric arc (denoted as prestrike) that burns until the contacts actually touch. The process of ac (sinusoidal) current interruption is as follows:

1. Initially the breaker contacts are touching (closed position) and current is flowing through them.
2. The breaker mechanism is tripped causing the movable contact to separate from the stationary contact.
3. Upon contact separation, an electric arc is formed between the separating contacts and continues to burn until the ac current reaches a "natural" current zero.
4. Immediately following arc extinction at current zero, a race develops between the increasing dielectric strength of the gap between the contacts (dielectric recovery) and the increasing circuit voltage across this gap (recovery voltage). If the plasma is cooled rapidly enough so that the rate of dielectric recovery within the intercontact region is greater than the rate of the recovery voltage rise across the contacts, the arc does not reignite during the recovery period and current interruption is successful.

Circuit breakers have been used since electric power has been available. Originally, large contact separations were necessary to make the electric arcs in air sufficiently unstable that circuit interruption was possible. Since the 1930s, a significant research and development effort has been devoted to increasing arc motion control and instabilities during the early part of the circuit-interruption process in order to reduce the arcing time. New arcing media have been introduced: first oil, then SF_6 for medium- and high-voltage breakers, and vacuum for medium-voltage breakers. At present, a variety of circuit breakers is available, and we have seen a continuous decrease in arcing times and in breaker size for a given interrupting capability.

4.2 Low-Voltage Air Circuit Breakers

Low-voltage breakers (110–1000 V) are usually air magnetic breakers rated for load currents from 15 to 4000 A, and short-circuit currents from 10 to 200 kA. The principles discussed here apply to both molded-case circuit breakers and power circuit breakers. The construction of a typical low-voltage air circuit breaker is shown in Figs. 21 and 22. The breaker consists of two contacts (one stationary and one movable), a mechanism, an arc chamber, and overcurrent detection circuits. Often there are two sets of contacts—"main" contacts and "arcing" or "arc runner" contacts (Lee and Slade, 1984). During high–fault-current interruption, the contacts separate, initiating an arc between the "main" contacts. The arc transfers rapidly to the "arcing" contacts by a magnetic blowout force and into the arc chamber.

During the interruption of the load and overload currents (less than twice the load current), the breaker mechanism is tripped either manually or by a thermally triggered actuator, and the movable contact is accelerated from the stationary contact forming an electric arc of increasing length. The interaction of the self-induced magnetic field *B* with the arc current density *j* produces a magnetic force on the arc column driving it into the arc chamber plates. In the arc

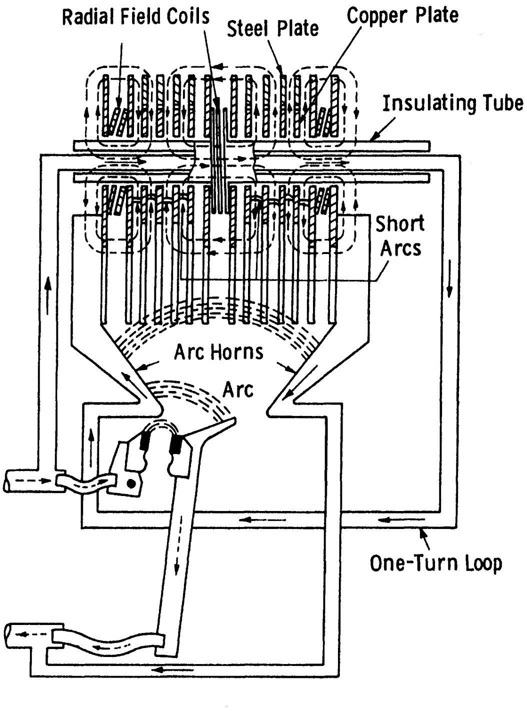

FIG. 21. Cross section of a low-voltage air circuit breaker (reprinted from Browne, 1984, p. 428, by courtesy of Marcel Dekker Inc.).

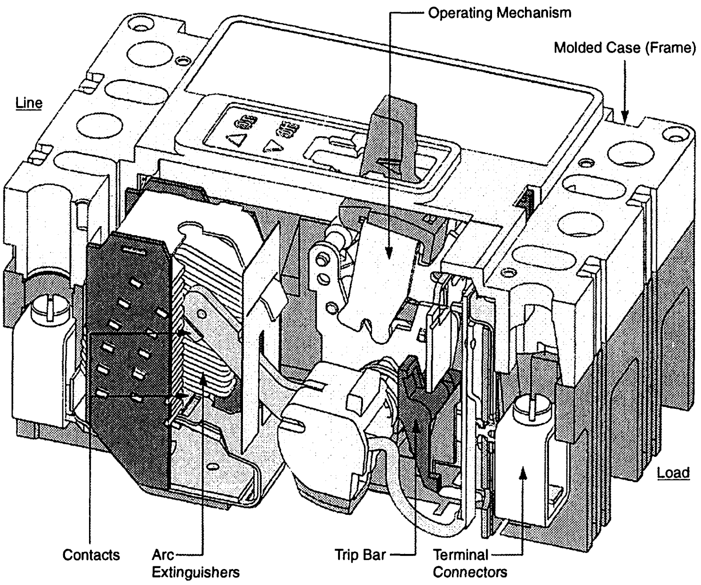

FIG. 22. Schematic of a molded-case circuit breaker (with kind permission of Cutler Hammer).

chamber, the arc divides into a series of short arcs each burning between adjacent U-shaped steel plates of the arc chamber. These short arcs are cooled by conduction to the steel plates, and an arc voltage of 25 V/gap (Lee and Slade, 1984) is generated. With 11 plates and 10 series arcs, a voltage of 300 V can be generated between the separated contacts. As the current approaches a zero value, the arc is extinguished and a recovery voltage appears across the contacts. The steel plates provide further rapid cooling of the arc plasma causing additional deionization of the hot gas in this region thus increasing the dielectric strength needed for successful current interruption.

For high–fault-current interruption, the arcing process is similar to that described except that the high arc current produces a larger-diameter and hotter arc that completely fills the arc chamber and is usually not broken into a series of shorter arcs. The plasma consists of a mixture of air, evaporated arc chute materials, and contact material vapors at about 10 000 K, with a high electrical conductivity (100 S at current crest). The cooling mechanisms for this arc are radial convection and conduction to the steel arc chamber plates, and ablation of material from the arc chamber walls. To promote high arc voltage, some breakers have means of enhancing the movable-contact opening speed with a "slot motor": This design produces an additional acceleration force on the contact arm by the interaction of the magnetic field created by the current through the contact arm with the U-shaped plates of the slot motor (see Fig. 23). As a result of the more rapid contact separation, a high arc voltage is developed quickly, thus limiting the let-through current. The current approaches zero sooner, the arcing time is shortened (e.g., from 8.3 ms or longer to 4–5 ms), and contact erosion is reduced. During the recovery period, the conductance of the arc column is decreased several orders of magnitude within microseconds by rapid cooling and deionization. Therefore, at current zero, the source voltage is low making both the rates of rise and the peak of the recovery voltage significantly lower. Thus the current-limiting effects of the thermal plasma lead to easier interruption of the fault current.

4.3 Oil Circuit Breaker

Medium-voltage (5–38 kV) oil breakers or reclosers have three sets of current interrupter elements immersed in an oil tank. Rods connected from the mechanism to the current-interrupting elements operate the contacts of the interrupter elements. Each element consists of a set of contacts. One is

a stationary "tulip"-shaped contact and the other is a cylindrical movable contact inserted in the tulip-shaped contact. A spring mechanism provides the movable electrode with a motion of several inches. These contacts are surrounded by pots or deion grids used to control and cool the arc plasma. During the current-interruption process, the contacts are separated, forming a thermal plasma between them. The hot arc plasma decomposes the oil into its elements such as carbon, hydrogen, and oxygen, and the gaseous mixture fills the intercontact region. The plasma is cooled by convection and evaporation of the oil and by conduction to the deion grids. The hydrogen gas within the arc mixes with the oil producing additional cooling. The hydrogen gas is essential during the recovery period because of its excellent dielectric properties and thermal heat capacity.

4.4 Vacuum Circuit Breaker

The medium-voltage vacuum circuit breaker consists of an insulated vacuum vessel, 4 to 7 in. (10 to 18 cm) in diameter and approximately 12 in. (30.5 cm) long, made from a cylindrical section of either ceramic or glass with metal end plates attached (see Fig. 24). The vessel contains a set of contacts

brazed to electrode stems of which one is fixed to the end plate. A mechanism provides motion (20 mm or less) to the movable contact through the opposite end plate via a metal bellows, which serves to maintain a vacuum of 10^{-6} Torr or less. Surrounding the contacts is a metal shield that protects the envelope from deposition of arc products.

Current interruption in vacuum is similar to that in gas, except that the ionized medium is metal vapor originating from the erosion of the contacts during the arcing process. At low arc currents, this metal-vapor arc is not a thermal plasma since strong nonequilibrium conditions prevail. The cathode has a multitude of highly mobile arc spots moving rapidly over the surface, each spot supporting about 100 A with a typical current density of 10^8 A/cm^2 (Jüttner, 1981). The voltage drop of the cathode region depends on the contact material (typically 18 V for Cu). The anode surface may have a diffuse current collection without anode spots or may have a constricted anode spot causing gross erosion of the anode surface (e.g., 10^{-4} g/C). A constricted anode spot occurs when there is an insufficient number of ions in the arc column to balance the charges of the current-carrying electrons. A space charge is formed leading to local heating of the anode surface and evaporation of anode material producing the constricted arc attachment (Kimblin *et al.*, 1984).

The column region can be either diffuse or constricted. For arc currents up to several hundred amperes, the arc column is diffuse and electrons flow from the cathode to the anode with a low column voltage. At higher currents (2000 A or greater) the positive column consists of electrons and ionized metal-vapor products generated by the material evaporated from the anode and cathode. The radius of the column is determined by the outward radial pressure of the ionized and neutral species balanced by the inward magnetic constriction pressure formed by the arc current (magnetic pinching). Under these conditions, the metal-vapor arc column is nearly in thermal equilibrium radiating strongly, and the arc voltage increases with current, reaching values as high as 200 V. Cooling of the arc column is primarily by radiation to the surrounding surfaces and by thermal conduction to the electrodes. To prevent excessive heating of the anode, the contacts are designed such that current flow in part of the contact generates a radial magnetic field that interacts with the arc current causing the arc roots to move rapidly in a circular motion.

As the current decays toward a natural current zero, the constricted column becomes a diffuse arc. Close to current zero, the arc becomes unstable and suddenly extinguishes, an effect known as "current chop" with a recovery voltage across the contacts. Electrons are rapidly lost from the interelectrode region leaving an expanding ion space charge at the anode surface producing a post-arc current (several amperes) that flows for several microseconds. The recovery voltage appears across the expanding ion space-charge region. If the rate of dielectric recovery determined by the loss of ions from the intercontact region is faster than that of the rate of rise of the recovery voltage, interruption will occur.

4.5 Compressed-Air and SF$_6$ Breakers

High-voltage circuit breakers (72 to 800 kV) have continuous currents from 600 to 4000 A, and fault currents of 20–63 kA. Because of the high circuit voltage, the current-interruption medium is usually compressed air or compressed SF$_6$ because both the heat capacity and dielectric strength of these gases increase with pressure. Construction of such a breaker consists of a separate interrupting element per phase, large insulators, and a pneumatically operated mechanism (see Fig. 25). The interrupting elements are contained in a tank, which can be ungrounded (alive tank breaker) or grounded (dead tank breaker).

The arcs produced during current interruption in this breaker are different from magnetic air breakers in that

1. the arc is confined in a channel and operates at higher ambient gas pressures, and
2. the arc is extinguished primarily by high-velocity axial flow providing convective cooling.

Figure 26 shows the basic double-flow electrode arrangement for such a circuit breaker. For current interruption, the movable contact separates from the stationary, and an arc is

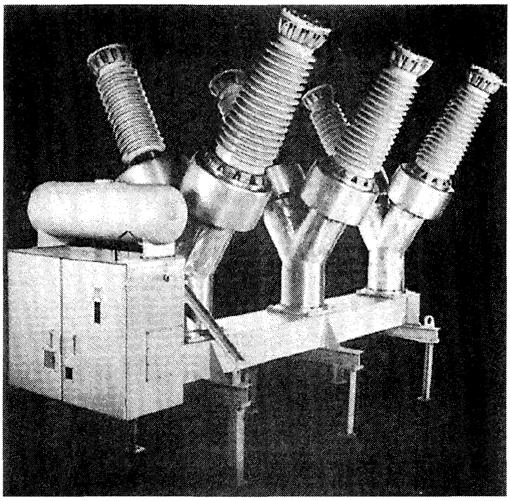

FIG. 25. Photograph of a high-voltage three-phase circuit breaker (reprinted from Browne, 1984, p. 417, by courtesy of Marcel Dekker Inc.).

initiated between the contact tips. Gas enters radially into the separated-contact upstream region and flows downstream through appropriately designed nozzles. The arc moves rapidly into the inside of the contacts, attaching to the inner contact walls. While there are a number of different high-voltage circuit breaker designs, the basic principle of cooling the arc through strong axial nozzle flows and generating instabilities due to turbulence close to current zero is the same.

Two fundamental physical models for the transient behavior of the arc column during current interruption have been developed. The first model, developed by Cassie (1953), treats the arc plasma, assumed to be in local thermodynamic equilibrium, as a hot fluid having a uniform temperature and a temperature-dependent electrical conductivity. The plasma temperature equation depends on the energy balance of the plasma. During the voltage recovery period, the second model, developed by Mayr, is used. This model assumes that the electron temperatures are greater than those of the heavy species and derives conditions for recovery depending on electron energy and recombination, ionization, and attachment processes (Browne, 1984).

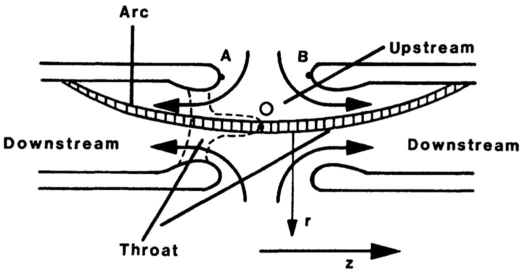

FIG. 26. Schematic of the arcing region of a double-flow high-voltage circuit breaker (reprinted from Browne, 1984, p. 158, by courtesy of Marcel Dekker Inc.).

4.6 Concluding Remarks

With circuit breakers, as with all other thermal-plasma devices, significant improvements in functional performance have been achieved through understanding the interaction of the plasma with its surroundings. In circuit breakers, motion induced by magnetic-field interaction and cooling of the plasma is used to generate the conditions for current interruption, while some of the same effects are used in other thermal-plasma devices to enhance stability of operation. Controlling the plasma using fluid dynamics, heat transfer, and magnetic fields remains the central issue for all thermal-plasma devices.

INTRODUCTION

In the broadest sense, thermal processes of a substance or a system are those occurrences that are effected by changes in enthalpy, energy, or temperature. By this definition, all possible processes or events are essentially thermal processes. The reading of this article, the manufacture of this book, the movement of the cosmos all are examples of complex thermal processes. The melting of an ice cube or the warming of a gas in an insulated flask are simpler thermal processes.

We are not so ambitious as to attempt to describe the functioning of the universe within this article. Instead, we restrict exposition to a description of the measurement of thermal processes and some of the underlying physical behaviors that cause some observed thermal-process behaviors. In the first section we present a brief discussion of thermodynamic and statistical-mechanical relations relevant to the measurement and interpretation of thermal processes. The second section describes, in general terms, the principles of measurement of thermal properties of materials and systems. The methods described are those collectively known as calorimetry, a means to monitor thermal processes directly and therefore to understand better the states of matter. The third section contains descriptions, in physical terms, of some thermal processes appropriate to an encyclopedia concerned with *applied* physics.

1. THERMODYNAMIC PRINCIPLES

Thermal processes are essentially thermodynamic processes. Certain aspects of thermodynamics are discussed here as they relate to the measurement of thermal processes. A more complete description of

thermodynamics is found elsewhere in the Encyclopedia (see THERMODYNAMICS, EQUILIBRIUM, and THERMODYNAMICS, NONEQUILIBRIUM). Also, because the thermal properties of gases are described elsewhere in the Encyclopedia (see THERMAL PROPERTIES OF GASES), they are excepted from the present discussion.

Thermal processes can be divided into two categories. The first is the change in thermodynamic properties of a system that is undergoing chemical or nuclear reactions. Although these are thermal processes, they are considered in detail elsewhere in the Encyclopedia (see THERMOCHEMISTRY) and so are not considered here. The second category consists of changes in thermodynamic properties of an individual substance that result from a change in its temperature. For either of these categories, the systems may be open or closed to mass transport.

Measured thermodynamic properties, or thermal processes, are essentially averages over an extremely large number of atoms or molecules, each of which may have a large number of distinct energy levels available to it. As a result, the thermal properties cannot tell us the nature of the energy levels or their specific populations. The thermal properties of a system may be calculated from a hypothetical description of the energy levels of a system and their populations. The link between the energy levels, and their populations, of a large sample of individual particles and thermodynamics is made through statistical mechanics (see STATISTICAL MECHANICS, CLASSICAL). Agreement between the hypothesized physical behavior of a system and its real behavior is often tested through measurement of the thermal (or other) properties. It is possible that more than one physical description of a molecular process may yield the same value of a particular thermal property. Often, different physical models can be differentiated by a comparison of each model's calculated thermal properties with measured values over varying temperatures (or other variables). Such tests of theory comprise an important use for measurements of the thermal properties of a substance or a process involving several substances.

Another important use of measurements of thermal properties is in their contribution to the knowledge of chemical potentials of substances as functions of temperature. The value of such direct measurements is enhanced because of the limited accuracy of physical models in the prediction of thermal properties. The chemical potentials of substances determine their relative thermodynamic stability and thus the extent of reaction of chemical systems (see THERMODYNAMICS, EQUILIBRIUM, and THERMOCHEMISTRY). Because of the importance of thermal properties to the chemical potential, we give a brief description of these properties, with a perspective related to the actual measurement of thermal processes.

1.1 Free Energy, Enthalpy, Entropy, and Chemical Potential of a Single Component

We begin with the extensive functions for a single-component system, originally defined by Gibbs (1875), and now generally termed the enthalpy and the free-energy functions:

$$H = U + pV, \tag{1}$$

$$A = U - TS, \tag{2}$$

$$G = H - TS = A + pV, \tag{3}$$

where H is the enthalpy, U is the internal energy, p is pressure, T is temperature, and V is volume. The two functions G and A are the Gibbs free energy and the work (*Arbeit*) function, respectively. All of these functions are state functions, requiring that they be path independent. The natural variables of G are T and p, and for A are T and V. The function A has also been called the Helmholtz energy, in honor of von Helmholtz who realized the usefulness of this function for some applications (von Helmholtz, 1882), some years after Gibbs proposed it for a wider range of applications (Pitzer, 1995).

Of the two free-energy functions, G and A, the Gibbs energy is the most commonly used, in part because its natural variables, T and p, can be most conveniently controlled in real applications. The work function A is useful when the primary interest is the determination of the maximum amount of work that could be obtained for an isothermal process (the maximum amount of work corresponds to thermodynamic reversibility). The work function is commonly used for molecular-dynamical and other calculational simulations of the properties of a system and also is somewhat more convenient than the Gibbs energy for creating mathematical descriptions of a fluid's equation of state near its critical point. However, because of the much greater importance of the Gibbs energy in thermodynamic calculations of real processes, the Gibbs energy and its derivative functions will be emphasized here.

In thermodynamic processes, the primary interest is in the *changes* in enthalpy and energy relative to some arbitrarily chosen state of the involved substances. This state is chosen primarily on the basis of convenience. As such, different choices of standard states might be used in similar calculations for the same system or process. Energetic contributions from such things as nuclear binding energy or mass-energy equivalence do not change significantly when a substance undergoes a thermal change or a chemical reaction; thus they are not exhibited explicitly in thermodynamic calculations. The small changes that do occur in these energies are included in the thermodynamic energy or enthalpy change. Indeed, thermodynamics was applied successfully many years before the nature of these energetics was known.

Consideration of the entropy of a substance often includes the entropy value at absolute zero, 0 K. Entropy is related to the probability of population of the energy levels available to the system. At 0 K, the entropy of a perfect crystal is related to the degeneracy of the lowest-energy state of the crystal. As such, the entropy of a perfect crystal with no degeneracy of the lowest-energy state is taken to be zero at 0 K. The degeneracy of the lowest-energy state for some substances is not zero, and these substances at 0 K have a nonzero entropy, referred to as the residual or configurational entropy.

For the reasons stated above, the measured quantities are the changes of enthalpy or energy that accompany a particular process. This concept is obvious as it relates to the measurement of an enthalpy change for a reaction. Less obvious is the determination of the enthalpy content of a single component or substance relative to some arbitrary set of conditions. Conceptually this is accomplished through changing the temperature of the material and determining the change in enthalpy required to effect the change in temperature. Such a measurement is known as an enthalpy increment and is characterized by the two temperatures and the enthalpy change.

The chemical potential in a single-component system is simply the Gibbs energy per mole of substance. Thermodynamic relations for multicomponent, homogeneous phases are more complex and are described elsewhere (see THERMODYNAMICS; also Pitzer, 1995).

1.2 Heat Capacity and Its Relation to Other Functions

Often, the discussion of thermal processes will involve the temperature derivatives of either the enthalpy or the energy. These temperature derivatives are known as heat capacities. The constant-pressure heat capacity, C_p, and constant-volume heat capacity, C_V, are defined as

$$C_p = \left(\frac{\partial H}{\partial T}\right)_p, \tag{4}$$

$$C_V = \left(\frac{\partial U}{\partial T}\right)_V. \tag{5}$$

There exists a fundamental difference in the enthalpy and the heat capacity of a system that is not immediately obvious from Eqs. (4) and (5). The extensive enthalpy of a system is the sum of the individual enthalpies of the individual entities that comprise the system

$$H = \sum_i n_i H_{m,i}, \tag{6}$$

where n_i is the number of moles of the ith substance and the subscript m denotes molar. The heat capacity is more complicated; it is

$$C_p = \sum_i n_i\left(\frac{\partial H_{m,i}}{\partial T}\right)_p + \sum_i \left(\frac{\partial n_i}{\partial T}\right)_p H_{m,i}. \tag{7}$$

Thus, the heat capacity of a complex system includes a thermodynamic component resulting from the change in distribution of entities among energy levels as well the interconversion of entities—for example, the change of amounts of products and reactants in a chemical reaction.

The constant-pressure heat capacity is also related to the entropy as

$$S_{T_2} - S_{T_1} = \int_{T_1}^{T_2} C_p d \ln T, \tag{8}$$

where S_{T_2} and S_{T_1} are the entropies at T_2 and T_1.

Often, the heat capacity is not measured directly but is obtained through manipulation of other measured values. As one example, the measured enthalpy change used to effect a change of a substance from one temperature to another (the enthalpy increment) will be divided by the difference of the two temperatures, and the resulting value will be termed heat capacity. Of course, this does not give the true differential shown in Eq. (4); it is only an approximation. Various schemes have been used to try to improve the approximation, but it nonetheless remains an approximation.

The interest in heat capacities arises primarily because they provide a visual magnification of the effects of physical phenomena on measured thermodynamic properties as indicated in Fig. 1. In Fig. 1(b) the enthalpy relative to an arbitrary temperature is shown for a substance undergoing a two-state effect (i.e., a physical behavior characterized by only two distinct energy states). Shown in Fig. 1(a) is the heat capacity for the system for the same temperature range. The enthalpy change for the two-state reaction is small compared to the total enthalpy of the material and so is not readily apparent in the figure showing enthalpy. However, it does appear in the picture of the heat capacity function. This visual magnification is the primary reason why measured enthalpy increments are converted into heat capacities.

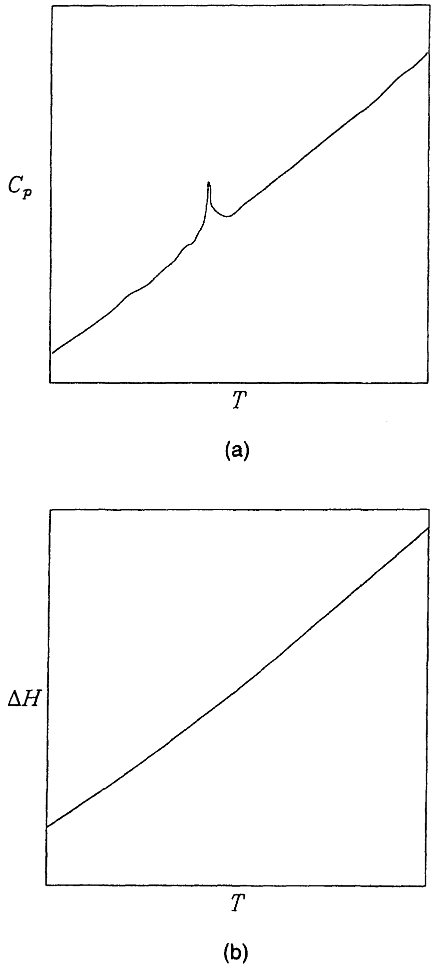

FIG. 1. Heat capacity and enthalpy functions for a substance that undergoes a tautomerization reaction. (a) Heat capacity against temperature. (b) Enthalpy against temperature; the enthalpy of the tautomerization two-state reaction is too small to be visible in the figure.

2. MEASUREMENT OF THERMAL PROCESSES

There exists a wide range of instrumentation for measurement of thermal processes, which reflects the variety of thermal processes encountered. This section provides general schemata for measurement of some thermal processes and a description of terminology associated with these instruments. The first division of classification is the type of process that is being measured. As all substances and reactions involve thermodynamic parameters, thermal processes can be quantified through measurements of heat, or energy, exchange with calorimeters. Other methods follow the change in some other property with respect to temperature; for example, differential thermogravimetric methods follow the change in mass of a sample as its temperature is changed and as a result the sample undergoes loss of a volatile component. Of all these methods the most diverse are the calorimetric methods.

2.1 Calorimetry

Calorimetry, at its simplest level, involves the measurement of the heat, or energy, exchange that accompanies some change in the sample. A calorimeter, the device that measures the heat, or energy, exchange can be considered as containing two separate thermodynamic systems, namely, the measured system and the surroundings. The measured system is comprised of the sample whose characteristics are to be determined plus any vessel or other means used to contain the sample. The measured exchange, or lack thereof, of the heat with the surroundings establishes the first set of adjectival descriptors of a calorimeter, namely, adiabatic, isothermal, and isoperibol. Occasionally, scanning is also included in this set.

Adiabatic conditions are those for which no heat or energy is exchanged between the measured system and the surroundings. Thus, under adiabatic conditions, any energy change undergone by the measured system must change its temperature, if the sample is contained either at constant pressure or at constant volume. (One exception is a substance undergoing a first-order phase change—e.g., melting.) Isothermal conditions are those in which the measured system's temperature is maintained constant, while it undergoes a change. In this case, all of the heat associated with the process is transferred between the measured system and the surroundings. Isoperibol refers to surroundings that are kept constant; usually the surroundings are maintained at a constant temperature. In this case, some portion, but not all, of the enthalpy change, or energy change, undergone by the measured system is transferred to the surroundings. All three of these conditions are limits that can be approached, but not exactly achieved, by careful design. Hence, "pseudo-adiabatic" or "quasi-adiabatic" have been used to describe imperfect adiabatic conditions in a calorimeter. Scanning refers to calorimeters in which a variable is changed continuously with respect to time. Usually this variable is temperature, but it can also be other parameters such as pressure or magnetic-field strength. Whereas the first three descriptors referred to the relation of the observed sample to its surroundings, "scanning" does not express this relation. As a result, scanning is not exclusive of the other three terms, so one can have, for example, an adiabatic scanning calorimeter.

Calorimeters can be either open or closed to the transport of mass through the measurement system. Calorimeters open to mass transport are "flow" calorimeters, whereas, those closed to mass transport are "static." Energy-mass equivalence prohibits an adiabatic flow calorimeter, in the strictest definition. The other two relations of surroundings to measured system are possible with flow calorimeters. Flow calorimeters find their importance in the measurement of thermal processes involving fluids.

Regardless of the relation of the surroundings to the measured sample, an energy equivalent of the measured system must be made. (The energy equivalent is the response of a measured variable with respect to known amounts of energy introduced into the calorimeter.) This is most often accomplished through an electrical calibration. Other determinations of the energy equivalent are also possible. For example, an energy equivalent can be realized by measuring the amount of substance undergoing a phase change, or some other thermal process, in the surroundings of a calorimeter.

Any apparent contradiction in the heating of a calorimeter that is described as adiabatic can be better understood by considering three thermodynamic systems: the measured system, a source of energy, and the surroundings to both. The measured system and the source of energy—for example, a battery that powers a resistive electrical heating circuit—are two systems both adiabatic relative to the third system, the surroundings. Heat, or energy, can be transferred from one system to the other in a controlled and measurable way, and thus one can heat an adiabatic calorimeter.

2.1.1 Static Calorimeters, Adiabatic

Adiabatic conditions are obtained through minimization of heat transfers from the measured system to the surroundings due to conduction, convection, and radiation. Heat exchanges due to conduction and convection are minimized by performing the measurements in a high vacuum and by reduction of thermal contact between the measured system and its surroundings through increased thermal resistance of electrical leads (i.e., by using very small-diameter or superconducting leads) and by the use of poor thermal conductors to support the measured system in the vacuum. The measured system is usually surrounded by a jacket whose temperature is maintained at that of the measured system to minimize radiative heat transfer. The electrical leads from the measured system are usually heat sunk to this jacket to reduce their conduction even further.

Because of the minimization of the heat transferred between the measured system and the surroundings, adiabatic calorimeters have the potential of great accuracy. They are often used in the determination of the relative enthalpy content of substances (the measurements of which are often reported in a heat-capacity form), especially for temperatures less than 400 K. The principal quantities measured in a determination of an enthalpy increment are the electrical energy used to heat the measured system and the temperature of the measured system as it is heated. Some error may arise as a result of incorrect accounting for power lost in the electrical leads of the calorimeter, creating small systematic biases in each particular calorimeter. However, this error diminishes with increasing sample size and so can be minimized in the characterization of calorimetric reference samples, which can then be used to determine the bias in a calorimeter designed for measurement of smaller amounts of samples. While the measurement of the heat or energy generated by current flow through a heating circuit is straightforward, determination of the temperature of the measured system is less so. Measurement of temperature (see TEMPERATURE) is accomplished by transfer scales. The primary temperature scales, and the subsequently transferred scales, are not perfect determinations of the true thermodynamic temperature. As such, they also may contribute to a systematic bias of measured thermal properties from the true values. Intercomparisons of enthalpy increment measurements with adiabatic calorimeters indicate that the better calorimeters have uncertainties in the range of 0.05% (Archer, 1995).

Adiabatic calorimeters have also been used to measure the energy change of a reaction occurring in either a constant-volume vessel, a common example of which is oxygen combustion calorimetry, or a constant-pressure reaction vessel such as a solution-reaction calorimeter. These are aspects of thermochemistry (*q.v.*) and will not be discussed here.

2.1.2 Static and Flow Calorimeters, Isothermal Two different techniques are used for the construction of isothermal calorimeters. In the first, the measured system undergoes a thermal process in a reservoir, or surroundings, of a substance that is undergoing a phase change. For example, one can place a system undergoing a thermal process in a reservoir containing both liquid and solid phases of a material, called the calorimetric substance. As long as both phases of the calorimetric substance coexist in the surroundings, the enthalpy transfer occurs at constant temperature. As the thermal process progresses, heat is transferred to or from the reservoir resulting in a change of the relative masses of its two phases. Determination of the mass of material converted from one phase to the other, combined with knowledge of the enthalpy of that transition, gives the change in enthalpy or energy of the measured system. These calorimeters have been used in the determination of the difference in enthalpy between two temperatures, one of which is the temperature of the calorimetric substance. These measurements are performed by establishing a constant temperature of the measured system and then rapidly transporting it into the isothermal calorimeter. This technique is capable of great accuracy. If sufficient attention is paid to detail, the limiting factor in the accuracy of this type of measurement can be determination of the temperature of the measured system before it is introduced into the calorimeter.

The second type of isothermal calorimeter is one in which the heat flux resulting from a change of the measured system passes through a measuring device between the measured system and a large thermal reservoir. The measuring devices are usually thermopiles or Peltier coolers (see THERMOELECTRIC DEVICES). It is difficult to arrange for all of the heat flux from the measured system to pass through the thermoelectric device. Compensation for the flux not transferred through the measuring device is usually accomplished by placement of a resistive heater on or near the measured system. The resistive heater is then used to calibrate the calorimeter. This calibration assumes that the same proportion of heat passes through the measurement device for both the electrical heater and the measured system. Imperfect matching of calibration and measured processes is often the limiting factor in the accuracy of these calorimeters. Several mass-flow calorimeters of this type have been constructed. Containment of fluids in small-diameter tubes that join and mix the flowing streams in the presence of an isothermal measuring device allows the determination of enthalpies of fast-reacting systems over a wide range of temperature. The accuracy of the best of these research instruments currently is on the order of 1%.

2.1.3 Static and Flow Calorimeters, Isoperibol In these calorimeters, the heat flux is between the measurement system and the constant-temperature surrounding and depends on the temperatures of both of them. In a static system, given sufficient time and in the absence of introduction of energy into the measurement system, a time-dependent heat flux between the measurement system and the surroundings exists and results in the temperature of the measurement system eventually reaching that of the surroundings. The heat flux, and its time dependence, between the measurement system and the isoperibol surroundings introduces further complications in matching a calibration energy to that of the measurement system. Yet the simplicity of creating constant-temperature surroundings, for example, by means of a constant-temperature bath or radiation shields controlled to the temperature of a large heat sink, makes these calorimeters attractive. Judicious care in the creation of a large thermal resistance between the static measurement system and the surroundings reduces the time rate of change of the heat flux between the two, which simultaneously improves matching the electrical calibration to the calorimetric response. In flow systems, constant-temperature surroundings do not cause the same time dependence of the heat flux between the measured system and surroundings. This is because the mass flow through the measurement system is equivalent to introduction of energy into the measurement system; thus a steady-state constant heat flux between measurement system and surroundings is established.

Isoperibol calorimeters are often used for determination of mixing enthalpies of fluid systems. Flow isoperibol calorimeters have been particularly useful in the determination of heat capacities of fluids.

2.1.4 Scanning Calorimeters Scanning calorimeters are those in which a process variable for the measured system is changed systematically with time, and some resultant thermal response is also monitored with respect to time. In most applications, the temperature is the altered process variable. However, pressure-scanning calorimetry has been reported, and the variation of applied magnetic or electrical fields on the measured system also constitute scanning calorimetry.

Temperature-scanning calorimetry appears in different designations: differential thermal analysis (DTA) and differential scanning calorimetry (DSC). However, the principle is similar. Typically, a small thermal resistance separates the measured system from the surroundings. The temperature of the surroundings is ramped with respect to time. As the temperature of the surroundings changes, the measured system's temperature also changes in the same direction because of the small thermal resistance. The heat flux into the measured system is derived from measurement of a thermoelectric device. Commercially available instruments are capable of measuring thermal effects for very small samples with an accuracy of a few percent; some claims of 1% accuracy with commercial instruments have been made. Although the accuracy of most of these instruments is not high compared to other types of calorimeters, they do have certain advantages. The combination of small sample size and rapid thermal response allows studies of kinetic effects, activation effects, and thermodynamically unstable systems, such as supercooled and superheated fluids.

3. THERMAL PROCESSES

3.1 Phase Changes

The variety of phase transitions observed in different systems underscores the vast scope of the study of thermal processes. Consideration of the transition between states, rather than the physics of phase equilibria, provides the focus of the study of thermal processes. These transformations are often most easily viewed by changing sample temperature.

First-order phase changes are those for which the chemical potential is continuous with respect to controlled variables such as temperature and for which the first derivatives of the chemical potential with respect to that variable are discontinuous. Under the conditions of this type of phase transition, energy is required to transform mass from one phase to the other without a change in the variables that characterize the transition. Therefore, second derivatives with respect to temperature, i.e., the heat capacities, are infinite at this transition. These phase transitions include changes in lattice structure, melting, vaporization, and sublimation.

Second-order phase changes are those for which both the chemical potential and its first derivative are continuous with respect to a variable. The second derivatives of the free energy show a discontinuity, but often are not infinite, at the transition. Higher-order thermal functions—e.g., dC_p/dT—do show an infinity. One example of a second-order phase change is the order–disorder transition that occurs in solid solutions.

Many phase transitions occur in solids without structural rearrangement of atoms. Often, these phenomena involve the electrons in the material, as for instance in magnetic transitions, superconductivity, or the excitation of electrons into conducting states. Examination of all of these effects may involve the intrinsic thermal properties of the material. Because the heat capacity visually magnifies changes in the thermal properties of a material with respect to temperature, the theoretical exposition of the effect of physical phenomena on thermal properties is often conducted in terms of heat capacities.

3.2 Atomic Vibration and the Heat Capacity of a Solid

The change in temperature of a solid near room temperature is, in principle, a simple thermal process. The associated enthalpy function or its temperature derivative, the heat capacity, reflects the motion of the atoms in the material. We first consider the case where the interatomic potential is similar for all of the atoms in a crystalline solid. Atoms in these crystalline solids arrange themselves in periodic structures and oscillate about their equilibrium positions. This vibration of atoms in these solids, for temperatures near room temperature, can be adequately approximated as a classical, harmonic oscillator, analogous to a pendulum or a mass on a spring. That is to say, the interatomic potential (sketched in Fig. 2) can be approximated with a parabola for small-amplitude displacements from equilibrium. A mass in a classical harmonic oscillator vibrates about an equilibrium position with an amplitude that depends upon the energy of the system. While the true potential experienced by atoms in solids is inherently asymmetric, the potential near to the atoms' equilibrium positions can be well approximated as harmonic. These three-dimensional oscillators then have an energy per atom of $3k_bT$, where k_b is the Boltzmann constant. The heat capacity of many solids near room temperature is found to be close to $3rNk_b$, or approximately $25 \cdot r$ J/(K mol) (where r specifies the number of atoms that constitute the stoichiometry of the material). Deviations of the values of observed heat capacities from this classical-mechanical Dulong and Petit constant provide insight into many thermal processes that occur in solids. In Fig. 3, two such deviations are illustrated that are intrinsic to all solids:

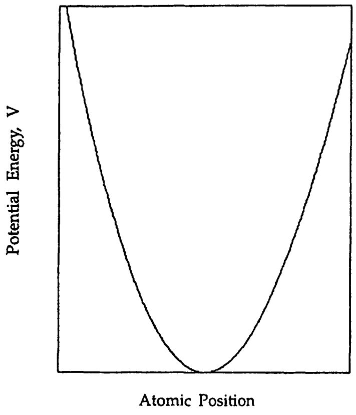

FIG. 2. Interatomic potential; potential energy against atomic position.

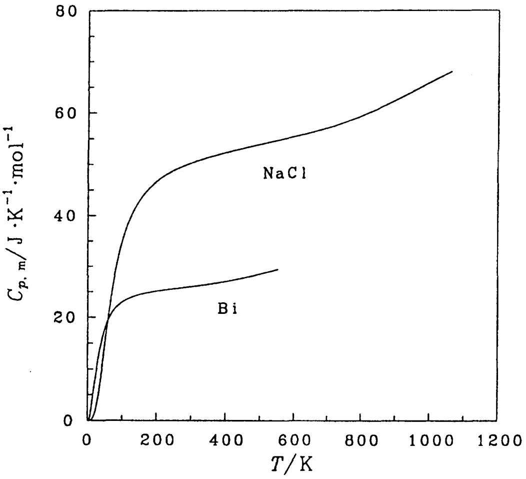

FIG. 3. Molar heat capacities of sodium chloride and bismuth.

1. Heat capacities generally approach zero as temperature approaches absolute zero, and
2. a monotonic addition to the Dulong–Petit constant is observed in the heat capacity of solids at temperatures generally near and/or above room temperature.

The observation (cf. Fig. 3) that heat capacities tend to vanish at low temperature reflects the quantum nature of harmonic oscillations of the atoms in a solid. In the quantum harmonic oscillator, instead of a continuous energy spectrum ($3k_bT$, for all $T \geq 0$), only discrete, quantized values of the vibration energy, E_n, of atoms occur. These energies are evenly spaced, with $E_n = (h/2\pi)\omega(n + 1/2)$, where n is any integer $n \geq 0$ and h is Planck's constant. This theory indicates that the vibrating atoms in a solid have a finite excitation energy, $(h/2\pi)\omega$. Therefore, as the average energy of the atoms in a solid decreases with decreasing temperature, it becomes less and less probable that an individual oscillator will be excited (i.e., have a nonzero value of n). Quantum mechanics indicates that the contribution to the heat capacity of a solid from vibrational energy goes to zero at low temperatures, as is observed. Whether these vibrations are modeled as isolated oscillators (Einstein first advanced this theory) or whether the collective vibrational nature of atoms within the crystal lattice is considered (as in the more sophisticated model of Debye, where the heat capacity is found to be proportional to the cube of the temperature at low temperatures), qualitative agreement with experimental thermal measurements is found. Quantitatively, the Einstein theory did not provide the correct thermal behavior as temperature approached 0 K because of its approximation that the frequencies of all atomic vibrations in a crystal were identical. The Debye theory predicted the correct temperature dependence of the thermal properties of atomic lattices at low and high temperatures (Dulong and Petit value of the heat capacity) but did not work as well at intermediate temperatures. Despite limitations of the Debye theory, it has the attractive quality of introducing a single parameter, the Debye characteristic temperature (Θ_D), that characterizes the thermal properties of a lattice. Most crystal lattices begin to show deviations from the Debye theory for temperatures greater than $\Theta_D/50$. Theories that treat lattice vibrations more rigorously than the Debye theory are available (see LATTICE VIBRATIONS, STATISTICS OF).

Generally it is an approximation to consider the atomic potential in solids to be harmonic, though, remarkably, deviations from harmonicity are generally small. Interatomic potentials, as functions of the interatomic distances, $V(r)$, are represented as

$$V(r) = ax^2 - bx^3 - cx^4 + \ldots, \tag{9}$$

where generally $b \ll a$. The x^3 term means that the potential is asymmetric. The first-order approximation is the harmonic potential, $V(r) = ax^2$. However, as energies increase and the amplitude of vibration of the atoms in the solid increases, the additional terms in the expansion for $V(r)$ become more important. The heat capacity becomes larger than would be expected on the basis of a harmonic oscillator; the extra contribution is approximately linear in temperature. In fact, a constant increase in the heat capacity with respect to temperature at temperatures above room temperature is a common observation. At temperatures approaching the melting point, equilibrium vacancy creation is generally believed to be the cause of a nonlinear portion of the heat capacity against temperature that has been observed for many substances (cf. Fig. 3.) Vacancy creation and annihilation are discussed below.

The contribution of atomic motion to the thermal properties of crystalline materials becomes significantly more complicated when one considers systems in which the interatomic potentials become increasingly anisotropic. Extreme anisotropy, or directionality, of interatomic potentials occurs in molecular crystalline solids such as frozen oxygen, methane, and larger organic molecules. In these materials, atomic motions are affected by both strong intramolecular potentials and weaker intermolecular potentials. Additionally, motions of groups of atoms, and of the molecule as a whole, is affected by intermolecular potentials. The total of these possible motions results in a wealth of thermal behaviors. One example is the free rotation of methane molecules within the lattice, which occurs cooperatively as the temperature increases through 20 K. This effect results in a second-order phase transition, indicated by a lambda peak in the heat capacity near 20 K, and is easily seen with calorimetric measurements, first reported by Clusius (1929), as shown in Fig. 4.

3.3 Electronic Effects

A variety of electronic effects are possible in solids. These effects are almost always accompanied by a thermal signature readily detected by calorimetry. Some electronic effects important for applied physics are described here.

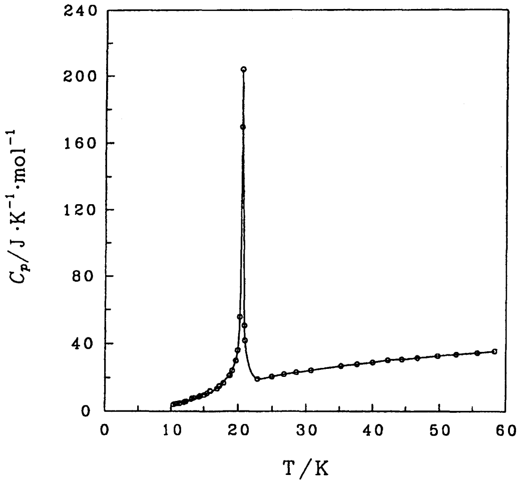

FIG. 4. Molar heat capacity of methane; measurements from Clusius (1929).

The heat capacity of electrically conducting materials includes a contribution from lattice vibrations, as outlined above, and an additional contribution from changes in electron energies. Near room temperature, only a tiny fraction of the electrons can occupy the higher energy states, resulting in a relatively small contribution to the heat capacity (see STATISTICAL MECHANICS, CLASSICAL, particularly discussion of Fermi–Dirac statistics). The heat capacity of metals is similar to that of insulators near room temperature. However, at temperatures of roughly $T < \Theta_D/50$, the intrinsic heat capacity of a conductor is given by

$$C = AT + BT^3. \tag{10}$$

As the contribution BT^3 from the lattice goes to zero with decreasing temperature, the heat capacity of the electrons, AT, becomes a more significant fraction of the total heat capacity and is best extracted from low-temperature thermal measurements. At higher temperatures, the conduction electrons also make a contribution proportional to temperature to the heat capacity. This contribution at higher temperatures occurs in combination with the similar vibrational contribution proportional to temperature that arises from the anharmonicity of the interatomic potentials. Thus, at higher temperatures, separation of these two contributions from measurements of thermal functions requires additional knowledge.

In considering the temperature dependence of physical processes, the quantity of interest is essentially the logarithm of thermodynamic temperature. In other words, a range of physical changes undergone by a solid substance from 100 to 1000 K would be comparable to a different set of physical changes that might be undergone from 10 to 100 K, from 1 to 10 K, and so on. As such, distinct variations from the behavior typified by Eq. (10) are often observed at yet lower temperatures. Thus, the low-temperature regime constitutes a vast expanse for the observation of low-energy thermal processes. Consider copper as an example. The heat capacity of copper at 1 K is 1/100 000 times its room-temperature value. Yet below this temperature there remains two additional orders of magnitude of temperature variation readily accessible by means of calorimetric measurements. For instance, in copper samples with less than 4 ppm concentrations of any magnetic impurities, a distinct anomalous contribution [$\Delta C = 3 \times 10^{-5}T^{-2}$ mJ/(K·mol)] to the heat capacity is observed below 0.2 K. This contribution to the heat capacity is as large at 0.03 K as values expected from Eq. (10) and may be due to a small ($\approx 4 \times 10^{-6}$ eV) Schottky-type splitting of an impurity electron state. A Schottky peak in the heat capacity is a distinct signature of discrete energy states and the thermal processes associated with their populations. A clear example of a Schottky peak is provided by the heat capacity of $CeS_{1.457}$ at temperatures between 0.5 and 20 K. Subtraction of the lattice and electronic contributions to the heat capacity, as estimated on the basis of Eq. (10) and the higher-temperature data, revealed a peak whose shape was consistent with a ground-state doublet with energy splitting 0.25 meV and corresponded to an entropy change of R ln2 = 5.8 J/mol K. This effect is shown in Fig. 5. The occupation of these energy levels is clearly an important thermal process in this temperature range.

Calorimetry is an effective way to study superconductivity. In fact, as epitomized by Methfessel *et al.* (1980), "Caloric measurements are the sole reliable way to ascertain the bulk superconductivity of a given compound or alloy." As the electrons in a material begin to condense into a coherent superconducting state at a critical temperature, with corresponding zero dc resistance and the expulsion of magnetic fields, the heat capacity shows a distinct jump. An example is provided in Fig. 6 for gallium. This change is consistent with a decreasing entropy associated with the ordering of the state. The contrast with the heat capacity in the absence of the superconducting transition, suppressed with a magnetic field, is apparent. These observations are important both in monitoring and in understanding the superconductivity of a material, because essential parameters such as the energy gap can be determined from such measurements.

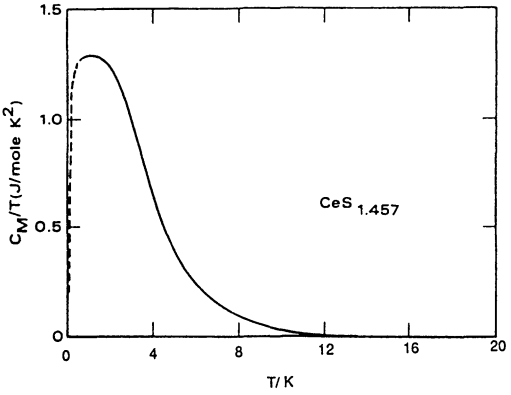

FIG. 5. The heat capacity due to a Schottky effect in $CeS_{1.457}$ (reproduced from Ho *et al.*, 1982).

There is a wealth of other electronic effects that occur with changing temperature. They involve various magnetic behaviors and low-energy electronic behaviors. The interested reader is referred to the books on these subjects listed below.

3.4 Thermal Expansion

Any change in the dimensions of a sample with a change in temperature is known as thermal expansion. A change in the volume

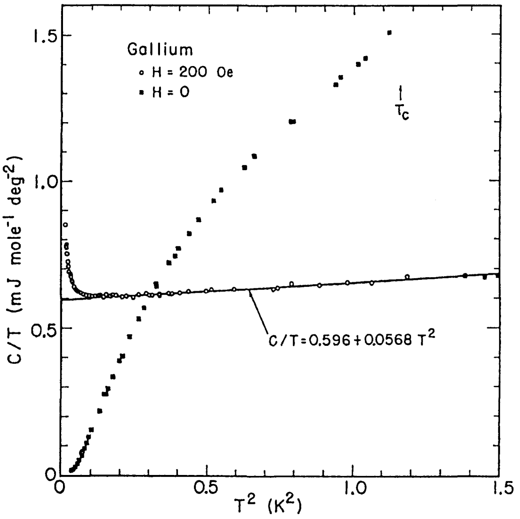

FIG. 6. The low-temperature heat capacity (divided by temperature) of gallium at two magnetic-field strengths vs the square of the temperature. Measurements of the superconductive state are the solid squares. The open circles are for the normal state (nonsuperconductive). (Reproduced from Phillips, 1964.)

of a material due to a change in temperature is a profound effect of the anharmonicity of the interatomic potentials in solids. For an infinitesimally small change in temperature of a substance, the ratio of the corresponding change in volume ΔV to the change in temperature ΔT, divided by the substance volume V, is the coefficient of thermal expansion β:

$$\beta = \frac{1}{V}\left(\frac{\Delta V}{\Delta T}\right)_p. \tag{11}$$

The subscript p indicates that the pressure is held constant. The thermal expansion of solids reflects changes in the configuration of the atoms in the material. Most substances expand with increasing temperature, reflecting the asymmetry in the interatomic potential due to the short-range atomic repulsion. As the temperature of a solid increases and the atoms in the solid vibrate with larger amplitudes, the average separation of the atoms, and the sample volume, increases.

The linear coefficient α of the thermal expansion of solids,

$$\alpha = \frac{1}{l}\left(\frac{\Delta l}{\Delta T}\right)_p, \tag{12}$$

is of practical consideration. Here l is the length of a sample, and Δl is the change in its length corresponding to an infinitesimally small change in temperature, ΔT. For isotropic solids $\beta \cong 3\alpha$. The values of α and β for solids are small. For example, common steel has a value of $\alpha = 11 \times 10^{-6}\ \mathrm{K}^{-1}$. A change in volume, $\Delta V = (l + \Delta l)^3 - l^3$, for an isotropic solid cube can be simply related to a change in length Δl with $\Delta V/V$ very close to $3\Delta l/l$, since α, and thus Δl, is small. Therefore $\beta = 3\alpha$ is an excellent approximation. Thermal expansion is important in the design of structures and devices. Of particular concern is differential thermal expansion: When two materials with different values of α are in contact, allowance must be made for the relative movements of these materials upon changes in temperature, or the relative movement of the objects must be constrained. Such design considerations are found in such very different scales as between the girders in skyscrapers and in the 60-μm space between chip and board in microelectronics packages. Examples of the differences of thermal expansion of different metals are shown in Fig. 7.

3.5 Quantification of Thermal Processes

While the subject of thermal processes clearly includes atoms in the liquid and vapor phases, many aspects may be illustrated with a continued examination of the motion of atoms in a solid. For instance, many processes are elucidated by the consideration of a relatively simple picture of atomic jumps between minima in the atomic potential energy in the solid; these jumps may well constitute diffusion. This simple picture is sketched in one dimension in Fig. 8. Models of atomic vibration, thermal expansion, defect production and annihilation, diffusion, and many aspects of phase transitions can be related to this picture. Many thermal processes can be characterized as thermally activated (or Arrhenius), such as in Eq. (14). In this case it is often assumed that the reaction rate $d(n/N)/dt$ is equal to the product of separable functions $f(n/N)$ and $g(T)$:

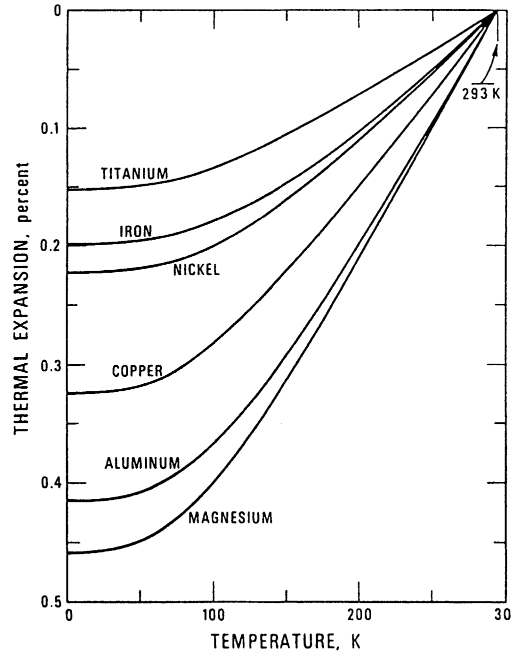

FIG. 7. Thermal expansion of some metals vs temperature (reproduced from Clark, 1983).

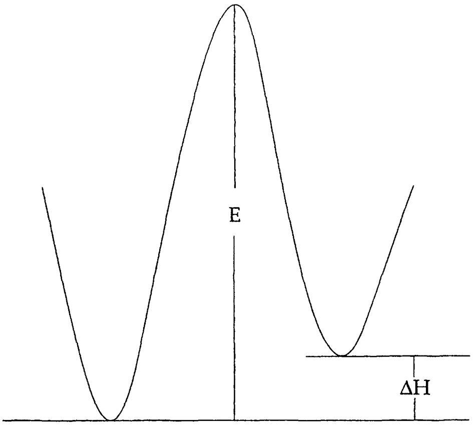

FIG. 8. Reaction-coordinate diagram showing the relation of equilibrium states of products and reactants to activation energy. The activation energy is *E*, and the thermodynamic energy or enthalpy difference between the two equilibrium states is *ΔH*. The two minima represent the equilibrium energies of products and reactants.

$$\frac{d(n/N)}{dt} = f(n/N)g(T), \tag{13}$$

where the function $g(T)$ depends on the temperature T and the function $f(n/N)$ depends on the fraction of the sample, n/N, that has reacted. The function $f(n/N)$ reflects the fundamental mechanisms of the reaction, while generally $g(T)$ is assumed to be characterized by an activation energy E_A and a constant g_0,

$$g(T) = g_0 \exp(-E_A/kT). \tag{14}$$

This formalism is used in the characterization of thermal processes as diverse as steel processing and electron drift in semiconductors. Nevertheless, the simple Arrhenius form of Eq. (14) is not always applicable. A determination of the appropriateness of Eqs. (13) and (14) for a particular reaction may be made from analysis of reaction rates obtained from calorimetric data. Additional quantitative study by measurements as diverse as electrical resistivity and diffraction of x rays and electrons, as functions of heat treatment, can yield insight into the forms of $f(n/N)$ and $g(T)$. The function $f(n/N)$ is best characterized on the basis of isothermal experiments, in order to separate out $g(T)$. The dependence of reaction rate on temperature can be deduced by comparing reaction rates at equal values of degree of conversion, n/N, as a function of temperature. In the case of reactions that can be characterized by Eqs. (13) and (14), a well-known technique advanced by Kissinger (1956) and more recently discussed by Ozsawa (1970) provides a simple identification of points of equal degree of conversion n/N for calorimetric data of different heating rates. Thus, the function $g(T)$ can be analyzed independently of $f(n/N)$. Characterization of these thermal processes is very important for many areas in applied physics, such as electronics processing, metals working, and polymer sets.

3.6 Defects in Materials

Materials processing often concerns the production or annihilation of defects in polycrystalline materials. The properties of materials depend strongly on their defect structure, grain size, and impurity and defect content. As defect structures are generally nonequilibrium, thermal processes related to these defects generally concern the agglomeration and/or annihilation of defects. Crystal defects include point defects, impurities, dislocations, and different grain-boundary structures. In the production of silicon crystals for integrated circuits, great care is expended to limit the number of most defects, while introducing a small number (e.g., 5 ppm) of special impurity defects. This is in contrast to the thermal processes associated with the production of some structural alloys, where high-temperature defect structures are quenched into the room-temperature material to increase hardness.

Crystals contain a finite density of point defects and vacancies in thermal equilibrium at temperatures above 0 K. Consideration of the concentration of these defects, and its variation with temperature, provides a better understanding of nonequilibrium defect densities, and the thermal processes associated with their annihilation and creation. The free-energy change ΔG for the formation of n vacancies in a particular amount of material, given by

$$\Delta G = n\Delta H - T\Delta S, \tag{15}$$

is minimized (condition of equilibrium) with a finite density of vacancies, where ΔH is the enthalpy of formation of a vacancy and ΔS

corresponds to the entropy change realized with the creation of n vacancies. This entropy change includes the configurational entropy associated with the degeneracy of energy states that correspond to the different possible locations of the vacancy. The equilibrium concentration, $c = n/N$, of vacancies (assuming, as is observed, that n is much less than the number of atoms in the crystal, N) is given by

$$c = A_v \exp(-\Delta H/kT), \tag{16}$$

where k is the Boltzmann constant.

The observed concentration of vacancies in solids is often greater than the equilibrium concentration given by Eq. (16), depending also on the thermal and mechanical history of the sample. The thermal process by which a crystal adjusts its vacancy concentration and distribution with a change in temperature involves long-range diffusion. These diffusion processes can be modeled by consideration of the movement of either the vacancy or an entity that borders the vacancy. For equilibrium to be realized, vacancies must be able to sample a large number of possible sites. To accomplish this, atoms must be able to move, or diffuse, through the sample. This requires a finite amount of time that depends on the sample temperature, size, atomic configuration, and chemistry. Thus it is possible to quench a nonequilibrium concentration of vacancies into a sample where the decay rate of these vacancies can be negligible at room temperature. Clearly this recovery rate is proportional to the diffusion constant D of atoms, where generally

$$D = D_0 \exp(-E_a/kT). \tag{17}$$

The activation energy E_a for diffusion will generally be greater than ΔH, because E_a reflects the highest-energy state an atom must attain in order to move (for instance E in Fig. 8) rather than the energy difference of final states reflected in ΔH.

The transformation of a polycrystalline solid with a variety of defects into a single crystal with a minimum of defects involves a number of different thermal processes, which are divided into the two general categories of recovery and recrystallization. Recovery concerns the annihilation of specific defect structures such as point defects and dislocations, while recrystallization includes the nucleation and growth of new, generally larger grains in a lower-energy configuration. Recovery processes generally have lower activation energies than those of recrystallization and thus are observed in a distinctly different, lower-temperature regime. Measurements can be made of the heat flow from a sample during recovery and recrystallization as in a scanning calorimeter. These heat flows, measured as a function of temperature, typically show two general peaks: the lower-temperature effect is associated with recovery, and the higher-temperature peak is associated with recrystallization. Individual processes, such as dislocation annihilation or defect–vacancy combination, may result in specific subpeaks. An example of heat flow vs temperature is shown in Fig. 9. The total integrated heat release provides a measure of the energy associated with the defects. Energies of up to 0.1 eV/atom have been observed, and so, clearly, this is an important thermal process.

Recovery and recrystallization are important thermal processes in the consideration of solids and materials processing. Extended defects, such as grain-boundary structures and other dislocations, are generally introduced into solids by mechanical means, such as by deformation during working, by ion bombardment, or by quenching from higher temperatures. Often a material's properties are enhanced by a given defect structure.

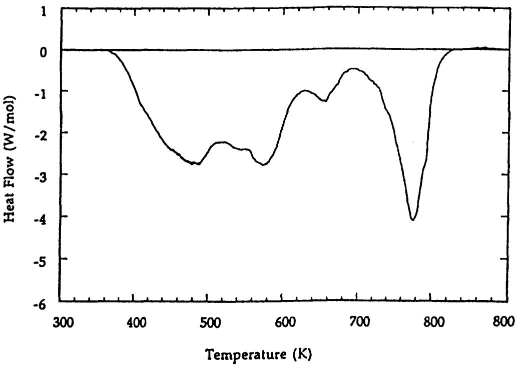

FIG. 9. Heat flow for conversion of a polycrystalline solid into a single crystal. The large heat flow centered near 520 K is due to recovery; the large heat flow centered near 775 K is due to recrystallization.

The processes of recovery and recrystallization also provide some insight into the nature of the defect structures themselves. Characterization of rate constants, including activation energies for these processes, can be related to specific atomic processes.

Another example of a thermal process, the crystallization of a metallic glass, is indicative of the relation of atomic motion to thermal processes. In Fig. 10, the heat flow from a NiZr metallic glass is plotted as a function of temperature for a constant heating-rate anneal. A broad, low-level heat release between temperatures of 450 and 600 K is observed and can be contrasted to the distinct crystallization peak at a temperature of 640 K. The lower-temperature process is structural relaxation, i.e., the progression of the glassy matrix to a denser glass with a more relaxed short-range order. This process involves atomic motion, but it does not involve the long-range collective motion of all the atoms in the glass, which would result in crystallization of the glass. A similarity with the recovery and recrystallization processes exists, in which some simple processes can occur at lower temperatures, whereas longer-range, collective rearrangement of atoms associated with recrystallization occur at higher temperatures.

A final example of a thermal process in the Ni–Zr system illustrates the importance of thermal processes in the fabrication of materials. Interdiffusion between pure, polycrystalline metals at relatively low temperatures (approximately half the pertinent melting temperatures) and over short distances can result in the formation of metastable, metallic glasses. In this example, multilayered Ni/Zr composites were produced by vapor deposition of polycrystalline layers of Ni and Zr in equal thicknesses of 45 nm. A measurement of the heat flow (Fig. 11) from such a composite reveals two separate reactions: The first, near 580 K, was related by means of structural analysis to the interdiffusion and amorphization of the original multilayers, while the second reaction, near 830 K, was correlated with the subsequent crystallization of the amorphous phase. These temperature ranges can be compared to those observed for recovery and recrystallization.

Metallic glass may form by solid-state reaction because a disparity in the mobility of the different atomic species in the diffusion couple provides a kinetic constraint on the formation of equilibrium intermetallic compounds. In the temperature range (≈400 to ≈650 K) where solid-state amorphization reactions (SSAR) are commonly observed in the Ni–Zr system, the relative diffusion coefficients of Ni and Zr in the growing amorphous phase differ by several orders of magnitude, with Ni (approximately 22% smaller atomic radius than Zr) being the faster diffusing species.

The DSC scan of Fig. 11 provides a direct measurement of the large negative enthalpy

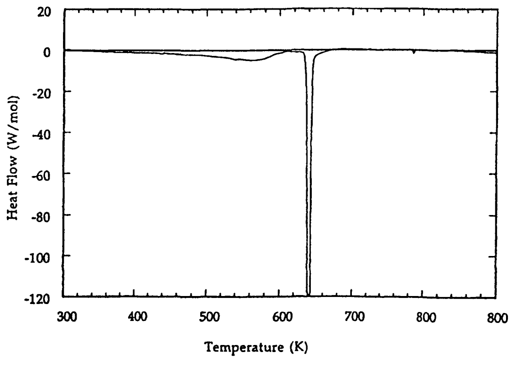

FIG. 10. Heat flow for relaxation and crystallization of a NiZr metallic glass. The lower-temperature process is due to rearrangement of the glass matrix. The higher-temperature process is due to crystallization of the glass.

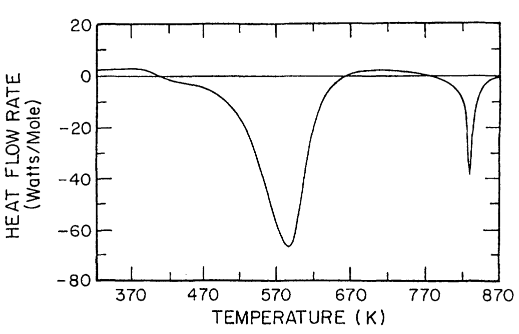

FIG. 11. The heat-flow rate as a function of temperature for a sputtered, multilayered thin film of average stoichiometry $Ni_{68}Zr_{32}$ measured at a constant scanning rate of 10 K/min. The thin film is comprised of equal-thickness (300 Å) layers of Zr and Ni with half-layer Zr caps.

INTRODUCTION

Accurate knowledge of thermal properties of gases is of fundamental importance in chemical technology. In reactions involving gases, the heat capacity is an important property for the determination of the Gibbs energy change under the experimental conditions, which provides the answer to whether the reaction is thermodynamically feasible under those conditions. Also, it is essential for the accurate calculation of equilibrium constants. This article commences with a short discussion of these applications and then describes methods for the measurement of the two heat capacities, the isochoric (C_V) and isobaric (C_P) heat capacities. Values of C_P under pressure are thermodynamically related to ideal-gas values, which can be determined from speed-of-sound measurement and, importantly, can be accurately calculated from spectroscopic information using the methods of statistical thermodynamics. The success of this approach has resulted in many "experimental" values being obtained in this way. Methods are described for their temperature representation, and for their estimation using group-contribution methods. Finally, in this section, the effects of molecular interaction at higher pressures and the behavior of heat capacities in the critical region are described.

The success of a chemical process plant depends on its optimum design, and here thermal properties are required for heat-transfer considerations. Besides the heat capacity, of prime importance is the thermal conductivity. In Sec. 4, methods are described for its measurement, its calculation for low-pressure monatomic and polyatomic gases, and its correlation at high pressure. Behavior in the critical region is also described. Thermal diffusion, thermal diffusivity, and thermal transpiration are briefly discussed.

Liquefaction of gases occupied the minds of many famous scientists. One method is by application of the Joule–Thomson effect, which must be understood to appreciate why a preliminary cooling of a gas, in the case of helium to very low temperatures, is neces-

sary before liquefaction can occur by this method.

As well as being of technological importance, these properties also have provided valuable information for the development of our detailed understanding of the interactions between molecules.

1. THERMAL EXPANSION

The isobaric coefficient of thermal expansion, or isobaric thermal expansivity, α, is the fractional change in volume with change in temperature at constant pressure,

$$\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P. \tag{1}$$

For an ideal gas, the P, V, T behavior is given by the relationship

$$PV = nRT, \tag{2}$$

where n is the number of moles of gas and R is the gas constant, 8.314 J K^{-1} mol^{-1}, and the isobaric coefficient of thermal expansion is then equal to $1/T$. At 300 K, therefore, α for an ideal gas has the value 3.3×10^{-3} K^{-1}.

The behavior of a real gas differs from that of an ideal gas because of molecular interactions. At relatively large separations R, a pair of real molecules will experience a long-range attractive interaction that falls off as R^{-6}, and, at close distances, there is a steep repulsive interaction energy that falls off exponentially with distance. The simplest model that takes into account these features of short-range repulsion and long-range attraction, by approximating them as a hard-core repulsion and a very weak very long-range attraction, is that of van der Waals (1873), whose equation for P, V, T is

$$(P + a/V_m^2)(V_m - b) = RT, \tag{3}$$

where V_m is the molar volume, b is the excluded volume due to the finite size of the hard-core molecules, and the a/V_m^2 term accounts for the attractive interaction.

For a van der Waals gas, α is given by the expression

$$\alpha = \frac{R}{V_m(P - a/V_m^2 + 2ab/V_m^3)}, \tag{4}$$

which gives the ideal-gas result when $a = b = 0$ (ideal gas) or V_m becomes very large, as for a real gas at low pressures.

Historically, measurements on gas expansion were important in defining the ideal-gas temperature scale. Here, the coefficient of expansion α_e was considered as the increase in volume at constant pressure for a one-degree temperature rise as a fraction of the initial volume of gas at 0 °C. Thus,

$$V_t = V_0(1 + \alpha_e t), \tag{5}$$

where t °C is the final temperature. For real gases, α_e extrapolated to zero pressure has the same value of 1/273.15 $°C^{-1}$. By defining the unit of temperature on this scale as the kelvin, the ice point became 273.15 K (and the triple point of water was set equal to 273.16 K). Constant-pressure air thermometers, and also constant-volume thermometers that are based on the linear variation in pressure with temperature change for a fixed mass of gas, have historical interest.

As pressure increases, α_e and hence α, which equals $(t + 1/\alpha_e)^{-1}$, differ from the ideal-gas value. There is an initial decrease at high reduced temperatures, where the temperature is divided by the critical temperature, for gases such as hydrogen and helium that exhibit small attractive interactions, but for the majority of gases the effect of attractive forces is to produce an increase in α, as expected from the van der Waals equation.

α becomes infinite at the critical point. The van der Waals equation predicts that, at the critical density, α would increase as $(T - T_c)^{-1}$, where T_c is the critical temperature, but in fact it increases even more rapidly.

2. HEAT CAPACITY

Heat-capacity values are essential in thermodynamics for calculating changes in entropy S and enthalpy H between different temperatures for pure gases, and also for determining the corresponding changes in these functions in reactions of gases. In order to determine whether, thermodynamically, a reaction can occur, it is necessary to calculate the Gibbs energy change ΔG, given by $\Delta H - T\Delta S$; ΔG must be negative. The equilibrium constant K is determined from the value for the Gibbs energy change ΔG^0 when all species are in their standard state, which, for a gas, is the (hypothetical) state where ideal-gas behavior is exhibited at the standard pressure (10^5 Pa):

$$\Delta G^0 = -RT \ln K. \tag{6}$$

In chemical engineering, heat-capacity data are required in problems of energy transfer and for making energy balances. Experimentally, measurements for gases are made under conditions of constant volume (isochoric heat capacity, C_V) or constant pressure (isobaric heat capacity, C_P). These heat capacities are related to the thermodynamic functions internal energy, denoted by U, and enthalpy,

$$C_V = \left(\frac{\partial U}{\partial T}\right)_V \quad \text{and} \quad C_P = \left(\frac{\partial H}{\partial T}\right)_P. \tag{7}$$

The relationship between these heat capacities is given by

$$C_P - C_V = T\left(\frac{\partial P}{\partial T}\right)_V\left(\frac{\partial V}{\partial T}\right)_P = \frac{\alpha^2 VT}{\kappa_T}, \tag{8}$$

where α is the isobaric coefficient of thermal expansion and κ_T is the isothermal coefficient of compressibility, $-(1/V)(\partial V/\partial P)_T$.

Changes in U, H, and in entropy S when 1 mole of a real gas goes from pressure P_1 and volume V_1 at temperature T_1 to pressure P_2 and volume V_2 at temperature T_2 are as follows:

$$U(T_2,V_2) = U(T_1,V_1) + \int_{T_1,V_1}^{T_2,V_1} C_V(T,V_1)dT + \int_{T_2,V_1}^{T_2,V_2}\left[T_2\left(\frac{\partial P}{\partial T}\right)_v - P\right]dV, \tag{9}$$

$$H(T_2,P_2) = H(T_1,P_1) + \int_{T_1,P_1}^{T_2,P_1} C_P(T,P_1)dT + \int_{T_2,P_1}^{T_2,P_2}\left[V - T_2\left(\frac{\partial V}{\partial T}\right)_P\right]dP, \tag{10}$$

$$S(T_2,P_2) = S(T_1,P_1) + \int_{T_1,P_1}^{T_2,P_1} \frac{C_P(T,P_1)}{T}dT - \int_{T_2,P_1}^{T_2,P_2}\left(\frac{\partial V}{\partial T}\right)_P dP. \tag{11}$$

For U and H there is no contribution from the final term for an ideal gas; for entropy, the contribution arising from the pressure change in this case is $R \ln (P_2/P_1)$ per mole.

2.1 Measurements at Constant Volume

Heat-capacity measurements at constant volume may be made by adiabatic calorimetry. In outline, a sample of known mass (and, hence, number of moles n) is confined to a vessel. Since measurements are usually made over a range of pressure, the vessel is referred to as a "bomb." A precisely measured amount of electrical energy, Q, is applied, and the resulting temperature rise ΔT is accurately measured. In a separate experiment, the amount of energy Q_0 to heat the bomb by the same ΔT is determined, and the molar heat capacity of the gas is then obtained from the relationship

$$C_v = (Q - Q_0)/n\Delta T. \tag{12}$$

The experiment can be repeated with the same charge of gas at different temperatures to give a set of isochoric heat capacities. At the end of the run some gas can be released and further measurements made at a lower density. In this way, a series of $C_V(\rho)$ isotherms can be obtained. In each case, the number of moles may be calculated from the measured bomb volume and an accurate equation of state for the gas that gives the density.

Figure 1 gives a diagram of the apparatus of Goodwin (1961) at the former National Bureau of Standards, Boulder, Colorado (now the National Institute of Standards and Technology), recently used by Magee (1994). The 5-cm-diameter type 316 stainless steel calorimeter has a Constantan wire heater varnished directly onto the sphere. The copper case protects the heater and serves as a reference temperature for two thermopiles, 1, which control a guard ring and an adiabatic shield. Temperature control is also aided by thermocouples 2, 3, and 4. The electrical energy is given basically by the product of potential and current and the heating interval. Details of the corrections to be applied for accurate results are given by Goodwin and Weber (1969a). As an example of C_V values, Goodwin and Weber (1969b) found for oxygen that between temperatures

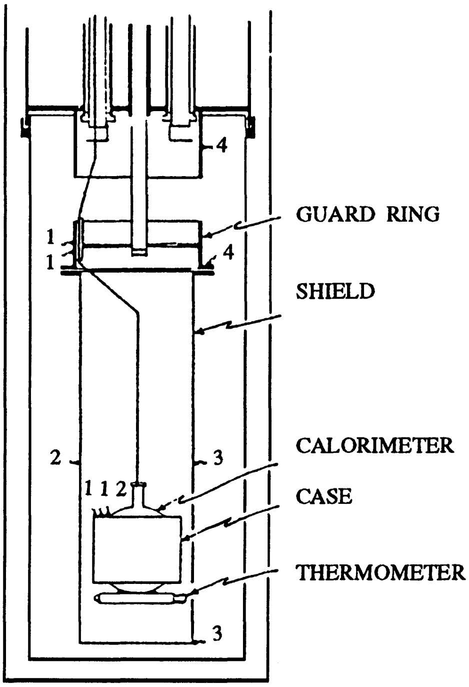

FIG. 1. Constant-volume adiabatic calorimeter, from Goodwin (1961), courtesy of National Bureau of Standards, Boulder, Colorado. 1, thermopiles; 2,3,4, thermocouples.

of 210 and 155 K, C_V showed a small increase at densities of 6.10 mol L^{-1} (22.6 to 27.8 J K^{-1} mol^{-1}) and 20.2 mol L^{-1} (24.3 to 28.6 J K^{-1} mol^{-1}). However, at 13.1 mol L^{-1}, the increase is from 23.9 to 47.9 J K^{-1} mol^{-1}. The increase of heat capacity with density is most pronounced in the neighborhood of the critical point (see Sec. 2.6 below).

Since the heat capacity of the bomb is several times that of the gas itself, Michels and Strijland (1952) adopted a differential method. Two identical calorimeters, one evacuated and one filled with gas, are heated simultaneously by an electric current. The temperature of the surroundings is made to follow that of the calorimeters automatically. The difference in temperature rise of the two calorimeters is accurately measured and the heat capacity determined from this and from the total temperature rise, the energy input, and the measured mass of gas.

2.2 Measurements at Constant Pressure

The heat capacity of a gas can be measured by adiabatic constant-flow calorimetry. The apparatus used by Wacker *et al.* (1947) is illustrated in Fig. 2. The gas enters at I and passes through the helical tube T_2, emerging into the evacuated chamber at the bottom at the bath temperature. It then passes through a series of baffles and is heated by heater H_C. The bath temperature is adjusted to follow that of the gas. After passing through more baffles to equilibrate the temperature, the gas leaves the calorimeter through throttle valve V. The rate of flow r of gas is determined by weighing the gas that passes through in a given time. The pressure of the gas before and after heating is measured by means of manometer M. The heat capacity at the mean pressure is determined from the power W applied to the heater and the measured temperature rise ΔT, according to

$$C_P = W/r(\Delta T + \delta t), \tag{13}$$

where δt is the decrease in temperature that arises as a result of Joule–Thomson cooling (see Sec. 3). It is measured by passing the gas through at the same inlet and outlet pressures without heating.

Values at different pressures can be extrapolated to zero pressure to give ideal-gas heat capacities.

2.3 Ideal-Gas Values

2.3.1 Speed-of-Sound Measurements In the absence of dispersion, the speed of sound u in a gas of molar mass M can be expressed in terms of the temperature T and molar density ρ as

$$u^2 = (RT\gamma/M)\{1 + \beta\rho + \ldots\}, \tag{14}$$

where γ is related to the ideal-gas heat capacity at constant pressure by $\gamma = C_P/(C_P - R)$, and β is termed the second acoustic virial coefficient.

The speed of sound is measured from low-order radially symmetric modes in a spherical resonator. Such modes are nondegenerate and have resonant frequencies that are insensitive to any geometric imperfections of the cavity. An apparatus used for the measurement of speed of sound in several simple gases over wide temperature ranges has been described by Ewing and Trusler (1989). Basically, the resonator is a sealed aluminum-alloy sphere of internal radius 40 mm and wall thickness 10 mm, constructed by machining and polishing two halves separately and then electron-beam welding them together. Two transducer ports, at 90° to each other, were machined in the upper half, one to take an electroacoustic source transducer and the other the detector transducer.

The speed of sound is calculated from the measured frequencies $f_{0,n}$ of the radial modes,

$$u = 2\pi a(f_{0,n} - \Sigma\Delta f)/\nu_{0,n}, \tag{15}$$

where a is the cavity radius, $\nu_{0,n}$ is an accurately known eigenvalue, and $\Sigma\Delta f$ gives the sum of correction terms to the simplified theory used. Ideal-gas heat capacities of high accuracy are derived from measurements at different pressures.

2.3.2 Calculation When simple gases are heated at constant volume, energy is taken up in molecular translation, rotation, and vibration. According to the kinetic theory of gases, the energy of 1 mole of a gas whose particles possess only translational energy is equal to $3RT/2$, and so the molar isochoric heat capacity C_V equals $3R/2$. This is in accord with the classical law of equipartition of energy, which gives the molar energy as $RT/2$ and the isochoric heat capacity as $R/2$, per squared term where, for translation, there are three squared terms since the velocity has components in three dimensions. For a diatomic molecule, in addition to translational motion, there is the possibility of rotation about two axes at right angles, and here there are two more squared terms, and the contribution to the total C_V will equal R. A diatomic molecule will also possess one mode of vibrational motion, but this is associated with kinetic and potential energy, and the contribution here is also equal to R. A linear polyatomic molecule containing N nuclei will also have a contribution R from rotational motion, and $(3N - 5)R$ from vibration. If the molecule is nonlinear, the contributions from rotation and vibration become $3RT/2$ and $(3N - 6)R$ respectively. These results are summarized in Table 1 and compared with experimental data corrected to zero pressure for some simple gases. For an ideal gas,

$$C_P/R = C_V/R + 1. \tag{16}$$

For monatomics such as argon there is excellent agreement between the classical value and experiment, but for polyatomic gases, the classical values are all higher than the experimental results at 298 K. The experimental values increase as the temperature is raised, but only in the case of bromine of the gases listed at 1000 K does the experimental value closely approximate the classical value. However, it is found that the experimental results at 298 K for nitrogen (and other diatomics such as oxygen, carbon monoxide, and nitric oxide) agree closely with the expected value without the vibrational contribution, namely, $3.5R$. Nonlinear polyatomics such as water similarly agree with the classical sum of the translational and rotational contributions plus R, namely, $4R$.

In order to understand why the heat ca-

pacities for molecules differ from these classical values, it is necessary to consider the results of quantum mechanics. This tells us that molecules exist in well-defined energy states, and it is the difference in energy between adjacent energy states that determines the amount of heat required to raise the temperature of the gas by one degree, and hence the heat capacity. Where the energy levels are closely spaced with respect to $k_B T$, where k_B is the Boltzmann constant, as in the case of translational energy, the input of heat will result in the excitation of a very large number of molecules and the heat capacity will be identical to the classical value. However, when the energy gap between adjacent levels is large with respect to $k_B T$, as is generally true for vibrational energy at 298 K, then few molecules get promoted to a higher level, and there is little increase in vibrational energy and hence only a small contribution to the heat capacity from vibrational motion.

The temperature dependence of the perfect-gas molar heat capacities for polyatomics can be understood by application of the methods of statistical thermodynamics, which are described in detail in texts such as Fowler and Guggenheim (1939) and Hill (1956). Just the main points are presented here. Molecules exist in different quantum states and, although it is not possible to state with certainty that a particular molecule will be in a specific state at a given moment, the probability of this occurrence can be given. The reason is that we are dealing with such a large number of molecules. According to the Boltzmann distribution, the probability $p(\epsilon_i)$ of finding a molecule in energy state ϵ_i at temperature T is given by

$$p(\epsilon_i) = \exp[-\epsilon_i/k_B T]/q, \tag{17}$$

where q, known as the molecular partition function, is obtained by summation over all energy states, $\Sigma \exp[-\epsilon_i/k_B T]$. The internal energy per mole of gas, relative to the gas where all molecules are in their ground state, is given by $N_A \Sigma p(\epsilon_i)\epsilon_i$, from which the molar heat capacity at constant volume is given by

$$C_V = 2RT\left(\frac{\partial \ln q}{\partial T}\right)_V + RT^2\left(\frac{\partial^2 \ln q}{\partial T^2}\right)_V. \tag{18}$$

To an excellent approximation, the total energy of a molecule can be considered as the sum of the translational, rotational, vibrational and electronic energies, and the molecular partition function is then given by

$$q = q_{\text{trans}} \times q_{\text{rot}} \times q_{\text{vib}} \times q_{\text{elect}}, \tag{19}$$

where q_{trans} depends on molecular mass m and volume V; h is the Planck constant:

$$q_{\text{trans}} = (2\pi m k_B T/h^2)^{3/2} V; \tag{20}$$

q_{rot} depends on the moment of inertia I and, for a diatomic molecule, is generally given by

$$q_{\text{rot}} = 8\pi^2 I k_B T/\sigma h^2, \tag{21}$$

where σ, the symmetry number, equals 1 for heteronuclear and 2 for homonuclear diatomics. The exception is where the moment of inertia is low, as for hydrogen, or the temperature is low so that the gap between adjacent energy levels is large with respect to $k_B T$. The rotational part of the molecular partition function then has to be evaluated by summation over the allowed energy states. Restrictions on the wave function for the nuclei of a diatomic molecule account for the existence of two distinct forms, the ortho and para forms, which possess different properties. Only for hydrogen and deuterium is this important in the calculation of heat capacities. See, for example, McLelland (1973).

For polyatomic molecules where rotation can occur about three mutually perpendicular axes, the expression for the rotational contribution to the partition function is

$$q_{\mathrm{rot}} = 8\pi^2(8\pi^3 I_A I_B I_C)^{1/2}(k_{\mathrm{B}}T)^{3/2}/\sigma h^3, \tag{22}$$

where the symmetry number has a value equal to the number of equivalent positions into which the molecule can be turned by rotation. For water, $\sigma = 2$, and for methane, $\sigma = 12$.

The contributions to the isochoric heat capacity from translation and rotation are $3R/2$ and R (linear polyatomic) or $3R/2$ (nonlinear polyatomic molecule), as given classically above.

The temperature dependence of the heat capacity arises from the vibrational contribution to the molecular partition function, which for a polyatomic molecule in the rigid-rotor harmonic oscillator model is given by

$$q_{\mathrm{vib}} = \prod_{i=1}^{n}\left[1 - \exp\left(-\frac{h\nu_i}{k_{\mathrm{B}}T}\right)\right]^{-1}, \tag{23}$$

where $n = 3N - 5$ for an N-atomic linear molecule and $n = 3N - 6$ for a nonlinear molecule. This has been evaluated relative to the ground energy state.

The corresponding contribution to the heat capacity is

$$C_{V,\mathrm{vib}} = \sum_{i=1}^{n} \frac{R(h\nu_i/k_{\mathrm{B}}T)^2 \exp(h\nu_i/k_{\mathrm{B}}T)}{[\exp(h\nu_i/k_{\mathrm{B}}T) - 1]^2}. \tag{24}$$

At high temperatures, when $T \gg h\nu_i/k_B$, $C_{V,\mathrm{vib}}$ has the classical value of R per vibrational mode.

The temperature dependence of $C_{V,\mathrm{vib}}$ is illustrated in Fig. 3 for a diatomic molecule ($n = 1$). The contribution at 298 K will depend upon the value of $h\nu_i/k_{\mathrm{B}}$, termed the characteristic vibrational temperature, denoted by Θ_{vib}. Values of Θ_{vib} in kelvins for some simple gases are oxygen 2239, nitrogen 3352, and carbon monoxide 3084. Thus, the contribution to the total heat capacity from vibrational motion for these gases at 298 K is very small.

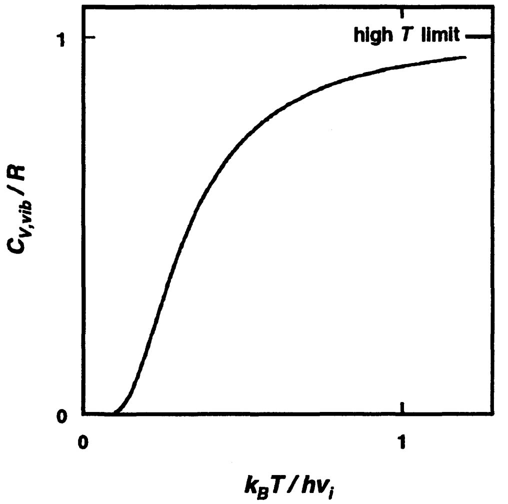

FIG. 3. Reduced temperature dependence of $C_{V,\mathrm{vib}}$ for a diatomic molecule.

When a molecule contains groups such as methyl, hydroxyl, carbonyl, or carboxy connected by a single chemical bond, then the molecule possesses a mode of torsional oscillation, or internal rotation. The evaluation of the partition function is then more complex. This contribution may be factored out of the vibrational contributions to the molecular partition function. It is then necessary to know the internal rotation energy levels, which are determined by solution of the Schrödinger equation with an appropriate expression for the potential energy. For a methyl group, a symmetric top with threefold symmetry, the potential energy function is usually given as a function of θ, the angle of internal rotation, by $\frac{1}{2}V_3(1 - \cos 3\theta)$, where V_3 is the internal rotation barrier height. Alternatively, the gas may be assumed to consist of a mixture of conformers, each corresponding to a minimum in the potential energy function for an internal rotation.

The electronic contribution to the partition function is normally equal to the degeneracy of the ground electronic energy level, since the energy gap between the ground and first excited energy level is higher than that for vibrational energies. For most molecules the ground electronic level is nondegenerate so that $q_{\text{elect}} = 1$. For some molecules, such as nitrogen (II) oxide, there is a low-lying electronically excited level, and this must be included in the summation for q_{elect}. The contribution of higher levels must also be included in calculations of heat capacities at very high temperatures.

Examples of details of these calculations, and a comparison of the calculated ideal-gas heat capacities with experimental data, are given by Chao *et al.* (1973) for ethane and propane, Chao *et al.* (1974) for chloroethanes, Chao and Zwolinski (1975) for ethylene and propylene, Chao *et al.* (1986) for C_1 to C_4 organic oxygen compounds, Chao and Hall (1984) for *o*-, *m*-, and *p*-xylenes, and Chao *et al.* (1990) for organic nitrogen compounds.

2.3.3 Representation Ideal-gas heat capacities are given in a number of compilations, including those of Gurvich *et al.* (1978), the tables produced by the Subcommittee on Technical Data, American Petroleum Institute (API) Research Project 44 (1974), the JANAF Thermochemical Tables (Stull and Prophet, 1971), and the Landolt-Börnstein tables (Schäfer and Lax, 1961). The API tables give, in addition, values for the difference between the real-gas heat capacity and the gas in its standard state for low–molecular-weight hydrocarbons up to 1500 K and a pressure of 500 atm (ethane) or 700 atm (higher alkanes).

For inorganic compounds, the compilation of Wagman *et al.* (1982) gives values of ideal-gas heat capacities at 298.15 K and 10^5 Pa. Barin and Knacke (1973) represent the temperature dependence of the heat capacity of inorganic compounds in their compilation by the equation

$$C_P = A + B \times 10^{-3}T + C \times 10^{-3}T^{-2} + D \times 10^{-6}T^2 \tag{25}$$

and give values for the parameters A, B, C, and D for a large number of substances. Mills (1974) uses this equation, with $D = 0$, to represent the heat capacities of sulfides, selenides, and tellurides.

Ideal-gas heat capacities for a number of technologically important substances have been tabulated in a series of monographs produced by the International Union of Pure and Applied Chemistry (see de Reuck and Craven, 1993, and references therein). These values are thermodynamically consistent with other equilibrium thermodynamic properties, all of which have been used to construct a reduced Helmholtz energy equation, from which values of these properties may then be calculated by mathematical manipulation.

2.3.4 Estimation Where ideal-gas heat-capacity data are not available, various estimation methods based on group contributions can be used. The method of Benson (1968) can be recommended. Numerical contributions are given for atoms or groups with specific neighboring groups, with adjustments for ring compounds. The ideal-gas heat capacity is then determined by identifying the various groups linked to each key atom and summing the corresponding contributions. Illustrative examples are given by Benson *et al.* (1969). Errors are generally less than 1%.

2.4 Effects of Molecular Interactions

Real gases have interactions between the molecules, and if these are represented by the van der Waals equation, Eq. (3), then, from the relationship between C_P and C_V given in the introduction to Sec. 2, on neglecting the term involving a^2,

$$C_P - C_V = R + 2aP/RT^2. \tag{26}$$

So, for a real gas, the difference in heat capacities is greater than for an ideal gas, and this difference becomes larger at high pressures and at low temperatures. Under given conditions, the difference is greater for substances with a higher value for the parameter a, which is a measure of the effect of attractive forces. When the equation of state of the gas is known, the difference is obtained directly from

$$C_P - C_V = T\left(\frac{\partial P}{\partial T}\right)_V\left(\frac{\partial V}{\partial T}\right)_P. \tag{27}$$

2.5 Critical Region

There is a critical anomaly in C_V, as illustrated in Fig. 4 by the results of Michels and Strijland (1952) for carbon dioxide. At the

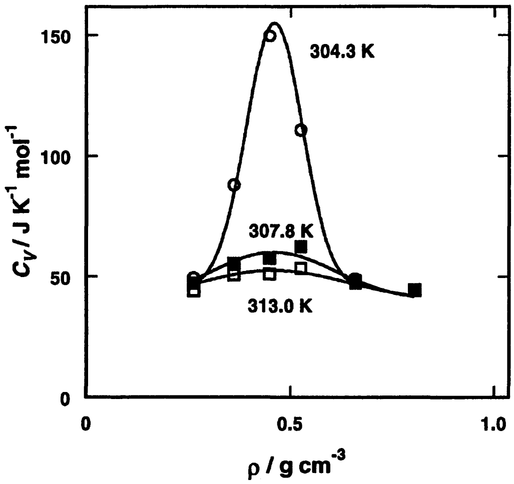

FIG. 4. Heat capacity of carbon dioxide.

critical density, C_V becomes infinite as ln $|T - T_C|$, or slightly greater. The van der Waals equation does not predict this anomaly. This divergence is significantly less than that of C_P, which diverges with the compressibility. The van der Waals equation predicts that the compressibility increases as $(T - T_C)^{-1}$, although in fact it increases more rapidly.

3. JOULE–THOMSON EFFECT

It was shown by Joule and Thomson (later Lord Kelvin) (1853) that when a gas at a constant pressure is passed through a porous plug of cotton wool or silk and emerges at a constant lower pressure, in an apparatus where no heat enters or leaves, then at room temperature the gas becomes cooler. Subsequent experiments with different porous plugs, such as earthenware, confirm this fall in temperature exhibited by most gases around room temperature, though hydrogen and helium show a heating effect under these conditions. This phenomenon is termed the Joule–Thomson effect. Its importance lies in the clear indication of the existence of intermolecular forces, and its application in the liquefaction of gases.

Under these experimental conditions, the process is isenthalpic, and the effect is quantified by introducing the Joule–Thomson coefficient μ_{JT}, defined as $(\partial T/\partial P)_H$. This can be determined from experimental measurements, when there is a cooling effect, of the quantity of electrical energy q passed through a heater immediately after the plug, or throttle, to keep the gas at the same temperature. This heat $q = \Delta H$ and division by the pressure drop ΔP gives $(\Delta H/\Delta P)_T$, which gives $(\partial H/\partial P)_T$ as $\Delta P \rightarrow 0$. μ_{JT} is obtained from the relation

$$\mu_{JT} = -C_P^{-1}\left(\frac{\partial H}{\partial P}\right)_T. \tag{28}$$

The Joule–Thomson coefficient is related to the equation of state for the gas by

$$\mu_{JT} = \left\{T\left(\frac{\partial V}{\partial T}\right)_P - V\right\}\Big/C_P, \tag{29}$$

which, for an ideal gas, gives $\mu_{JT} = 0$.

Real gases behave similarly under identical reduced conditions. At high reduced temperatures (where the temperature is divided by the critical temperature) there is a heating effect, and at low reduced temperatures there is a cooling effect. Thus, there is a temperature, known as the inversion temperature, where a real gas behaves like an ideal gas in that there is no observed temperature change. This is pressure dependent, and part of an inversion curve.

For a van der Waals gas, the Joule–Thomson coefficient is given generally in terms of the molecular parameters a and b by

$$\mu_{JT} = (2a/RT - b) \tag{30}$$

and at the inversion temperature, $T = 2a/Rb$.

When the PVT behavior is represented by the virial equation,

$$PV/RT = 1 + B/V + \ldots, \tag{31}$$

where B is the second virial coefficient, then

$$\mu_{JT} = \left\{T\left(\frac{dB}{dT}\right) - B\right\}C_P^{-1}. \tag{32}$$

The technological importance of the Joule–Thomson effect is in the liquefaction of gases. The first major applications of this technique were made by von Linde (1895) and Hampson (1895). Gas at a pressure of about 200 atm (20 MPa) streamed through a valve, or throttle, and emerged at a pressure of 20 atm (2 MPa) (von Linde) or 1 atm (0.1 MPa) (Hampson). Below its inversion temperature, the gas will cool; it then passes over the outer surface of the tube bringing the incoming gas to the expansion jet, which in turn is further cooled. After further cycles, the gas liquefies. The collection, and storage, of liquefied gas was made possible by the invention of the double-walled vacuum vessel, or Dewar flask, by Dewar (1893).

For hydrogen and helium, whose inversion temperatures are about 190 and 100 K, respectively, it is necessary to cool the gases below this temperature before further cooling and eventual liquefaction will occur by the Joule–Thomson effect.

4. THERMAL CONDUCTIVITY

Fourier's phenomenological law of heat conduction relates the heat (energy) flux Q across an area A to the temperature gradient (dT/dz) by the expression

$$Q = -\lambda A \frac{dT}{dz}, \qquad (33)$$

where λ is the thermal conductivity. Accurate values for the thermal conductivity of gases are of vital importance to chemical and mechanical engineers concerned with heat-transfer processes—for example, in heat exchangers. Dilute-gas data also provide information about the pair-interaction potential energy function.

4.1 Measurements

The methods for measurement of the thermal conductivity of a gas can conveniently be classified into two groups. In the first of these, the steady-state experiments, a constant temperature difference is maintained between two surfaces in the gas and the heat flux is measured. The instruments are usually based on parallel plates or concentric cylinders and have the advantage of simple working equations. The main difficulty in such experiments is the minimization of the effects of other mechanisms of heat transfer, such as convection and radiation. The accuracy of such methods is typically ±(1 to 3)%. The second group, the transient methods, eliminates the convective contribution by imposition of a small temperature gradient to a gas initially at equilibrium. In close approximation to the ideal model, this perturbing heat flux is normally produced by electrical dissipation in a thin, cylindrical wire. The thermal conductivity of gases can be measured with an accuracy of ±0.3% by this method. Examples of each of these types of measurement are described below.

4.1.1 Concentric-Cylinder Method

This method is based on the idealized model of two coaxial cylinders, in which a heat flux generated in the inner cylinder is conducted radially through the gas contained between the cylinders to the outer cylinder in steady-state conditions. If the external radius of the inner cylinder, termed the emitter, is r_1 and the internal radius of the outer cylinder, termed the receiver, is r_2 and the temperatures of these surfaces are respectively T_1 and T_2, then the heat flux per unit time per unit length is given by

$$\Phi = 2\pi\lambda(T_1 - T_2)/\log(r_2/r_1). \qquad (34)$$

The thermal conductivity determined from the heat flux and the temperature difference is the value at the average temperature $(T_1 + T_2)/2$.

In practice, the cylinders are not infinite in length, and heat can be transported across the ends. However, if end pieces of the same diameter as the inner cylinder are placed at either end of this cylinder, separated from it by a gap of similar magnitude to the distance between the cylinders, and maintained at the same temperature as the inner surface of the outer cylinder, the heat flux is again proportional to the temperature difference and the thermal conductivity, with a proportionality constant that depends on the geometry of the instrument. This may be determined directly from capacitance measurements to give absolute values for the thermal conductivity, or determined from measurements using a gas of known thermal conductivity, in which case the measurements are relative.

As an example of the many designs of such instruments, the coaxial cylinder cell of Le Neindre (1969) and Tufeu (1971) is illustrative. The cell was made of silver with its axis vertical. The inner cylinder was 120 mm in length, with an outer diameter of 19.6 mm. The outer cylinder had an inner diameter of 20 mm, giving an annular gap of 2 mm, an outer diameter of 50 mm, and a length of 200 mm. A heating element 112 mm in length was formed from Pt/25% Rh wire of diameter 0.3 mm, helically wound on an alumina tube of 4-mm external diameter, and set up in the central hole of the inner cylinder. The temperature difference was measured by eight Pt/10% Rh thermocouples, four in each cylinder. Temperature differences of about 2 K were measured with a precision of 0.003 K. The heat emitted from the inner cylinder was determined from the measured voltage and current intensity in the heating element. Corrections were applied for heat losses through conduction through the cylinder element, electric leads, and ceramic supports. Measurements made with this instrument were recently reported by Sousa *et al.* (1992) for HCFC-142b.

To reduce the problem of axial heat loss, the two end pieces are maintained at the same temperature as the inner cylinder, and then all the heat passes radially from one cylinder to the other. The instrument of Tanaka *et al.* (1991) is a good illustration of an instrument with two such guard cells.

4.1.2 Parallel-Plate Method In this method, the gas is confined between two horizontal circular plates, usually made of copper, with the upper one heated to a higher temperature. For an infinite gaseous layer, of thickness δ, between two parallel plates with a temperature difference ΔT, application of the Fourier law gives an average thermal conductivity. This equals the thermal conductivity at the mean temperature of the plates, assuming that the thermal conductivity varies linearly with temperature, which is normally a good approximation. In practice, the distance δ is maintained constant by the use of spacers made from a low–thermal-conductivity material, and is in the range 0.2–0.5 mm to reduce possible effects of convection. The plates are highly polished and protected against oxidation to reduce the emissivity and lower the radiation correction. Information on the magnitude of this effect can be determined by repeating the measurements with a different plate separation. Account must be taken of the finite diameter of the plates. Radial and axial heat losses can be minimized by use of guard heaters. Thermal-conductivity measurements by this method can be either relative or absolute. A brief history of early measurements has recently been given by Sirota (1991). Special mention should be made of the work of Michels *et al.* (1962), who confirmed the existence of an anomalous increase in the thermal conductivity of carbon dioxide in the critical region. That this was not due to convection, which increases heat transfer significantly in this region, was demonstrated by repeating the experiments for different plate distances and temperature differences, and showing that the results were independent of the Rayleigh number. The parallel-plate method has recently been used for measurements on polar alternative refrigerant gases by Hammerschmidt (1995). Although this method has lower accuracy than the transient hot-wire method, described in the following section, there are no electrical or chemical interaction problems to consider.

4.1.3 Transient Hot-Wire Method The advantage of transient methods over the methods described above is that convective contributions to the heat transfer can be eliminated. There are exact working equations for this technique, which leads to absolute measurements for all regions of the phase diagram except the critical region very close to the critical point. The ideal model is of an infinitely long, vertical line source of heat, with zero heat capacity and infinite thermal conductivity, immersed in an infinite isotropic gas at the same initial equilibrium temperature. A time-dependent perturbation, in the form of a stepwise heat flux q per unit length, is applied, and the temperature response of the gas is monitored. In practice, instead of a line source, a cylindrical wire of radius r_0 is used. This has a uniform temperature equal to that of the gas at distance r_0 in the ideal model, and for small values of r_0 the temperature rise $\Delta T_{id}(r_0,t)$ is given by

$$\Delta T_{id}(r_0,t) = \frac{q}{4\pi\lambda} \ln\left(\frac{4at}{r_0^2 C}\right), \qquad (35)$$

where $C = \exp(\gamma)$, where γ is Euler's constant (0.5772157 . . .), and a is the thermal diffusivity, given by $a = \lambda/\rho C_p$ and taken as constant.

The thermal conductivity of a gas may be determined from a plot of $\Delta T_{id}(r_0,t)$ vs ln t, and the thermal diffusivity can be obtained by substitution for a measured value of $\Delta T_{id}(r_0,t)$ at any given time.

In any practical instrument, a finite length of metallic wire provides the source of heat and acts as a resistance thermometer. The measured temperature rise ΔT_w equals the sum of the ideal value ΔT_{id} plus corrections δT_i. Most of these corrections were considered by Healy *et al.* (1976), and a more extensive treatment was given by Assael *et al.* (1991). Careful apparatus design will reduce these corrections to less than 0.5% of ΔT_{id}. Use of a supported wire of finite length results in the temperature field decreasing near the wire supports as a result of heat losses. To eliminate these "end effects," two wires are employed instead of one. These wires differ solely in their length, and, if they are sufficiently long, then the end effects will be the same when they are subjected to the same heating current. Measurements of the difference in resistance of the two wires at specific times will be equivalent to the resistance of a finite length of an infinitely long wire. The wires are typically made of platinum, 7 to 10 μm in diameter and with the short wire about 70 mm and the long wire 170 mm in length. The mounting of these wires is the key to accurate thermal conductivity measurement. They must be vertical, subject to constant tension, and unaffected by changes in temperature and pressure. To overcome the lateral movement resulting from temperature changes when the wire is fixed to rigid supports at either end, a beryllium-copper alloy spring has been fastened to the upper end of the wire to keep the wire under tension. Figure 5 shows the mounted wires in the transient hot-wire cell of Haran and Wakeham (1982) for measurements in gases from 77 to 520 K at pressures from 0.1 to 10 MPa.

The two cells are machined from a single stainless steel block. The supports for the platinum wires are formed from brass terminal posts set in a stainless steel cylinder in a ceramic bush with a stainless steel sleeve.

Experimentally, the change in resistance of the wires is followed over a period of about 1 s after the heating cycle, using a bridge circuit. In the method of Roder (1981), two arms are standard resistors of 100 Ω, and the resistance of the other arms, each of which contains one of the wires with the leads and ballast resistors, can be adjusted to 100 Ω. The bridge is balanced prior to the start of an experiment, the power supply is activated, and the voltage developed across the bridge is read and stored at fixed time intervals. The accuracy of the measured thermal conductivity is estimated to be better than 1%. An alternative procedure, employed by Mardolcar *et al.* (1986), uses a bridge with one arm arranged to provide a series of preset balance points as the resistance difference between the two wires increases. The times at which these balances occur provides a set of data of temperature

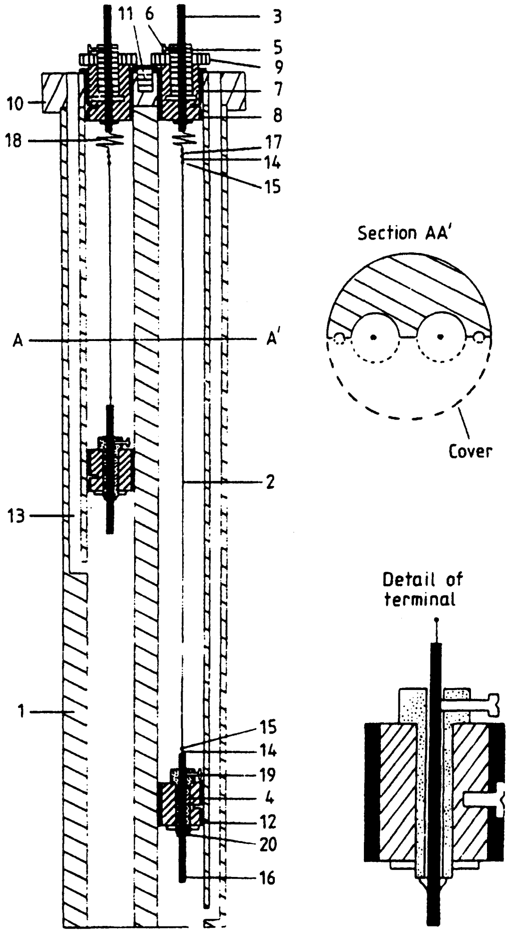

FIG. 5. Transient hot-wire cell, from Haran and Wakeham (1982), courtesy of IOP Publishing Ltd.

rise vs time. Use of a computer-controlled bridge by Charitidou *et al.* (1987) increased the number of $(\Delta T,t)$ points to 1024 for a single run of 1-s duration and improved the precision of the thermal conductivity measurements to about ±0.1% and the accuracy to ±0.3%.

4.1.4 Experimental Results Values for the thermal conductivity of a number of simple gases at 0.1 MPa are given in Table 2.

At 0.1 MPa, the thermal conductivity increases with increase in temperature, as a result of purely kinetic effects. The rate of increase diminishes as the pressure is raised until, for pressures above about 20 MPa, $(\partial\lambda/\partial T)_p$ has the opposite sign as collisional transfer predominates. This mechanism is highly dependent on density. In fact it is density that is the important variable for the theoretical interpretation of thermal-conductivity data, as is illustrated by the regular dependence illustrated in Fig. 6 for argon, with the experimental results of Michels *et al.* (1963) at 273.6 and 348.2 K. Data of Calado *et al.* (1987) for liquid argon at 140.1 K are included for comparison.

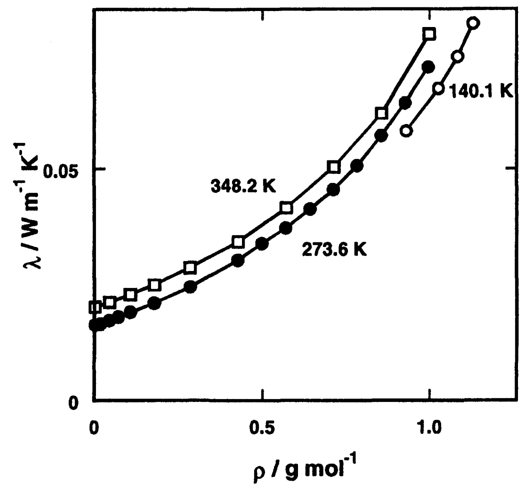

FIG. 6. Density dependence of the thermal conductivity of argon.

However, as the temperature decreases toward the critical temperature, the thermal conductivity vs density plots exhibit a maximum, as shown in Fig. 8 (Sec. 4.5) for carbon dioxide. The critical enhancement of the thermal conductivity is apparent at densities from about 0.1 to 2.1 times the critical density, decreasing in magnitude to about 1% of the total thermal conductivity at these extremes. It is greatest at the critical density and persists at temperatures up to about 1.4 times the critical temperature.

4.2 Theoretical Description for Monatomics

In the simple kinetic theory of gases (see, for example, Jeans, 1962), the thermal conductivity of a gas is related to the temperature and to the mass m and diameter σ of the molecules, considered as hard spheres, by the expression

$$\lambda_{\mathrm{HS}} = \frac{c_V}{3\pi\sigma^2}\left(\frac{8k_BT}{\pi m}\right)^{1/2}, \tag{36}$$

Table 2. Thermal conductivity data (mW m^{-1} K^{-1}) for some representative gases.

		T(K)			
Substance	Reference	200	300	400	600
	Low-pressure limiting values				
Helium	Kestin *et al.* (1984)	119.3	156.7	190.6	252.4
Argon	Kestin *et al.* (1984)	12.4	17.9	22.6	30.6
Xenon	Kestin *et al.* (1984)	3.6	5.5	7.3	10.4
Hydrogen	Assael *et al.* (1986)	131.7	186.9	230.4	
Nitrogen	Stephan *et al.* (1987)	18.7	26.0	32.3	44.0
Carbon monoxide	Millat and Wakeham (1989)		25.0	32.3	45.7
Carbon tetrafluoride	Uribe *et al.* (1990)		16.0	24.1	39.9
	0.1 MPa				
Methane	Younglove and Ely (1987)	22.5	34.3	49.1	84.1
Ethane	Younglove and Ely (1987)	11.0	21.3	35.4	70.5
Propane	Younglove and Ely (1987)		18.0	30.6	61.9
Butane	Younglove and Ely (1987)		16.4	28.4	59.1

where c_v is the molecular heat capacity at constant volume. The rigorous expression differs in the numerical factor; $2\sqrt{2/3\pi}$ is replaced by 25/32.

This theory predicts that thermal conductivity is pressure independent. Experimentally, the effect of an initial pressure increase is small; for example, for argon at 348.2 K and at 0.1 MPa, a 50-fold increase in pressure produces only a 9% increase in thermal conductivity. The effect of a temperature increase on the thermal conductivity of a gas at 0.1 MPa is correctly predicted, but experimentally the magnitude of the effect is greater than the $T^{1/2}$ dependence that is predicted. It is necessary to describe the interactions between molecules by a more realistic pair-interaction potential-energy function, $U(r)$. The thermal conductivity can then be calculated to the required order of approximation from reduced collision integrals (see Maitland *et al.*, 1981). To first-order approximation,

$$\lambda = \lambda_{HS}/\Omega^{(2,2)*}(T^*). \qquad (37)$$

Values for the reduced collision integral $\Omega^{(2,2)*}(T^*)$ have been tabulated by Maitland *et al.* (1981) for different pair-interaction potential-energy functions at different reduced temperatures, $T^* = k_BT/\epsilon$, where ϵ is the depth of the attractive potential well.

The thermal conductivity of noble gases at low pressure can be calculated from measurements of their viscosity η, since it can be shown theoretically that to a good approximation

$$\lambda = 15k_B\eta/4m. \qquad (38)$$

4.3 Theoretical Description for Polyatomics

In principle, a quantum mechanical treatment is required to account for energy exchange on collision between internal states, and between internal states and translational motion. This becomes very complicated, and it is therefore customary to use semiclassical theory, as given by Wang Chang and Uhlenbeck and independently by de Boer (see Wang Chang *et al.*, 1964). Here, each internal energy state is considered essentially as an independent chemical species, and the translational motion is treated classically. Evaluation of the formal expression for the thermal conductivity is possible by substitution of various contributions to the integrals by other experimental quantities, as shown by Monchick *et al.* (1965). In this way, the thermal conductivity is related to the viscosity to the equivalent of first-order approximation (see Maitland *et al.*, 1981).

4.4 Correlations for Dense Gases

Thermal-conductivity data for gases at temperatures and pressures where there is no significant critical enhancement fall on parallel curves when plotted as isotherms vs density, as shown in Fig. 6. The data are very satisfactorily correlated by a plot of the excess thermal conductivity $\Delta\lambda(\rho,T)$ against density, where $\Delta\lambda(\rho,T)$ is the difference between the value at density ρ and the dilute-gas value. This is illustrated by experimental results for isobutane, shown in Fig. 7. The points fall on a single curve and do not exhibit any temperature dependence.

4.5 Critical Region

The thermal conductivity of a gas at temperature T and density ρ, $\lambda(\rho,T)$, is conveniently represented as the sum of three contributions:

$$\lambda(\rho,T) = \lambda^{(0)}(T) + \Delta\lambda(\rho,T) + \Delta\lambda_c(\rho,T), \qquad (39)$$

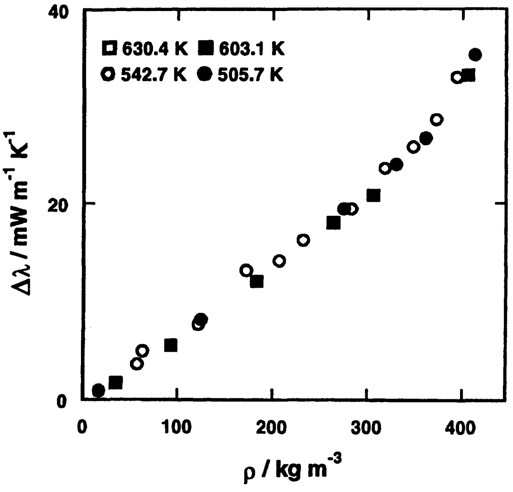

FIG. 7. Excess thermal conductivity for isobutane.

where $\lambda^{(0)}(T)$ is the dilute-gas value, obtained by extrapolation of results at different pressures to zero pressure; $\Delta\lambda(\rho,T)$ is the excess thermal conductivity; and $\Delta\lambda_c(\rho,T)$ is the critical enhancement. Large density fluctuations in the gas in the neighborhood of the critical point lead to a significant contribution from $\Delta\lambda_c(\rho,T)$. Even at temperatures up to 50% above the critical temperature, and densities up to twice the critical density, the contribution is more than 1% of the total thermal conductivity. Asymptotically close to the critical point, the thermal conductivity has a singular behavior, which is given in terms of a correlation length ξ by the equation

$$\Delta\lambda_C = \frac{R_D k_B T \rho c_P}{6\pi\eta\xi}, \tag{40}$$

where c_P is the isobaric specific heat capacity, and R_D is a universal amplitude, with a value of about 1.02. To cover the range from this limit to conditions where the critical enhancement is negligible, a crossover function is used (Sengers and Luettmer-Strathmann, 1996). This was developed from mode-coupling theory of the critical fluctuations and contains only one adjustable parameter, a microscopic cutoff distance, which has been found to have a value of about 0.2 nm for argon and ethane. The correlation length ξ lies also about 0.15–0.2 nm.

The density dependence of the thermal conductivity is illustrated in Fig. 8 for ethane along different isotherms. Agreement between the values calculated as above and the experimental measurements of Mostert *et al.* (1990), obtained with a parallel-plate apparatus, is very good, even close to the critical region where the discrepancies are greater, for here there are larger uncertainties in the density.

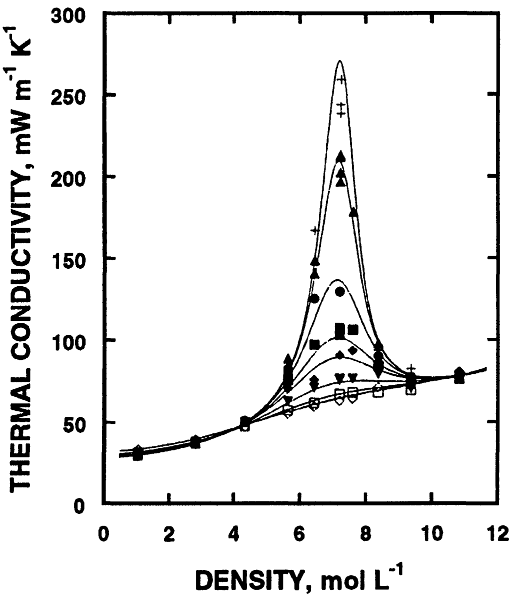

FIG. 8. The thermal conductivity of ethane. Solid line is calculated from Eq. (39). Experimental data, Mostert *et al.* (1990): cross, 305.46 K; solid triangle, 305.56 K; solid circle, 306 K; solid square, 307 K; solid diamond, 308 K; inverted solid triangle, 312 K; open square, 320 K; open diamond, 333 K. Figure from Vesovic *et al.* (1994), courtesy of Plenum Publishing Corp.

5. THERMAL DIFFUSION

Thermal diffusion is the process whereby an initially uniform mixture of gases will partially separate when a temperature gradient is applied. The extent of the separation is denoted by the thermal-diffusion factor, which can be expressed by kinetic theory in terms of quantities related to the molecular masses, and to the potential energy functions for the various binary interactions, as described by Maitland *et al.* (1981). This property is very sensitive to the form of the potential function, but accurate measurement is difficult, although in principle the method is straightforward. In its simplest form, the apparatus consists of two bulbs connected by a tube and maintained at different temperatures, T_1 and T_2. The mole fractions $x_{a,1}$ and $x_{a,2}$ of the heavier gas in each of the bulbs are determined under steady-state conditions. The thermal-diffusion factor, α_T, is obtained from the relation

$$\log\left(\frac{x_{a,1}/(1 - x_{a,1})}{x_{a,2}/(1 - x_{a,2})}\right) = \int_{\log T_2}^{\log T_1} \alpha_T d(\log T). \tag{41}$$

In practice, $x_{a,1} - x_{a,2}$ is typically about 0.05 for a temperature difference of 100 K. The first experimental confirmation of thermal diffusion in gases was obtained by Chapman and Dootson (1917), who filled their two-bulb apparatus with $H_2 + CO_2$ (and $H_2 + SO_2$) and heated one bulb, which became enriched with hydrogen by (2–3)%. This method has been widely used, with modifications for accurate analysis, since the separation is small, and a detailed description of various two-bulb devices has been given by Taylor (1991). This reference also describes the Trennschaukel and thermal-diffusion column apparatus, which are usually employed to magnify the effects.

6. THERMAL DIFFUSIVITY

The thermal diffusivity a is defined as $\lambda/\rho C_P$, that is, the ratio of the thermal conductivity λ to the product of density ρ and isobaric molar heat capacity C_P. Values for thermal diffusivity have been determined from measurements of thermal conductivity combined with calculations of density and heat capacity from accurate equations of state. They can also be determined by the technique of dynamic light scattering, which gives thermal diffusivity by analysis of the frequency spectrum of the light scattered from a gas by local statistical temperature fluctuations in the absence of any applied gradient. The signal is greater in a gas close to the critical temperature, but recently the method has been applied at temperatures further away from the critical temperature by Liepertz (1988) and by Kruppa *et al.* (1988). The principle of the method is as follows (Kraft and Leipertz, 1994). When laser light is incident on a pure fluid at equilibrium, it is scattered by hydrodynamic modes in all directions. The spectrum of the scattered light consists of three lines. There is an unshifted Rayleigh line resulting from entropy (temperature) fluctuations, and two symmetrically shifted Brillouin lines caused by pressure fluctuations. The spectral linewidths depend on the scattering vector q_{sv}, and on the thermal diffusivity, in the case of the Rayleigh line. For small observation angles Θ, q_{sv} is given in terms of the laser wavelength λ_1 by the relation

$$q_{sv} = 2\pi \sin\Theta/\lambda_1. \tag{42}$$

The Rayleigh linewidth is given by aq^2, from which the thermal diffusivity is calculated. In view of the narrowness of the lines, dynamic light scattering or photocorrelation spectroscopy is used to determine the linewidth. Full experimental details are given in references in the article by Kraft and Leipertz (1994). As an indication of the values for the property, their results for refrigerant R152 vapor along the saturation line decrease from 10.2×10^{-8} m^2 s^{-1} at 86.9 K to 0.49×10^{-8} m^2 s^{-1} at 112.7 K.

7. THERMAL TRANSPIRATION

Under the conditions for thermal-diffusion measurement (see above), where two bulbs containing a gas mixture at different temperatures are joined by a tube, there is unlikely to be any pressure difference set up. If, however, the tube is replaced by one, or more, capillary tubes or a porous membrane or plate, then a pressure difference results whether the bulbs are filled with a gas mixture or a pure gas. This phenomenon is termed thermal transpiration. It is important in the investigation of gas–surface interactions, in the determination of surface diffusion of adsorbed molecules, especially for flow through porous media, and for the evaluation of the translational part of the thermal conductivity, and other quantities required for a complete description of the thermal conductivity of polyatomic molecular gases.

A summary of the experimental methods employed to measure the pressure difference ΔP (the "thermomolecular pressure difference") and the theoretical evaluation of parameters in a kinetic theory description have been given by Millat (1991).

GLOSSARY

Calorimeter: An instrument for measuring heat changes.

Critical Temperature: The highest temperature at which a substance can exist in the liquid state.

Intermolecular Potential Energy Function: A representation of the dependence of the potential energy of a pair of molecules on their separation (and relative orientation).

Inversion Temperature: The temperature at which Joule–Thomson expansion produces no temperature change in a real gas.

Isobaric Heat Capacity: The amount of heat to raise the temperature of a substance by one degree at constant pressure.

Isochoric Heat Capacity: The amount of heat to raise the temperature of a substance by one degree at constant volume.

Joule–Thomson Effect: The temperature change that is observed when a real gas passes from a constant-pressure region through a throttle to a region of lower constant pressure.

Thermal Conductivity: The heat flux through unit area per unit temperature gradient.

Thermal Diffusion: The partial separation of an initially uniform gas mixture when it is subjected to a temperature gradient.

Thermal Diffusivity: The ratio of thermal conductivity to the product of density and molar heat capacity at constant pressure.

Thermal Transpiration: The process whereby a temperature gradient between two bulbs connected by capillaries and containing a gas, or gas mixture, results in a pressure developing.

van der Waals Equation: An equation that relates gas pressure, molar volume, and temperature and takes into account the finite size of molecules and their attraction.

INTRODUCTION

Electrons may be released from metals by several mechanisms: by heating, by application of a high electric field, by bombardment with photons or charged particles, or by a combination of these. Thermionic emission is provoked by heating the metal, to temperatures of the order of 2500 °C for tungsten or about 1100–1700 °C for lanthanum hexaboride, the most commonly used filament materials. The energy thus furnished to free electrons inside the metal enables them to pass over the potential barrier at the surface, which confines them to the interior at lower temperatures. In practice, an electric field is often present outside the metal. When this field is strong enough to lower the potential barrier but not sufficient to cause electrons to tunnel through it, we speak of Schottky emission.

Thermionic emission is widely used to produce the electron beams needed in cathode-ray tubes, x-ray tubes, and electron microscopes. The last are now capable of achieving resolutions of a few ångströms (1 Å = 100 pm = 0.1 nm), though for the very highest resolution, field emission (see FIELD EMISSION AND FIELD IONIZATION) is preferable. Thermionic emission is characterized by the total current produced, by the current density, and by the current density per unit solid angle, which is known as the brightness (measured in A m^{-2} sr^{-1}). This is closely analogous to, but not identical with, the radiant intensity of light sources, which is measured in W sr^{-1}. Other important characteristics of thermionic sources are the angular and energy distributions of the electrons.

1. PRINCIPLES

1.1 The Physics of Thermionic Emission

Thermionic emission is excited by heating a metal, but few metals begin to emit significantly before melting. In practice, only tungsten and certain borides, notably lanthanum hexaboride (LaB_6) and cerium hexaboride (CeB_6), are employed. The most robust is tungsten, the melting point of which is about 3380 °C; the working temperature of tungsten cathodes, T_c, is typically of the order of 2500 °C. At this temperature, tungsten slowly evaporates, limiting the cathode lifetime to between 12 and 20 h. The mean lifetime decreases rapidly with temperature, from some 200 h at 2200 °C to a mere 5 h at 2600 °C. Lanthanum hexaboride emits at a lower temperature—working values are 1100–1700 °C—thanks to its significantly lower work function ϕ_W (for LaB_6, ϕ_W = 2.6 eV, while for tungsten, ϕ_W = 4.5 eV), but a much better vacuum is required to protect the filament from bombardment by positively charged stray ions. For tungsten, a vacuum pressure

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

of 1–10 mPa is sufficient, whereas LaB_6 requires 10–100 μPa. Cerium hexaboride has been found to be superior to lanthanum hexaboride in some respects (Christman *et al.*, 1991) and is now available commercially. The work function of clean CeB_6 is very close to that of LaB_6, but the former can be much less volatile and hence have a longer lifetime. At a temperature of about 1480 °C, the material loss rate for LaB_6 is about four times that of CeB_6; at 1530 °C, the ratio has fallen to two, and at 1580 °C, the rates are about the same. In addition, CeB_6 is more resistant to contamination by carbon than LaB_6, an important property since such contamination leads to an increase in the work function and hence to deterioration of the emissive characteristics.

The theory of electron emission from metals resulting from thermal motion of the conduction electrons is based on a simple model describing the confinement of these electrons within the conductor, introduced by Sommerfeld (1928; see Sommerfeld and Bethe, 1933). The metal is treated as a box, inside which the potential is uniform, and at low temperature, the electrons fill the lowest-energy one-particle states up to a level known as the Fermi level. At higher temperatures, the energy (E) of the electrons is governed by the Fermi–Dirac distribution

$$f(E,T) = \frac{1}{1 + \exp\{(E - \phi_F)/kT\}}, \qquad (1)$$

in which k is Boltzmann's constant ($k = 1.38 \times 10^{-23}$ J/K) and ϕ_F is the Fermi energy level, at which $f(\phi_F,T) = \frac{1}{2}$ for all T (Fig. 1).

The various quantities that characterize the emission may be calculated with the aid of the function $f(E,T)$ together with a transmission coefficient $D(\mathbf{r},\mathbf{p})$; the latter denotes the ratio of the wave-mechanical intensity after and before passage through the barrier, where $\mathbf{r}$ and $\mathbf{p}$ denote position and momentum, respectively. For example, the electron charge density is given by

$$\rho(\mathbf{r}) = -\frac{2e}{h^3}\iiint f(E,T)D(\mathbf{r},\mathbf{p})d^3p \qquad (2)$$

where $-e$ is the charge on the electron ($e = 1.6 \times 10^{-19}$ C) and h is Planck's constant ($h = 6.62 \times 10^{-34}$ J·s). More important, the current-density vector $\mathbf{j}$ is given by

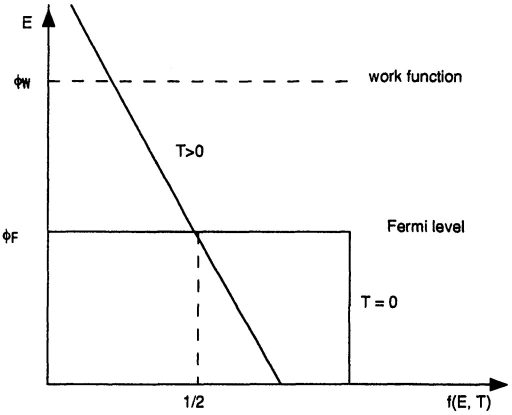

FIG. 1. The Fermi–Dirac distribution, shown as E vs $f(E,T)$ for $T = 0$ and a nonvanishing temperature. Note that $f(E,T) = \frac{1}{2}$ for all T at the Fermi energy level ϕ_F.

$$\mathbf{j}(\mathbf{r}) = \frac{2e}{mh^3}\iiint f(E,T)\mathbf{p}D(\mathbf{r},\mathbf{p})d^3p. \qquad (3)$$

We shall see in the next section how practical expressions for the quantities that describe real electron sources can be derived from these simple formulas.

1.2 Plane Barriers

The emitter in an electron gun usually consists of a hairpin-shaped filament, but only a small zone close to the tip emits significantly. It is hence a reasonable first approximation to neglect the curvature of the emissive area and consider transmission of electrons through a plane barrier. The potential barrier can then be represented by a function $V(z)$ of the coordinate perpendicular to the barrier, which we denote by z (Fig. 2). Conservation of energy then tells us that

$$\begin{aligned}(1/2m)(p_x^2 + p_y^2) &= \text{const.} = U_t,\\ (1/2m)p_z^2 + V(z) &= \text{const.} = U_n,\end{aligned} \qquad (4)$$

and of course $U_t + U_n = E = \text{const.}$ After a simple calculation, we find that the current density is given by

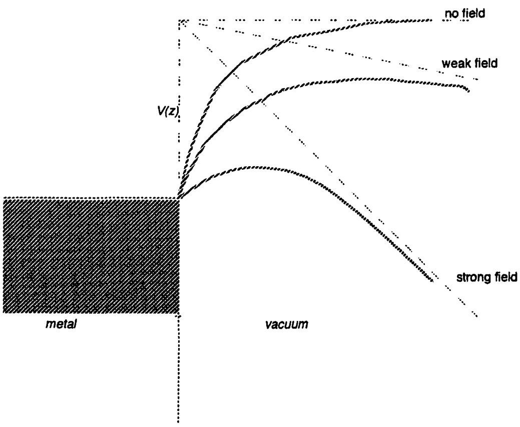

FIG. 2. Potential energy diagram for pure thermionic emission (no field), Schottky emission (weak field), and field emission (strong field). Note the lowering of the potential barrier in the weak-field case. (After Reimer, 1993, courtesy of Springer Verlag.)

$$j_z = \frac{4\pi mekT}{h^3} \times \int_{-\infty}^{\infty} \ln\left(1 + \exp\frac{\phi_F - U_n}{kT}\right) D(U_n)dU_n \qquad (5)$$

in the direction normal to the surface.

If it is permissible to neglect any electric field outside the filament, the potential function $V(z)$ will have the form of a step function:

$$V(z) = \begin{cases} -(\phi_F + \phi_W) & \text{for } z < 0, \\ 0 & \text{for } z \geq 0, \end{cases} \qquad (6)$$

in which the work function ϕ_W is a property of the material of which the cathode is composed. It is slightly temperature dependent. Electrons can escape only if $U_n \geq 0$, which implies that the transmission factor $D(U_n)$ is zero if $U_n < 0$ and unity if $U_n \geq 0$. The unit term in $f(E,T)$ is here negligible compared with the exponential. Because of the choice of zero of potential adopted in Eq. (6), the term $(E - \phi_F)$ in Eq. (1), where the origin of E was left arbitrary, becomes $(E + \phi_W)$, and we may hence write

$$f(E,T) = \exp\left(-\frac{E + \phi_W}{kT}\right). \qquad (7)$$

The current density is given by

$$j_s = A(kT)^2 \exp(-\phi_W/kT) \qquad (8)$$

in which

$$A = 4\pi me/h^3, \quad Ak^2 = 120\ \mathrm{A\,K^{-2}\,cm^{-2}}. \qquad (9)$$

Equation (8) is the Richardson–Dushman formula for the saturation current density, and we have written j_s rather than j_z to emphasize that this is an upper limit.

This formula was in fact originally obtained by Richardson (1902) on the basis of thermodynamic reasoning and the Drude model of electron conduction of 1900. Dushman (1923) later obtained the same expression by quantum-mechanical arguments and established the expression for A (apart from a factor 2, omitted since the notion of spin had not yet been introduced). The theory was later completed by Fowler (1928) and Nordheim (1929). In practice, the value of A may be appreciably lower than this theoretical value.

We can now calculate the various emission characteristics. The element of current density, d^3j, takes the form

$$d^3j = S(E,T)\cos\theta dE d\Omega \qquad (10)$$

in which the function

$$S(E,T) = \frac{1}{\pi} AE \exp\left(-\frac{E + \phi_W}{kT}\right) \qquad (11)$$

is known as the spectral radiance. The angle θ measures the direction of emission relative to the normal to the barrier (the z axis). $d\Omega$ is the element of solid angle, $d\Omega = \sin\theta d\theta d\varphi$, and φ is an azimuthal coordinate,

$$p_x = (2mE)^{1/2}\sin\theta\cos\varphi,$$
$$p_y = (2mE)^{1/2}\sin\theta\sin\varphi.$$

The total energy distribution of the current is given by integrating over all possible emission angles ($0 \leq \varphi \leq 2\pi$ and $0 \leq \theta \leq \pi/2$):

$$dj = AE\exp\left(-\frac{E + \phi_W}{kT}\right)dE, \qquad (12)$$

and a final integration over E again gives us (8). The mean energy is easily found to be

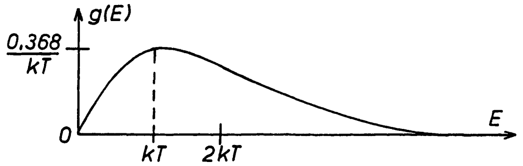

FIG. 3. The normalized current density as a function of energy. The long tail of the spectrum is striking. (After Reimer, 1993, courtesy of Springer Verlag.)

$\langle E\rangle = 2kT$ with standard deviation $\Delta E = kT\sqrt{2}$.

It is usual to define a normalized current-density distribution, $g(E)$, as follows:

$$g(E)dE = dj/j_s, \tag{13}$$

so that

$$g(E) = \frac{E}{(kT)^2}\exp\left(-\frac{E}{kT}\right). \tag{14}$$

This function is shown schematically in Fig. 3, where the most probable energy, $E_m = kT$, is indicated. The long tail of high-energy electrons is usually undesirable since for many applications, a small energy width is essential; energy-loss spectroscopy and high-resolution electron microscopy are examples of situations in which such a wide energy spread cannot be tolerated.

The full width at half-height is given by $\delta E = 2.45kT_c$; for $T_c = 2500$ °C, therefore, this energy width is about 0.5 eV. In practice, the energy width is increased by the Boersch effect (Boersch, 1954), caused by electron–electron interactions in regions where the current density is high. As a result, δE is typically of the order of 2 eV for thermionic guns. These interactions are extensively discussed by Rose and Spehr (1983) and Jansen (1991).

The angular emission distribution is obtained by integrating (10) over energy, which gives

$$\tilde{B}(\theta) = \frac{dj}{d\Omega} = \frac{j_s\cos\theta}{\pi}. \tag{15}$$

This bears a close resemblance to Lambert's cosine law for light sources. Like that law, it is obtained only if the transmission through the barrier is independent of emission direction.

The other parameter of interest in characterizing gun performance is the brightness (*Richtstrahlwert*). This quantity (B) measures the current density per unit solid angle:

$$B = j/\pi\theta_{\max}^2, \tag{16}$$

in which $\theta_{\max}$ is the largest angle of emission; B is given to a good approximation by

$$B = j_s E/\pi kT_c. \tag{17}$$

Typical values are listed in Table 1. The

Table 1. Typical values of the characteristics of thermionic and field-emission cathodes.

	Thermionic emission from tungsten (hairpin filament)	Thermionic emission from LaB$_6$	Field emission from tungsten
ϕ_W (eV)	4.5	2.7	4.5
Ak^2 (A cm^{-2} K^{-2})	75–120	30	—
js (A cm^{-2})	1–5	25–50	10^4–10^6
Maximum current emitted (μA)	10–100	40	1–10

Vacuum (mPa)	1–10	10^{-2}–1	10^{-5}–10^{-4}

brightness is of great importance because it can be shown to be invariant: the brightness of an electron beam remains constant as it traverses lenses and diaphragms (stops). This invariant property is strictly true only for the generalized brightness function (see Hawkes and Kasper, 1989, Chap. 47, for full discussion, and Sec. 4 below) but can be regarded as valid for the mean brightness B. An important consequence is that, for a given brightness, the current density j is proportional to $\theta^2_{\max}$ [Eq. (16)]. In some practical applications, such as low-angle electron diffraction and the electron microscope study of magnetic specimens, the angular spread of the beam must imperatively be kept very small, with the result that the current density is low and long exposure times are necessary. For this reason, field-emission sources, which have much higher brightness, are to be preferred for such applications. Such sources are also indispensable when a very small probe is required in scanning microscopes to keep the scan time per frame within reasonable bounds. The replacement of thermionic guns by field-emission guns has opened up a new range of studies to scanning electron microscopes (see Reimer, 1985, or Joy, 1985, Tuggle *et al.*, 1985, and Orloff, 1985). The development of field-emission guns was the essential step in the development of the scanning transmission electron microscope by A. V. Crewe (Crewe, 1973).

1.3 Schottky Emission

We have assumed above that any electric field in the space outside the emissive filament is negligible. In practice, the electrons are accelerated immediately after emission to the required energy by applying the appropriate voltages to the anodes of the electron gun, as discussed below. The filament is hence usually not in field-free space, and, in order to estimate its emission characteristics realistically, the surrounding field must not be neglected. The simplest way of accounting for such fields is to replace the work function ϕ_W in the Richardson–Dushman equation (8) by a smaller value,

$$\phi_S = \phi_W - (e^3F/4\pi\epsilon_0)^{1/2}, \tag{18}$$

where F denotes the electric-field strength at the emitter surface. The emission is thereby increased by virtue of the "Schottky effect." The terms "Schottky emission" and "Schottky effect" are reserved for the current increase in the thermionic emission regime: the potential barrier is lowered and narrowed, but the electrons continue to escape thanks to their thermal energy. The electric-field strength is far too low to generate any perceptible current by tunneling. In practice, however, guns are frequently operated in an intermediate regime, in which the electric field is high enough to provoke some tunneling, though far less than in the case of true field emission. This situation is known as "extended Schottky emission." It can be modeled very simply by using a more complicated model for $D(U_n)$; instead of setting the latter equal to zero or unity, we write

$$D(U_n) = \frac{1}{1 + \exp[(\phi_m - U_n)/c]}, \tag{19}$$

in which

$$c = \frac{\mathrm{tr}(4\pi\epsilon_0 eF^3)^{1/4}}{\pi m^{1/2}} \tag{20}$$

and ϕ_m is the potential maximum at the barrier. We then find that

$$j_s = A(kT)^2 \exp\left(-\frac{\phi_s}{kT}\right)\frac{\pi q}{\sin\pi q}, \tag{21}$$

in which

$$q = c/kT \geq 0.7. \tag{22}$$

The standard deviation of the energy distribution is now

$$\Delta E = \sqrt{2}kT\,\pi q/\sin\pi q. \tag{23}$$

Extended Schottky emission is typically obtained from a zirconiated tungsten filament, ZrO/W; the absorbed zirconium oxide lowers the work function of the tungsten to about 2.7 eV, and a suitable working temperature is 1500 °C. We give more details in Sec. 2.

2. DEVICES

Thermionic emission has been used in a host of devices, some of which have declined in importance, notably the vacuum tubes or "valves" that have been replaced by transistors so completely that older equipment must often be completely replaced when a vacuum tube fails for want of the spare part. Emitters have been designed with large surface areas to provide broad beams; dispenser cathodes, in which an active material such as barium diffuses through a sintered, porous form of a base metal, typically tungsten or molybdenum, provide the high current densities required in some applications, in microwave tubes for example. The three-electrode or triode gun remains of great importance in many instruments, and we have therefore chosen to describe this example in detail here. The three electrodes are the emissive filament, or cathode; the control electrode or "grid," usually known as the wehnelt; and the anode. Such guns, especially those using LaB_6 emitters, are under further development in the expanding field of electron nanolithography.

2.1 Typical Triode Electron-Gun Properties

Conventional thermionic guns consist of three electrodes:

1. the filament, which has the form of a hairpin or a sharp point supported on a V-shaped support, through which the heating current passes;
2. the wehnelt or control electrode (Wehnelt, 1903; Wehnelt and Jentsch, 1909), the potential of which is negative relative to that of the filament; and
3. the anode, at high positive potential, which accelerates the electrons to the desired "accelerating voltage," which can reach 200 kV;

beyond this, extra electrodes are required and we enter the realm of particle accelerators. The behavior of triode guns is determined by the geometry of the three electrodes and the values of the applied voltages. A first distinction is between short-focus and telefocus guns. In the former, the electrons emitted by the filament are rapidly brought to a focus or crossover zone, whereas in telefocus guns, the filament may well protrude beyond the wehnelt, which is often conical, and the electrons are brought to a focus far from the gun (Fig. 4).

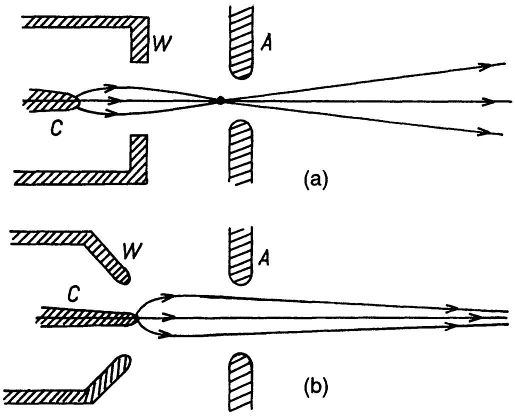

FIG. 4. Schematic diagram showing typical rays in (a) a short-focus and (b) a long-focus or Fernfokus gun. (After Hawkes and Kasper, 1989, courtesy of Academic Press.) C, cathode; W, wehnelt; A, anode.

The principal features of a short-focus gun are shown schematically in Fig. 5. Pencils of rays are seen to emerge from various points on the filament tip. They are brought to a focus in a broad region, the narrowest

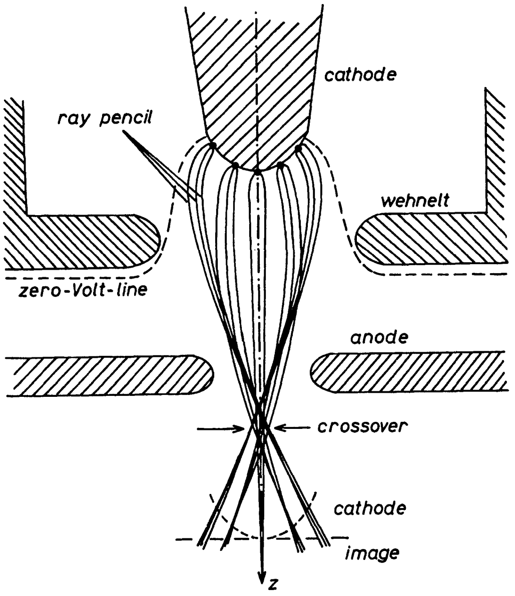

FIG. 5. Crossover formation in a conventional triode gun. The zero-volt line limits the zone that contributes to the beam. The crossover and not the cathode image is the effective source for any subsequent lenses. (After Hawkes and Kasper, 1989, courtesy of Academic Press.)

part of which is known as the crossover. An important element is the "zero-volt line," which delimits the zone on the filament surface from which electrons will be emitted. We shall see below that the position of this line moves across the filament as the wehnelt bias is altered; if it is brought to the axis, no electrons are emitted and the corresponding voltage is the cutoff bias.

It is usual to supply the bias not from an external voltage source but by introducing a large resistor (of resistance $R_W = 1 - 10$ MΩ) in the high-voltage supply (Fig. 6). In this situation, the current emitted saturates at a value determined by R_W; this saturation has often been attributed to the buildup of space charge in front of the cathode. This does indeed occur but is not the cause of the saturation, which is a consequence of the behavior of the circuit containing the large resistor; space charge has a harmful effect only at high filament temperatures.

The detailed behavior of short-focus guns may be understood qualitatively, and to a limited extent quantitatively, with the aid of a model that has been extensively studied by Lauer (reviewed in Lauer, 1982). In this, the electric field in the vicinity of the emitting area of the filament is assumed to have spherical symmetry, which is very plausible for both pointed and hairpin tips. Between the wehnelt and the anode, the electric field is taken to be uniform, at least close to the optic axis. Careful examination of this model shows that the pencils of electron rays emerging from the cathode appear to come from a virtual cathode, smaller in radius than the real tip; if one pursues the rays further back toward the center of the cathode, they are found to define a circular zone, the entrance pupil of the gun (Fig. 7). This entrance pupil is conjugate to the circle of least confusion outside the gun if the crossover is formed beyond the anode, and this exit pupil and the crossover then coincide. If, however, the crossover is formed between the wehnelt and the anode, as is often the case, the exit pupil will be virtual. In both cases, the effective source for further calculations, of illumination conditions in microscopes for example, is the crossover as seen from the space beyond the anode.

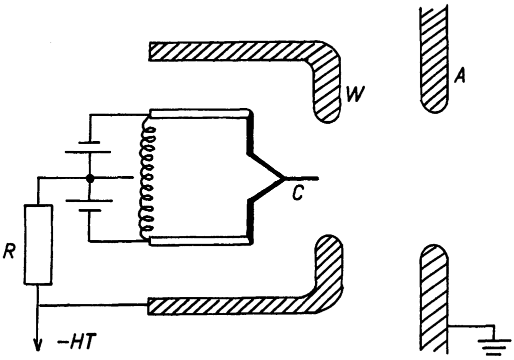

FIG. 6. The autobias circuit of a triode gun. The resistor *R*, of a few megohms resistance, provides the wehnelt bias, and the associated feedback stabilizes the emission. (After Hawkes and Kasper, 1989, courtesy of Academic Press.)

We have seen that the voltage applied to the wehnelt determines the position of the zero equipotential at the filament and hence the size of the emitting area. Figure 8 shows three situations, in which the wehnelt bias is progressively more negative from (a) to (c). The zero equipotential is seen to move toward the optic axis, and a small further increase will cut off the emission altogether. The emissive area is not the only parameter affected by the wehnelt voltage, however. As the wehnelt bias is made less negative, the structure of the beam changes in a characteristic way (Fig. 9). Initially a full beam, close to cutoff, the beam becomes hollow, in the sense that the current density is higher around the periphery than at the center. A further (positive) increase renders the beam compact again, then a particularly narrow waist is formed (the telefocus mode), after which the beam again becomes hollow (Fig. 9). Full details are to be found in Lauer (1982).

The foregoing theory is essentially paraxial, in the sense that the quantitative predictions assume that the paraxial approximation of electron optics (see CHARGED-PARTICLE OPTICS) is applicable. In fact, the electrons may be emitted relatively far from the axis and travel at steep angles to it, for the first part of their trajectories at least, and geometric aberrations are hence to be expected. We illustrate this in Fig. 10, where effects due to the failure of the paraxial approximation are illustrated.

The filament material is commonly tungsten or thoriated tungsten. At the cost of a better vacuum, higher brightness can be ob-

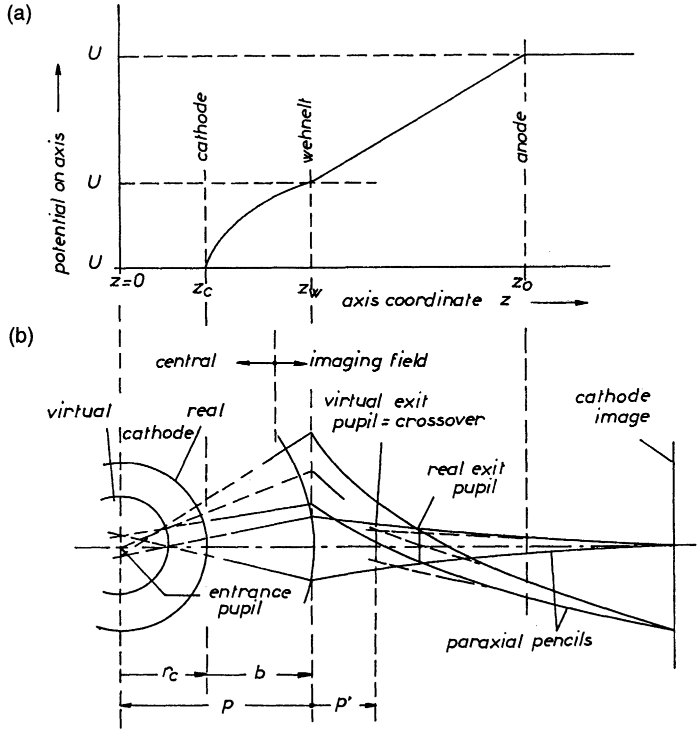

FIG. 7. Model used to study the characteristics of triode guns. The associated vocabulary is defined here. (After Hawkes and Kasper, 1989, courtesy of Academic Press.)

tained by the use of single-crystal lanthanum hexaboride cathodes. The emission characteristics are closely related to the crystal orientation, and ⟨100⟩ and ⟨346⟩ have been found suitable on both experimental and theoretical grounds for the rod axis (Table 2). The advantages of using rare-earth and alkaline-earth oxides were pointed out long ago by Lafferty (1951): the peak emission density can be high (1 A/mm^2), the lifetime can be of the order of 100 h, and the improved vacuum that is necessary is far worse than that required for field emission. The early exploitation of these oxides, LaB$_6$ in particular, which rapidly established itself as the most suitable, was hampered by the fact that indirect heating seemed to be inevitable because of the high chemical reactivity of the lanthanum hexaboride with the material on which it was supported. Once this problem had been solved (Crawford, 1979), reliable mountings emerged and direct heating became usual; some typical designs are shown schematically in Fig. 11. A modern mounting of the "mini-Vogel" type is also shown.

The emission from LaB$_6$ depends on the source geometry, of course, but above all on the shape and radius of the cathode tip. The latter is usually conical with a pointed end portion that is approximately spherical, of the order of 2–5 μm in radius. However, a better performance is obtained by forming a faceted tip (Fig. 12), the faces of which are typically (110) planes since the work function for these is low (2.6 eV); the angle of the cone is 90°. Figure 13 shows the brightness as a function of temperature for a range of tip shapes.

A significant improvement in performance can in principle be achieved by artificial limitation of the area from which electrons are emitted and by suppression of the wehnelt electrode. The calculations of Broers *et al.* (1991) suggest that the current density and brightness could be increased by more than an order of magnitude in this way.

2.2 Extended Schottky-Emission Guns

Here, the electric field at the filament is not negligible. The emissive tip protrudes beyond the wehnelt (Fig. 14) so that the anode potential exerts a direct effect on the tip. The

combined effects of heating to about 1500 °C and the application of an electric field, of the order of 0.5–1 V/nm, cause migration of surface atoms on the filament in order to achieve minimum surface free energy. A facet forms at the tip of the filament, as shown in Fig. 14 (dashed line). The properties of this geometry have been studied experimentally and by computer modeling by Tuggle and Swanson (1985). Figure 15 shows their calculated Schottky plots of current density against (applied field)$^{1/2}$ on a logarithmic-linear scale for several values of the work function. A useful comparison of these guns, true field-emission guns, and LaB_6 guns is given in a survey by Orloff (1984).

3. BRIGHTNESS

Source brightness and source coherence are extremely important in electron microscopy. In scanning instruments, a high brightness is essential if a high-resolution image is to be generated in a reasonably short time. In the traditional scanning electron microscope (SEM), it is usually sufficient to use a lanthanum hexaboride cathode, but for scanning transmission electron microscopy (STEM) and for very high-resolution SEM, field emission is the only choice. In conventional transmission electron microscopy, the image resolution is degraded by effects caused by wavelength spread, since the chromatic aberration of electron lenses is enormous, and by the size of the source. The latter may be understood by recalling that the electron microscope image is the result of scattering in the specimen and not of absorption; electrons arriving from different points on an extended source will create images at slightly different places in the image plane, and the superimposition of all these will blur the resulting overall image. Both the wavelength spread and the source size must hence be kept very small, which is equivalent to requiring the source to be highly coherent, both temporally (negligible wavelength spread) and spatially (negligible source size). In energy-loss spectroscopy, too, it is essential to maintain the energy spread of the electron-beam incident on the specimen as narrow as possible.

3.1 Definitions

The measured brightness of electron sources is inevitably a mean brightness, $\bar{B}$:

$$\bar{B} = \Delta I / \Delta a \Delta \Omega \tag{24}$$

in which ΔI is the current flowing across an area Δa into a solid angle $\Delta\Omega$. The formal theory of brightness, on the other hand, is concerned with a function, the brightness function, defined by

$$B(x,y,z,x',y') = \lim_{\Delta a \to 0} \lim_{\Delta\Omega \to 0} \left(\frac{\Delta I}{\Delta a \Delta \Omega} \right). \tag{25}$$

Here, Δa is the element of area $\Delta x \Delta y$ in the neighborhood of a point (x,y,z), and $\Delta\Omega = \Delta x' \Delta y'$ is the element of solid angle

around the direction characterized by the gradient (x',y'). The prime denotes differentiation with respect to z, the optic axis. This is essentially a paraxial definition, and this restriction led to the introduction of a *generalized* brightness function $B(\mathbf{r},\mathbf{s})$, in which $\mathbf{r}$ is the position vector (x,y,z) and $\mathbf{s}$ is a unit vector in an arbitrary direction. The element $\Delta\Omega$ is around the direction $\mathbf{s}$, and the area Δa is normal to $\mathbf{s}$.

(After Gesley and Swanson, 1984, and Swanson *et al.*, 1980.)

With the aid of this function, we can obtain an explicit expression for the brightness of thermionic sources:

$$B(\mathbf{r},\mathbf{s}) = \frac{e j_s(\mathbf{r})}{\pi k T}\, \Phi_T(1 + \epsilon \Phi_T) \qquad (26)$$

in which j_s is the saturation current calculated earlier [Eq. (8)] and $\epsilon = e/2m_0c^2$. If Φ is the accelerating voltage, then Φ_T denotes

$$\Phi_T = \Phi + kT/e. \qquad (27)$$

We see that B is independent of $\mathbf{s}$, a reminder that Lambert's law applies to thermionic sources. At the cathode surface, where by convention Φ vanishes, the brightness is just j_s/π; it is clearly the maximum value of the angular distribution function $\tilde{B}(\theta)$ of Eq. (15). Beyond the anode, and hence far from the cathode, the term Φ (of the order of tens or hundreds of kilovolts) is much larger than kT/e ($\sim$0.3 V), and the brightness is proportional to the (relativistically corrected) accelerating voltage $\Phi(1 + \epsilon\Phi)$. The quantity $B/\Phi(1 + \epsilon\Phi)$ is known as the normalized brightness.

From Eq. (25), it is seen that

$$\Delta I = B(\mathbf{r},\mathbf{s};\nu)\cos\theta \Delta a \Delta \Omega. \qquad (28)$$

In this formula, we have introduced the frequency ν to emphasize that the relation is to be understood to apply to a particular wavelength or frequency; this is not of importance in traditional radiometry but will be necessary when we come to consider the relation between the radiometric quantities and coherence. It is usual to introduce the radiant intensity J and the radiant emittance E:

$$J(\mathbf{s},\nu) = \int B \cos\theta da, \qquad (29)$$

$$E(\mathbf{r},\nu) = \int B \cos\theta d\Omega, \qquad (30)$$

so that

FIG. 11. FIG. 12. The tip shape of LaB$_6$ emitters: (a) Cone-shaped tips; several crystallographic planes (with different work functions) participate in the emission. (b) Faceted tip, only a single family of planes emit, typically (110). (After Hohn, 1985, courtesy of Scanning Microscopy International.)

$$\begin{aligned} I &= \int J(\mathbf{s},\nu)d\Omega, \\ &= \int E(\mathbf{r},\nu)da. \end{aligned} \tag{31}$$

We note in passing that when B is independent of the direction $\mathbf{s}$, then I collapses to $J_0 \cos\theta$, where J_0 is a constant for a given source: the fact that Lambert's cosine law is obeyed only when B is a function only of position and frequency is now obvious.

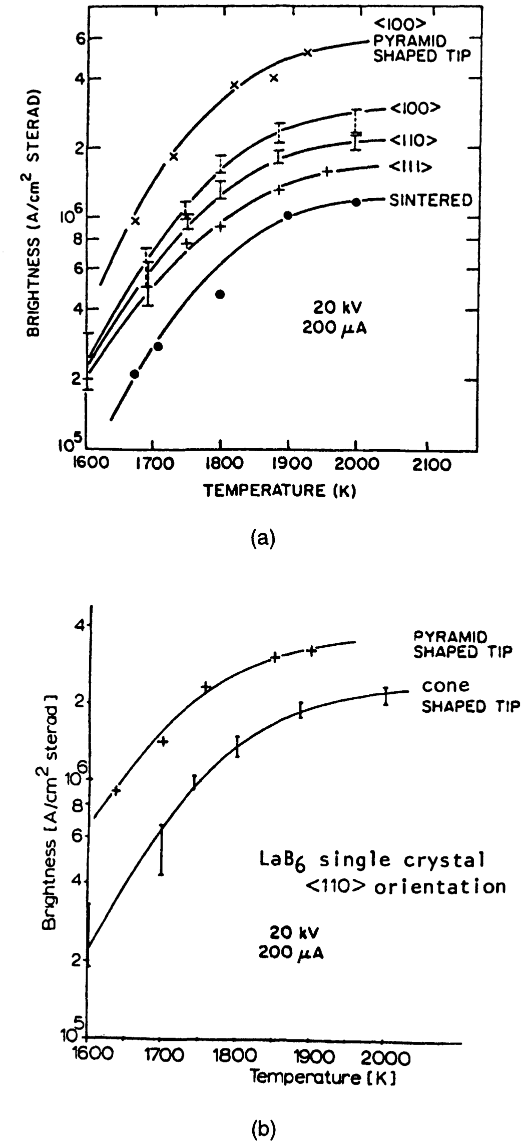

FIG. 13. Mean brightness as a function of temperature for various LaB$_6$ tips. (After Hohn, 1985, courtesy of Scanning Microscopy International.)

3.2 Coherence and Radiometry

Most of the foregoing material is based on classical mechanics, apart from the discussion of the emission process itself, where some elementary quantum mechanics was required. An important characteristic of all sources is, however, their degree of coherence, and in order to study this, we need to bring together the classical and the quantum approaches. The degree of coherence of a source, whatever its nature, is a measure of any relation between the emission from different points on the source and at different wavelengths. It is therefore expressed in terms of a correlation function, which gives a quantitative measure of this relation. It is important in practice to understand the coherence properties of the source used, in microscopy and holography in particular; in the former, the source coherence is directly re-

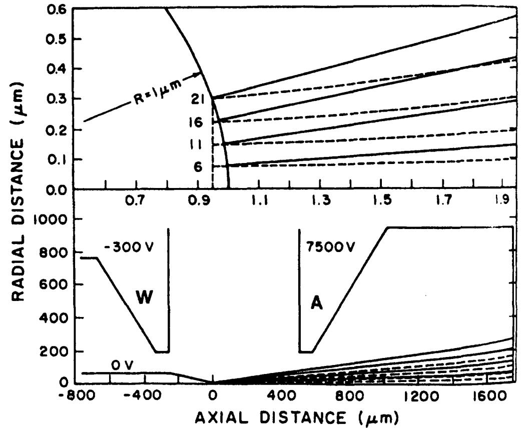

FIG. 14. Schottky emission from a ZrO/W tip. A facet forms at the tip as shown in the enlargement (above). Notice that the tip protrudes beyond the wehnelt (W) toward the anode (A). (After Tuggle and Swanson, 1985, courtesy of the American Vacuum Society.)

lated to the performance of the instrument, and in the latter, a high degree of coherence is imperative.

We shall see that coherence, brightness, and the associated radiometric quantities are intimately related. It is on this aspect of source coherence that we concentrate here.

In the practical study of coherence, it is convenient, and in almost all cases permissible, to discuss temporal coherence and spatial coherence separately. The temporal coherence of a source is determined by the range of wavelengths and hence of particle energies in the beam emitted. The spatial coherence is a measure of source size, the smallest sources being the most coherent. These are important quantities for electron microscope imaging, for the highest resolutions can be obtained only if the illumination is both temporally and spatially highly coherent. For a detailed and self-contained account of this semi-classical approach to the effect of partial coherence of electron image formation, see Chap. 66 of Hawkes and Kasper (1994). The formal theory of coherence (presented in detail in Born and Wolf, 1980, Chap. 10) is expressed in terms of the mutual coherence function, which is just the cross-correlation between the values of electron wave function (in electron optics) or of the analytic signal associated with, for example, the electric-field vector (in light optics) at two points; it is denoted by $\Gamma(\mathbf{r}_1,\mathbf{r}_2;\tau)$, in which $\mathbf{r}_1$ and $\mathbf{r}_2$ are the coordinates of two points and τ is the difference between the times of arrival of the wave fronts at some other point (see Born and Wolf, 1980, or Hawkes and Kasper, 1994, Chap. 78 for extensive explanation). The temporal Fourier transform of the mutual coherence function plays an important role in the following argument. It is essentially the (temporal) spectrum of $\Gamma(\mathbf{r}_1,\mathbf{r}_2;\tau)$. We write

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2;\tau) = \int_0^\infty W(\mathbf{r}_1,\mathbf{r}_2;\nu)\exp(-2\pi i\nu\tau)d\nu \tag{32}$$

and refer to W as the cross-spectral density.

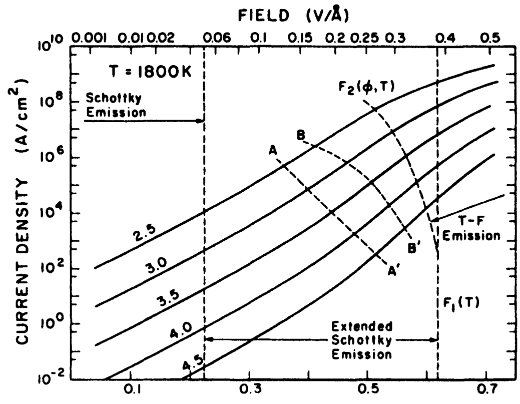

FIG. 15. Current emitted vs electric field at the tip for various regimes, for ZrO/W. (After Tuggle and Swanson, 1985, courtesy of the American Vacuum Society.)

The spatial spectrum of $\Gamma(\mathbf{r}_1,\mathbf{r}_2;\tau)$ is also of central importance. It is convenient to introduce the frequency ν rather than the time τ in this function, $A(\mathbf{s}_1,\mathbf{s}_2;\nu)$:

$$W(\mathbf{r}_1,\mathbf{r}_2;\nu) = \int_{-\infty}^{\infty} A(\mathbf{s}_1,\mathbf{s}_2;\nu)\exp\left\{\frac{2\pi i}{\lambda}(\mathbf{s}_1\cdot\mathbf{x}_1 + \sigma_1 z_1 - \mathbf{s}_2\cdot\mathbf{x}_2 - \sigma_2 z_2)\right\}d^3s_1d^3s_2, \tag{33}$$

where $\sigma^2 = 1 - \mathbf{s}\cdot\mathbf{s}$ and $\mathbf{r} = (\mathbf{x},z)$. It can be shown straightforwardly that, far from the source, the current J is given by

$$J(\mathbf{r}) = \Gamma(\mathbf{r},\mathbf{r};0) \sim \int\left(\frac{\lambda}{r}\right)^2\cos^2\theta A(\mathbf{s},\mathbf{s};\nu)d\nu \tag{34}$$

(the symbol $\sim$ denotes "tends asymptotically to").

But a change of coordinates

$$\begin{aligned}\mathbf{r}' &= \mathbf{r}_1 - \mathbf{r}_2,\\ \mathbf{r} &= \tfrac{1}{2}(\mathbf{r}_1 + \mathbf{r}_2),\end{aligned} \tag{35}$$

enables us to write

$$A(\mathbf{s},\mathbf{s};\nu) = \frac{1}{\lambda^2 \cos\theta}\int b(\mathbf{r},\mathbf{s};\nu)d^3r, \tag{36}$$

where $\mathbf{r}$ is now assumed to lie in the source plane and b denotes

$$\begin{aligned} b(\mathbf{r},\mathbf{s};\nu) = \frac{\cos\theta}{\lambda^2}\int W\left(\frac{\mathbf{r}+\mathbf{r}'}{2}, \frac{\mathbf{r}-\mathbf{r}'}{2}; \nu\right)\\ \times \exp\left(-\frac{2\pi}{\lambda}\mathbf{r}'\cdot\mathbf{s}\right)d^3r'. \end{aligned} \tag{37}$$

The far-field intensity is hence

$$I = \int_{2\pi} d\Omega \cos\theta \int b(\mathbf{r},\mathbf{s};\nu)d^3r, \tag{38}$$

and the function b plays exactly the same role in the radiometric formulas as the "incoherent" brightness B [Eq. (16)]. It seems therefore that the "generalized radiance" b, introduced tentatively by Walther (1968) and studied thoroughly by Marchand and Wolf (1974), is the partially coherent counterpart of the incoherent brightness B.

Unfortunately, the function b proves to possess certain properties incompatible with the intuitive notion of brightness. It is certainly real—b and its complex conjugate are identical—but it is not necessarily positive, even though the integral over any real source area is positive. It is as though a few electrons in a beam from a partially coherent source might be found to be traveling in the wrong direction! Worse, it may fail to vanish in the source plane outside the emitting area. Both of these unacceptable features vanish for a certain class of sources, known as *quasihomogeneous sources.* For these, the cross-spectral density $W(\mathbf{r}_1,\mathbf{r}_2;\nu)$ can be written in separated form:

$$W(\mathbf{r}_1,\mathbf{r}_2;\nu) = I\left(\frac{\mathbf{r}_1+\mathbf{r}_2}{2}, \nu\right)m(\mathbf{r}_1 - \mathbf{r}_2; \nu). \tag{39}$$

Here I is a *slow* function of its spatial argument whereas m is a *fast* function of $\mathbf{r}_1 - \mathbf{r}_2$. The brightness b now separates into two factors, one of which is essentially I at the source while the other is the (spatial) spectrum of m. The brightness is now never negative and behaves in all respects like a classical radiometric brightness.

GLOSSARY

Brightness: Quantity that measures the current density emitted by a source per unit solid angle.

Conventional Transmission Electron Microscope: Electron microscope in which a broad beam of electrons illuminates the specimen and lenses are used to enlarge the resulting image in the plane of recording or observation.

Cross-spectral Density: Temporal Fourier transform of the mutual coherence function.

Electron Gun: A structure typically consisting of three electrodes: an emitter (cathode), a control electrode (wehnelt), and an accelerating electrode (anode), capable of providing an electron beam.

Fermi Level: The maximum energy level of electrons in a metal at absolute zero temperature; it is the energy at which the Fermi–Dirac distribution reaches the value 0.5 for all temperatures.

Mutual Coherence Function: Cross-correlation function of the wave functions at two points.

Scanning Electron Microscope: Electron microscope in which the illuminating beam is focused to a small spot on a massive specimen; deflection fields cause the focused spot to explore the specimen, thereby giving rise to various signals (backscattered electron current, secondary electron current, x rays, cathodoluminescence, electron-beam–induced current), which are collected and used to form images on monitors scanned in synchronism.

Scanning Transmission Electron Microscope: Electron microscope in which the illuminating beam is focused to a small spot on a thin specimen and the transmitted beam is collected on various detectors placed downstream from the specimen; the signals obtained are displayed on monitors scanned in synchronism.

Work Function: Smallest energy required to take an electron from inside a metal to just outside it.

INTRODUCTION

We usually think of a sound wave in a fluid (gas or liquid) as consisting of coupled pressure and displacement oscillations, but temperature oscillations also occur. Near a solid surface, the combination of these temperature oscillations with the pressure and displacement oscillations produces a rich variety of "thermoacoustic" effects.

Although thermoacoustic effects are too small to be readily noticed in everyday life, they can be harnessed to produce powerful refrigerators and heat engines, using intense acoustic standing waves in suitable geometries. Whereas typical engines and refrigerators have crankshaft-coupled pistons or rotating turbines, standing-wave thermoacoustic engines and refrigerators have no moving parts, or have flexing moving parts (as in a loudspeaker) with no sliding seals. Such thermoacoustic systems appear attractive because of their elegance, reliability, and low cost, in spite of only modest efficiency.

While standing-wave thermoacoustic systems have matured only recently, Stirling engines and refrigerators have a long, rich history. Recently, new insights have resulted from applying a thermoacoustics viewpoint to Stirling systems, treating them as traveling-wave thermoacoustic systems. Although Stirling systems are usually regarded as a separate subject, we will include some discussion of thermoacoustic aspects of Stirling systems here.

To be consistent with the article HEAT ENGINES AND REFRIGERATORS, we will adopt the convention that "heat engines" (sometimes called prime movers) are thermodynamic devices that convert heat to work and that "refrigerators" (including heat pumps) are devices that use work to transfer heat from low temperature to high temperature.

1. SIMPLE EXAMPLES

The Sondhauss tube, shown in Fig. 1(a), is the earliest reported thermoacoustic engine. Over 100 years ago, glassblowers noticed that when a small, hot glass bulb was being blown on a cool glass tubular stem, the stem tip sometimes radiated sound. Early investigators understood that the sound was generated by oscillatory thermal expansion and contraction of the air in the tube, which in turn was due to acoustic motion of the air toward and away from the hot

FIG. 1. Examples of thermoacoustic engines and refrigerators. (a) Sondhauss tube, the earliest thermoacoustic engine. (b) A heat-driven refrigerator, comprising a thermoacoustic engine and a thermoacoustic refrigerator sharing the same standing wave. (c) Orifice pulse-tube refrigerator, a traveling-wave system.

end of the tube. The Sondhauss tube was a heat engine, converting heat into mechanical work in the form of sound. It utilized a predominantly standing acoustic wave, with the bulb and stem forming a resonator.

In the 1960s it was realized by Carter *et al.* (1962) that the performance of such devices could be greatly enhanced by inclusion of proper heat-exchange components, especially what is now known as the "stack." The heat-driven thermoacoustic refrigerator shown in Fig. 1(b) illustrates these components, as well as the heat pumping/refrigerating function in thermoacoustics. The refrigerator's resonator consists of a cylindrical tube, closed at the top and opening at the bottom into a spherical bulb. Near the top is the heat-engine stack, which is an array of thin, uniformly spaced solid plates aligned parallel to the tube axis. Above the stack is the hot heat exchanger, consisting of well-spaced conducting strips; below the stack, a similar set of strips forms a room-temperature heat exchanger, cooled by circulating water. This is the heat-engine assembly, producing acoustic work from heat: When enough heat is supplied to the hot heat exchanger by an external heat source, the gas oscillates spontaneously, maintaining a high-amplitude acoustic standing wave in the gas.

Just below the heat engine in Fig. 1(b), another stack and pair of heat exchangers function as a refrigerator, which is driven by the acoustic work generated in the heat-engine stack. The refrigerator stack is identical to the engine stack, and its upper, room-temperature heat exchanger and lower, cold heat exchanger are made from copper strips. When the hot heat-exchanger temperature is high enough that the gas oscillates, the cold heat exchanger cools and absorbs an external heat load, as heat is pumped thermoacoustically up the refrigerator stack, from the cold heat exchanger to the room-temperature heat exchanger. Hence, the whole system functions as a refrigerator, with no moving parts, powered by heat delivered to the hot heat exchanger at high temperature.

Ceperley (1979, 1985) has discussed thermoacoustic engines and refrigerators using traveling waves. One example of such a refrigerator is the orifice pulse-tube refrigerator (Radebaugh, 1990) shown in Fig. 1(c). In this refrigerator, an oscillating piston functions as a source of acoustic work at one end of the refrigerator, and an orifice and tank act as a sink of acoustic work at the other end. Between them, a regenerator, heat exchangers, and an open tube are filled with gas. The regenerator and adjacent heat exchangers function just like those of a Stirling-cycle refrigerator and are the heart of this refrigerator. The oscillatory motion of the piston at the top and the orifice and tank at the bottom cause the gas to experience pressure oscillations and to move with the correct amplitude and phase relative to the pressure oscillations. The gas is thereby carried through four steps: compression, displacement downward, expansion, and displacement upward. The expansion cools the gas at the cold end of the pulse tube adiabatically, so that it can absorb heat in the cold heat exchanger when it is displaced upward. The so-called "pulse tube" itself functions as a temperature buffer space between the cold heat exchanger and the warm orifice; its length is larger than the gas displacement, so that the part of the gas that stays in the pulse tube throughout the cycle acts as a thermally insulating, compressible piston. With the hot heat exchangers anchored at room temperature, the cold heat exchanger of a pulse-tube refrigerator reaches typically 50 K, and refrigeration is produced with a coefficient of performance as high as $\frac{1}{4}$ of Carnot's.

2. IMPORTANT LENGTH SCALES

In most thermoacoustic engines and refrigerators, the acoustic oscillation is essentially a pure tone, so that velocity, pressure, and temperature essentially vary sinusoidally with time, at the oscillation frequency f. The wavelength $\lambda = a/f$, where a is the sound speed, is an important length scale, especially in the direction of the gas displacement oscillations. For example, in the heat-driven refrigerator of Fig. 1(b) above, the distance from the hot end cap at the top of the tube to the tube–bulb junction is approximately $\lambda/4$, so that the tube is essentially a quarter-wave acoustic resonator, with pressure maximum and velocity node at the top, and pressure node and velocity maximum at the entrance to the bulb. In thermoacoustic systems designed to date, 10 cm $\lesssim \lambda \lesssim$ 10 m. The lengths of stacks are much less than λ.

The amplitude x_1 of the gas displacement oscillations is a second important length scale. Typically, x_1 is everywhere much smaller than both the wavelength and the overall length of the system. Within the stack x_1 is typically smaller than the length of the stack, and in the heat exchangers x_1 is typically comparable to the length of the exchangers.

In the directions perpendicular to the displacement oscillations, the key length scale is the thermal penetration depth $\delta_\kappa = \sqrt{\kappa/\pi f \rho c_p}$, where κ is the thermal conductivity of the gas, ρ is its density, and c_p is its isobaric heat capacity per unit mass. The thermal penetration depth is approximately the distance that heat can diffuse through the gas in a time $1/\pi f$. Gas much farther than this from the nearest solid surface experiences adiabatic oscillations and will not participate in thermoacoustic effects. Thus, the spacing in stacks and heat exchangers cannot be much greater than δ_κ. In typical thermoacoustic systems, δ_κ is a fraction of a millimeter. In standing-wave thermoacoustic devices, a key geometrical requirement is that the smallest transverse dimension in the stack be roughly 1 to 3 times δ_κ; in traveling-wave systems, the smallest transverse dimension must be much smaller than δ_κ.

Closely related to the thermal penetration depth is the viscous penetration depth $\delta_\nu = \sqrt{\mu/\pi f \rho} = \sqrt{\nu/\pi f}$, which is approximately the distance over which momentum can diffuse in a time $1/\pi f$. (Here μ is viscosity and ν is kinematic viscosity.) Thus, within δ_ν of solid surfaces, viscous shear causes gradients in the oscillatory velocity and displacement. The ratio $\delta_\nu/\delta_\kappa = \sqrt{\mu c_p/\kappa}$ is the square root of the Prandtl number, a dimensionless measure of the ratio of viscous to thermal effects, and is of order 1 for ideal gases. Hence, in general, viscous effects are important whenever thermoacoustic effects are important. In some of the heuristic discussion below, we will neglect viscosity; but it must be included when quantitatively accurate results are desired.

3. DISSIPATIVE ACOUSTIC PROCESSES

To introduce the concepts and notation of thermoacoustics, we begin with a review of ordinary acoustic dissipation at solid boundaries, which arises from viscous and thermal contact. We consider sound propagating in the x direction in an ideal gas within a duct with constant cross section. We adopt the usual complex notation for time-oscillatory quantities (pressure p; temperature T; velocity components u, v, and w; density ρ; and entropy per unit mass s):

$$p = p_m + \mathrm{Re}[p_1(x)e^{i\omega t}] + \ldots, \tag{1}$$

$$u = \mathrm{Re}[u_1(x,y,z)e^{i\omega t}] + \ldots, \tag{2}$$

$$T = T_m + \mathrm{Re}[T_1(x,y,z)e^{i\omega t}] + \ldots, \tag{3}$$

$$\rho,\ s,\ \text{etc.} = \text{similar to } T, \tag{4}$$

$$v,\ w = \text{similar to } u, \tag{5}$$

with μ, κ, etc. constant. In the acoustic approximation, all the time dependence appears in the factor $e^{i\omega t}$, with $\omega = 2\pi f$. The mean values (subscript m) are real, but the small amplitudes (subscript 1) are, in general, complex to account for the time phasing of the oscillating quantities. We will assume that this expansion to lowest order in the acoustic amplitude suffices for all variables.

To develop quantitative understanding of viscous effects, we begin by finding the y and z dependence of the gas velocity, using the x component of the momentum (Navier–Stokes) equation, for which the acoustic approximation is

$$i\omega\rho_m u_1 = -\frac{dp_1}{dx} + \mu\left[\frac{\partial^2 u_1}{\partial y^2} + \frac{\partial^2 u_1}{\partial z^2}\right]. \tag{6}$$

The x derivatives of u_1 have been neglected because they are of order $1/\lambda$ and hence are much smaller than the y or z derivatives, of order $1/\delta_\nu$. Equation (6) is a partial differential equation for $u_1(y,z)$. With boundary condition $u_1 = 0$ at the solid surface, its solution is

$$u_1 = \frac{i}{\omega\rho_m}[1 - h_\nu(y,z)]\frac{dp_1}{dx}, \tag{7}$$

where $h_\nu(y,z)$ depends on the specific geometry under consideration. Below, we will need the spatial average (over y and z) of Eq. (7):

$$\langle u_1\rangle = \frac{i}{\omega\rho_m}(1 - f_\nu)\frac{dp_1}{dx}, \tag{8}$$

where f_ν is the spatial average of h_ν. Table 1 displays the functional forms (Arnott *et al.*, 1991; Swift and Keolian, 1993) of h_ν and f_ν, and Fig. 2 shows f_ν, with the hydraulic radius r_h characterizing the size of the duct. In the pin array, gas flows in the space between cylinders of radius r_i aligned with the x axis and arranged in a triangular lattice with center-to-center separation $\sqrt{2\pi}r_o/\sqrt[4]{3}$.

These functions describe how viscosity reduces the magnitude of the oscillatory velocity and shifts its phase. Gas that is much closer than δ_ν to the nearest solid surface is nearly at rest. Gas that is much farther than δ_ν from the nearest solid surface experiences essentially no viscous shear; it moves with a

Table 1. Complex function h and its spatial average f for several geometries. In the second column, the origin is at the center of symmetry of the geometry, except in the boundary-layer limit where it is at the surface. In cases with a sort of circular symmetry, $r = (y^2 + z^2)^{1/2}$. The hydraulic radius r_h is the ratio of gas volume to gas–solid contact area.

Geometry	h	f
Parallel plates, spacing $2y_0$; $r_h = y_0$	$\dfrac{\cosh[(1+i)y/\delta]}{\cosh[(1+i)y_0/\delta]}$	$\dfrac{\tanh[(1+i)y_0/\delta]}{(1+i)y_0/\delta}$
Circular pores, radius R; $r_h = R/2$	$\dfrac{J_0[(i-1)r/\delta]}{J_0[(i-1)R/\delta]}$	$\dfrac{2J_1[(i-1)R/\delta]}{J_0[(i-1)R/\delta](i-1)R/\delta}$
Pin array (triangular lattice), pin radius r_i, centers' separation $(2\pi)^{1/2}r_o/3^{1/4}$ $\simeq 1.905r_o$; $r_h = (r_o^2 - r_i^2)/2r_i$	$\simeq \dfrac{Y_1(\xi_o)J_0(\xi) - J_1(\xi_o)Y_0(\xi)}{Y_1(\xi_o)J_0(\xi_i) - J_1(\xi_o)Y_0(\xi_i)}$, where $\xi = (i-1)r/\delta$	$\simeq -\dfrac{2\xi_i}{\xi_o^2 - \xi_i^2}\dfrac{Y_1(\xi_o)J_1(\xi_i) - J_1(\xi_o)Y_1(\xi_i)}{Y_1(\xi_o)J_0(\xi_i) - J_1(\xi_o)Y_0(\xi_i)}$
Rectangular pores, $2y_0 \times 2z_0$; $r_h = y_0z_0/(y_0 + z_0)$	$1 - \dfrac{16}{\pi^2}\sum_{m,n\ \mathrm{odd}}\dfrac{\sin(m\pi y/2y_0)\sin(n\pi z/2z_0)}{mnY_{mn}}$, where $Y_{mn} = 1 - i\dfrac{\pi^2\delta^2}{8y_0^2z_0^2}(m^2z_0^2 + n^2y_0^2)$	$1 - \dfrac{64}{\pi^4}\sum_{m,n\ \mathrm{odd}}\dfrac{1}{m^2n^2Y_{mn}}$
Boundary-layer limit	$e^{-(1+i)y/\delta}$	$\dfrac{(1-i)\delta}{2r_h}$

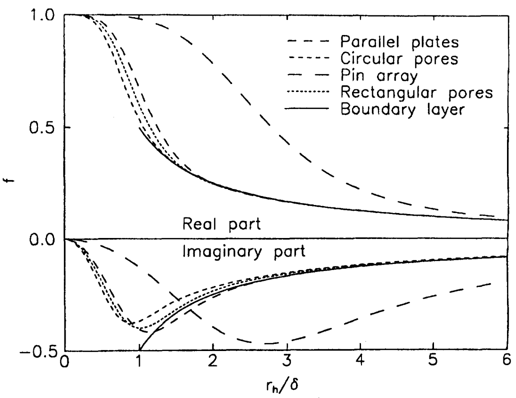

FIG. 2. Spatial-average function f for several geometries. (See text and Table 1 for a more complete description.) The rectangle here has 6:1 aspect ratio, and the pin array has $r_o/r_i = 6$. The hydraulic radius r_h is the ratio of gas volume to gas–solid contact area. The boundary-layer limit is approached at large r_h for all geometries.

velocity that is independent of y and z. Gas that is roughly δ_ν from the nearest solid surface moves with a reduced velocity and significant phase shift. The acoustic power dissipation per unit volume, which is proportional to the square of ∇u_1, is in general greatest at the solid surface, where the velocity gradients are highest.

Similarly, to find the dependence of the oscillatory temperature on y and z, we begin with the general equation of heat transfer, for which the acoustic approximation is

$$i\omega\rho_m c_p T_1 - i\omega p_1 = \kappa\left[\frac{\partial^2 T_1}{\partial y^2} + \frac{\partial^2 T_1}{\partial z^2}\right]. \tag{9}$$

In general, the solid has sufficient heat capacity and thermal conductivity to enforce $T_1 = 0$ on the gas at the solid surface. Equation (9) is a partial differential equation for $T_1(y,z)$, similar in form and boundary condition to Eq. (6) for $u_1(y,z)$. Exploiting the similarity, the solution can be written

$$T_1 = (1/\rho_m c_p)[1 - h_\kappa(y,z)]p_1, \tag{10}$$

and its spatial average can be written

$$\langle T_1\rangle = (1/\rho_m c_p)(1 - f_\kappa)p_1, \tag{11}$$

where f_κ and h_κ are the same as f_ν and h_ν, but with δ_ν replaced by the thermal penetration depth δ_κ.

Similar to the effect of viscosity discussed above, thermal contact with the solid surface reduces the magnitude and shifts the phase of the oscillatory temperature. Gas that is much closer than δ_κ to the nearest solid surface is nearly isothermal. Gas that is much farther than δ_κ from the nearest solid surface is essentially adiabatic, experiencing adiabatic temperature oscillations $T_1 = (1/\rho_m c_p)p_1$ in phase with the pressure oscillations. At approximately δ_κ from the nearest solid surface, these oscillations are reduced in magnitude and shifted in phase.

To find the time-averaged acoustic power $d\dot{W}$ *dissipated in length* dx of the duct, we write

$$\frac{d\dot{W}}{dx} = -\int \frac{d(\overline{pu})}{dx}\,dy\,dz, \tag{12}$$

where the overbar denotes time averaging and the integral is over the cross-sectional area A of the duct. Rewriting Eq. (12) in complex notation and expanding the derivative gives

$$\frac{d\dot{W}_2}{dx} = -\tfrac{1}{2}A\,\mathrm{Re}\left(\langle\tilde{u}_1\rangle\frac{dp_1}{dx} + \tilde{p}_1\frac{d\langle u_1\rangle}{dx}\right), \tag{13}$$

where the tilde denotes complex conjugation. We can obtain dp_1/dx from Eq. (8) above. To find $d\langle u_1\rangle/dx$, we will use our expression for $\langle T_1\rangle$ in the continuity equation $\partial\rho/\partial t + \nabla\cdot(\rho\mathbf{v}) = 0$, which can be averaged with respect to y and z in the acoustic approximation to obtain

$$i\omega\langle\rho_1\rangle + \rho_m\frac{d\langle u_1\rangle}{dx} = 0. \tag{14}$$

Using $d\rho = -(\rho/T)dT + (\gamma/a^2)dp$ (where γ is the usual ratio of isobaric to isochoric specific heats), we can express the spatially averaged density as $\langle\rho_1\rangle = -(\rho_m/T_m)\langle T_1\rangle + (\gamma/a^2)p_1$. Substituting this into Eq. (14), using Eq. (11) for $\langle T_1\rangle$, and eliminating c_p by means of the thermodynamic identity $\gamma - 1 = a^2/Tc_p$ yields

$$i\omega[1 + (\gamma - 1)f_\kappa]p_1 + \rho_m a^2\frac{d\langle u_1\rangle}{dx} = 0 \tag{15}$$

as an acoustic expression of the continuity equation that can be solved for $d\langle u_1\rangle/dx$.

Finally, substituting Eqs. (15) and (8) into Eq. (13), we obtain

$$\frac{d\dot{W}_2}{dx} = \frac{A\omega}{2}\left[\frac{\rho_m|\langle u_1\rangle|^2}{|1-f_\nu|^2}\,\mathrm{Im}(-f_\nu) + \frac{(\gamma-1)|p_1|^2}{\rho_m a^2}\,\mathrm{Im}(-f_\kappa)\right]. \tag{16}$$

The first term gives the viscous damping of sound, and the second term gives the less intuitively obvious thermal damping. The work thus lost from the sound wave appears as heat, at the temperature T_m. In the boundary-layer approximation, in which all dimensions of the duct are much larger than the penetration depths, Eq. (16) reduces to

$$\frac{d\dot{W}_2}{dS} = \tfrac{1}{4}\,\rho_m|\langle u_1\rangle|^2\delta_\nu\omega + \tfrac{1}{4}\frac{|p_1|^2}{\rho_m a^2}(\gamma-1)\delta_\kappa\omega, \tag{17}$$

where S is surface area of the duct. This expression is readily interpreted in terms of the acoustic energy density:

- The mean kinetic energy per unit volume $\rho|\langle u_1\rangle|^2/4$ times δ_ν is roughly the kinetic energy in the gas within a viscous penetration depth of the solid surface, per unit area of the surface; the viscous dissipation term shows that this energy is dissipated by viscous shear at an average rate ω. Intuitively, we imagine layers of gas sliding relative to one another, with viscous "friction" between the layers turning mechanical energy into heat.
- Similarly, the thermal dissipation term shows that the mean adiabatic compressive energy density $|p_1|^2/4\rho_m a^2$ stored in unit volume of the gas is dissipated at an average rate $(\gamma - 1)\omega$ within a region of thickness δ_κ near the solid surface. The extra factor $(\gamma - 1)$ appears because this thermal dissipation is proportional to the difference between the isothermal and adiabatic compressibilities, which is proportional to $\gamma - 1$. Here, the intuitive picture is more subtle than for viscous dissipation. Gas immediately adjacent to the surface experiences isothermal density and pressure oscillations, which are reversible; gas far from the surface experiences adiabatic density and pressure oscillations, which are also reversible. We imagine the gas approximately δ_κ from the surface experiencing a complex cycle of density changes in response to the pressure oscillations: first an increase in density due to quasi-adiabatic compression by the sound wave, then a further increase in density as thermal contact with the surface removes heat from the gas, then a decrease in density due to quasi-adiabatic expansion by the sound wave, and finally a further decrease in density as thermal contact with the surface delivers heat to the gas. Since this gas experiences thermal expansion at low pressure and thermal contraction at high pressure, it absorbs work from the sound wave. This gas, approximately δ_κ *from the surface,* is the most effective at absorbing work from the sound wave, whereas in the case of viscous dissipation the gas *at the surface* is most effective.

4. LAGRANGIAN VIEW OF THERMOACOUSTIC PROCESSES

In the derivation of acoustic dissipation above, we adopted the usual Eulerian point of view of fluid mechanics, focusing attention on what happens at *a given point in space* as the gas moves by. Qualitative insight into thermoacoustic processes will be gained in this section by considering the alternative, Lagrangian point of view, focusing attention on the position, pressure, volume, and temperature of *a given parcel of gas* as it moves. It is simplest here to imagine square-wave motion and pressure in the gas, with pressure and displacement in phase for standing waves and pressure and velocity in phase for traveling waves. However, real thermoacoustic systems operate sinusoidally, with a variety of phases between motion and pressure. Viscosity is ignored in this section, even though it has a significant, harmful effect on thermoacoustic efficiency. With these conceptual simplifications, the thermodynamic cycle for standing waves becomes identical to the Brayton cycle, with two reversible adiabats and two irreversible constant-pressure heat transfers, while the cycle for traveling waves becomes two isotherms and two reversible polytropic processes.

Time phasing is an important factor in

the operation of traditional heat engines and refrigerators: Pistons, valves, and sparks must have the correct relative timing in order to produce the desired thermodynamic cycle in the working gas. Thermoacoustic systems often contain no obvious moving parts to perform these functions, yet the acoustic transport of heat and the generation (or absorption) of acoustic work point to some type of timed phasing of thermodynamic processes, here achieved in a remarkably simple way.

One source of phasing in thermoacoustic systems is the presence of two thermodynamic media: gas and solid. As the gas oscillates along the solid at the acoustic frequency, it experiences oscillations in temperature. Part of the temperature oscillations comes from compression and expansion of the gas by sound pressure, and the rest is a consequence of the local temperature of the solid itself. In Sec. 3 above, the local solid temperature was constant. In this section, the temperature gradient along the stack ensures that each moving parcel of gas "sees" a *time-dependent* local solid temperature because of its motion along the temperature gradient.

In keeping with the square-wave assumption of this section, we need not retain complex notation to account for the phase of time-dependent variables. Hence, in this section only, all variables with subscript 1 are real and positive.

4.1 Standing-Wave Refrigerator

The standing-wave thermoacoustic refrigerator can be understood with reference to Fig. 3(a), where the four steps of its cycle are displayed for one typical parcel of gas. In response to the standing wave, the gas parcel is pressurized and moves up along the adjacent solid in step 1, and it is depressurized and moves down along the adjacent solid in step 3, absorbing and doing work dW''. In this picture, the pressure changes in steps 1 and 3 are adiabatic, so that the gas parcel experiences adiabatic temperature changes proportional to the pressure changes. Steps 2 and 4 allow thermal equilibration between the gas parcel and the adjacent solid. In these two steps, net work $dW - dW'$ is absorbed from the sound wave by the gas parcel, as it thermally contracts at high pressure in step 2 and thermally expands at low pressure in step 4. If the sign of dT_m/dx is as shown (with higher T_m toward the nearest pressure antinode), the net thermal effect of the parcel of gas is to move heat $dQ \approx dQ'$ a short distance along the solid, from slightly lower temperature to slightly higher temperature, during each cycle of the sound wave. Hence the system functions as a refrigerator, with acoustic work being absorbed to pump heat from a lower temperature to a higher temperature.

If $dT_m/dx = 0$, the situation is identical to that described quantitatively in Sec. 3 (but with $\mu = 0$ here). In this case, $dW - dW'$ represents the thermal damping of sound, given by the second term in Eq. (16) or (17).

There is a so-called critical temperature gradient $\nabla T_{\text{crit}} \equiv (dT_m/dx)_{\text{crit}} = p_1/\rho_m c_p x_1$ at which no heat is transferred in steps 2 and 4. This occurs when the temperature rise due to adiabatic compression in step 1, $2p_1/\rho_m c_p$, exactly matches the rise in adjacent solid temperature that the gas sees because of its motion along the solid, $2x_1 \nabla T_{\text{crit}}$. For all temperature gradients less than ∇T_{crit}, heat transfer between gas and solid has the signs shown in Fig. 3(a), with heat flow dQ from gas to solid in step 2, at the higher temperature and position, and heat flow dQ' from solid to gas in step 4, at the lower temperature and position. For such low temperature gradients it is also true that $dW > dW'$, so that the gas absorbs work from the standing wave. Hence, a standing-wave system acts as a refrigerator only if $dT_m/dx < \nabla T_{\text{crit}}$.

In Fig. 3(a), we label the parcel's distance from the solid as $\sim\delta_\kappa$ because imperfect thermal contact between gas and solid is required for the cycle to operate as described. If thermal contact between gas and solid were perfect, the gas would arrive at its uppermost position at the end of step 1 already equilibrated at the local solid temperature, so that no heat would be transferred during step 2; and similarly for steps 3 and 4. At the other extreme, if thermal contact were nonexistent, no heat could be transferred in steps 2 and 4. Thus, intermediate, *imperfect* thermal contact between gas and solid is required for the cycle to operate as described. For the sinusoidal motion and pressure of real systems, this imperfect thermal contact is achieved for gas neither much closer than δ_κ to the nearest solid nor much farther than

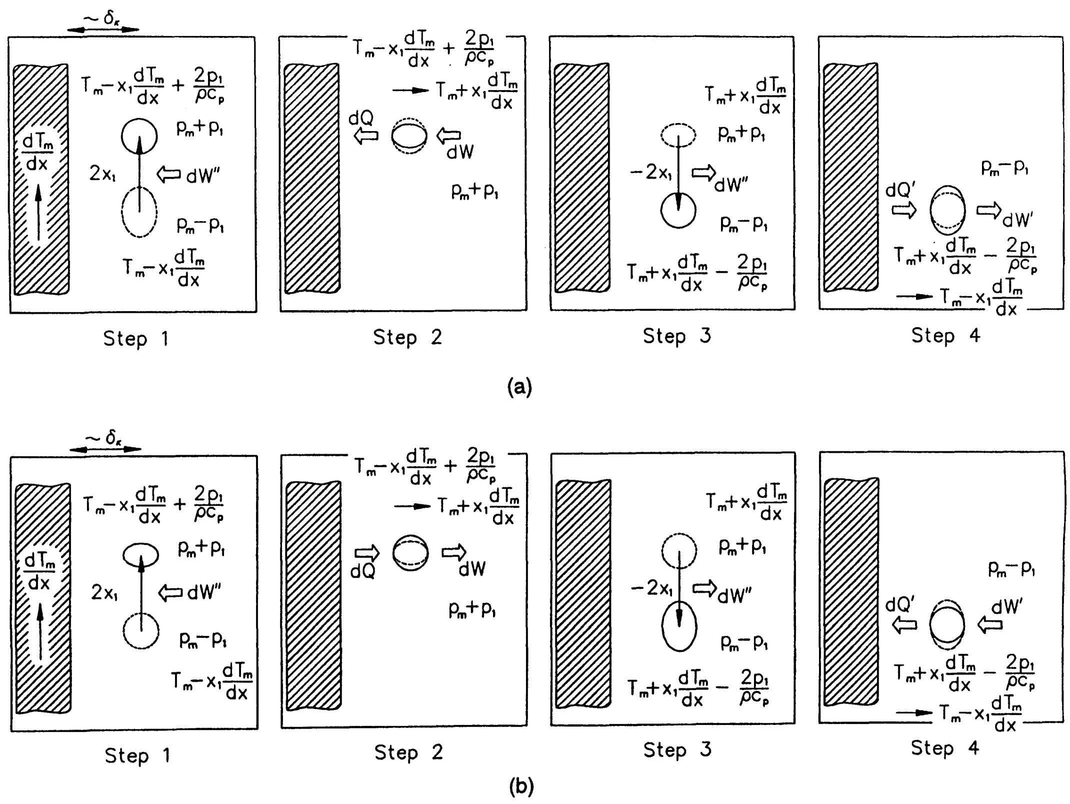

FIG. 3. (a) A typical gas parcel executing the four steps of the cycle of a standing-wave thermoacoustic refrigerator, assuming an inviscid gas and square-wave acoustic motion and pressure. In each step, the dashed and solid ellipses show, respectively, the initial and final positions and volumes of the parcel, while labels show the initial and final temperatures and pressures of that step; and broad arrows show directions of attendant heat flows dQ or dQ' (between parcel and solid) and work flows dW, dW', or dW'' (into or out of the parcel). The solid temperature at the average location of the gas parcel is T_m. Averaged over one cycle, the parcel absorbs work $dW - dW'$ from the sound wave. In Figs. 3 and 4, we have dropped our usual complex notation, so that all variables here are positive real numbers. (b) A typical gas parcel executing the four steps of the cycle of a standing-wave thermoacoustic engine, assuming an inviscid gas and square-wave acoustic motion and pressure. Averaged over one cycle, the parcel delivers work $dW - dW'$ to the sound wave.

δ_κ from the nearest solid. As suggested by the thermal dissipation term in Eq. (16), the quantitative measure of the correct geometry is $\mathrm{Im}(-f_\kappa)$. Thus, effective thermoacoustic systems contain stacks that fill the entire cross section of the resonator, with spacings of a few thermal penetration depths, as shown in Fig. 1(b); and with $\mathrm{Im}(-f_\kappa)$ as large as possible, suggesting (cf. Fig. 2) that parallel plates and pin arrays are the best stack geometries.

4.2 Standing-Wave Engine

To understand the conversion of heat to acoustic work in a standing-wave thermoacoustic engine, consider the magnified view of part of the stack shown in Fig. 3(b), which shows a typical parcel of gas at four instants of time during one cycle of the acoustic wave. The standing wave carries the parcel up and down, compressing and expanding it, with phasing such that it is at its most compressed state when at its upper position, and its most expanded state at its lower position. Here, the solid temperature gradient is greater than ∇T_{crit}, and so the directions of heat transfer in steps 2 and 4 are reversed relative to the standing-wave refrigerator. Thus, the net thermal effect of the parcel of gas shown is to move a little heat down the solid, from higher to lower temperature; again, all parcels have a similar effect, so that overall a substantial amount of heat is carried down along the solid from the hot heat exchanger to the cold heat exchanger.

Since heat flows into the gas in step 2, and out of it in step 4, the gas expands at high pressure in step 2 and contracts at low pressure in step 4. Thus, the net effect in the thermoacoustic heat engine is the production of work, at the acoustic frequency, by this and all other gas parcels. One can imagine all the gas in the stack region of a thermoacoustic engine thermally expanding and contracting because of its displacement along the temperature gradient, with the correct phasing relative to the oscillatory standing-wave pressure to do net work. In the Sondhauss tube, for example, this net work maintains the standing wave against viscous and thermal dissipation in the resonator and provides power to radiate into the room.

4.3 Traveling-Wave Systems

Ceperley (1979, 1985) introduced the idea that Stirling engines (*q.v.*) and refrigerators, and related devices such as pulse-tube refrigerators, may be regarded as traveling-wave thermoacoustic systems. This point of view is possible because the phasing between displacement and pressure in such engines and refrigerators is substantially that of traveling waves, with displacement and pressure substantially out of phase. A second difference between standing- and traveling-wave systems is the typical spacing between solid elements: In traveling-wave systems, this distance is typically $\ll\delta_\kappa$, ensuring excellent thermal contact between gas and solid at all times.

These features are illustrated for the traveling-wave refrigerator in Fig. 4. Isothermal compression in step 2 transfers heat from the gas parcel to the solid at a higher temperature, and isothermal expansion at step 4 transfers heat from solid to gas at a lower temperature. The other two steps serve to preheat and precool the gas, reversibly storing and recovering heat in the solid. The net effect of one parcel over an entire cycle is, again, to move a little heat a short distance up the solid, up the temperature gradient. Excellent thermal contact between gas and solid is required in steps 1 and 3 for effective preheating and precooling, respectively; in realistic, sinusoidal traveling-wave systems, this is achieved by maintaining transverse dimensions much smaller than a thermal penetration depth.

Traveling-wave engines are also possible in principle; from the perspective of thermoacoustics, all Stirling engines can be considered as such in the low-amplitude limit.

5. COMPONENTS

The first efficient thermoacoustic refrigerator, designed, built, and studied by Tom Hofler (1986, 1988), is shown in Fig. 5(a). It illustrates several features of many of today's standing-wave thermoacoustic devices. Figure 5(b) shows some of the data obtained

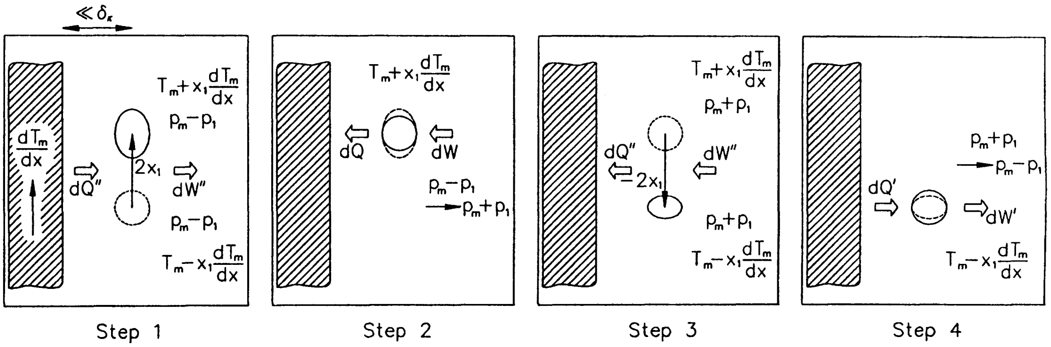

FIG. 4. A typical gas parcel executing the four steps of the cycle of a traveling-wave thermoacoustic refrigerator, assuming an inviscid gas and square-wave acoustic motion and pressure. Symbols have the same meaning as in Fig. 3.

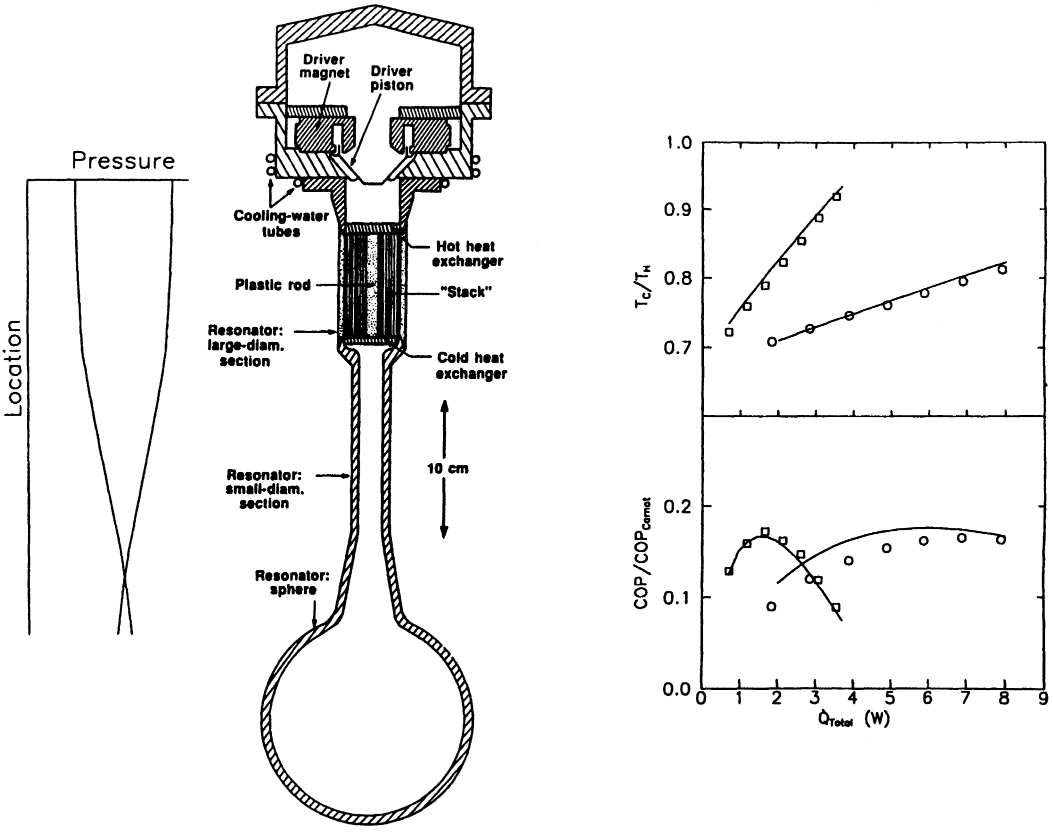

(a) (b)

FIG. 5. (a) An early thermoacoustic refrigerator and (b) some of its measured and calculated performance, with 500-Hz pressure oscillations in 10-bar helium gas and with hot heat-exchanger temperature $T_H = 300$ K. Data from Hofler (1988): squares, $|p_1|/p_m = 0.015$; circles, $|p_1|/p_m = 0.03$. Lines calculated using Ward and Swift (1994). The cold temperature T_C was measured in the cold heat exchanger. The gross cooling power $\dot{Q}_{Total}$ includes the deliberately applied load plus some small parasitic loads such as heat leak from room temperature (see Hofler, 1988, for details). COP $= \dot{Q}_{Total}/\dot{W}$, with $\dot{W}$ the acoustic power delivered to the resonator.

with this refrigerator, which had a cooling power of several watts with acoustic pressure amplitudes of 3% of the mean pressure.

5.1 Stacks and Regenerators

The heart of a thermoacoustic system is its stack (or, in the case of a traveling-wave system, its regenerator). For standing-wave systems, Fig. 2 indicates that parallel plates and pin arrays are the best stacks known, because they have the largest values of $\mathrm{Im}(-f_\kappa)$. As yet there have been no experimental studies using pin arrays, and so the parallel plates are a preferred geometry. Figure 2 suggests that the spacing of parallel plates should be about $2.2\delta_\kappa$, although viscous and system-wide effects often modify the optimum significantly.

For ease of construction and structural rigidity, parallel-plate stacks have usually been spirally wound. The stack in Fig. 5 was a plastic spiral wound around a small plastic rod, with numerous tiny, parallel plastic rods serving as spacers between layers of the spiral. Hence the stack channels were not ideal parallel plate; they were essentially rectangular channels with 13:1 aspect ratio, and with slight curvature. Spiral stacks have also been built with spacing determined by internal bumps throughout the stack or by radial ribs at the ends of the stack.

Typically stack materials are thin enough to block only 10–20% of the total cross-sectional area of the stack. Generally any stack material rigid enough to support its own weight and survive routine handling has sufficient heat capacity to enforce the $T_1 = 0$ boundary condition at the surface. [Liquid-metal thermoacoustics (Migliori and Swift, 1988) is a rare exception.] Hence the key requirement on the stack material is a low thermal conductivity, lest heat be wastefully conducted along the stack from hot to cold. Near and below room temperature, plastics have generally been used; above room temperature, stainless steel, nickel alloys, and ceramics have been used.

Other stack geometries that have been tested include metal honeycomb with hexagonal cells and ceramic honeycomb with square cells (from automotive catalytic converters).

In traveling-wave systems, for which the "stack" is known as a regenerator, the requirement that the spacing be $\ll \delta_\kappa$ makes it difficult to construct parallel plates with uniform spacing. Hence, enhanced heat-transfer surfaces such as screen beds or intricately etched foils (Yaron *et al.*, 1996) are generally used. These geometries are not discussed here, but they can be treated by thermoacoustic methods (Ward and Swift, 1994).

5.2 Resonators

A resonator is required for standing-wave thermoacoustic systems. It should satisfy many requirements, which we illustrate with Fig. 5. Most fundamentally, it should have the desired resonance frequency, and permit location of the stack at a location with the desired ratio of $|p_1|/|\langle u_1\rangle|$. The resonator of Fig. 5 is essentially a quarter-wavelength resonator [even though $p_1(x)$, shown at left, is not exactly a cosine], with the pressure antinode at the driver piston and the pressure node near the sphere. The stack is located close to the pressure antinode, where $|p_1|$ is nearly equal to its value at the pressure antinode and $|\langle u_1\rangle|$ is significantly smaller than it is at the pressure node. (In Sec. 6 we discuss this choice of location in terms of efficiency.)

A conceptually simpler quarter-wavelength resonator would comprise a uniform-diameter tube $\lambda/4$ long connected to an essentially infinite sphere. The resonator of Fig. 5 differs from this in important, advantageous ways. First, the tube consists of two sections of different diameters. The small-diameter section near the pressure node allows the tube to be significantly shorter than $\lambda/4$, reducing the overall size and weight. More subtly, this configuration also reduces the dissipation of acoustic power in the resonator, which is governed by Eq. (17). Basically, as the diameter of the lower section of the tube is reduced, its surface area decreases while $|\langle u_1\rangle|$ increases and $|p_1|$ remains about the same. For a modest reduction in diameter, as in Fig. 5, the net effect is a reduction in the total dissipation, by as much as a factor of 2.

The resonator of Fig. 5 also suppresses harmonic content in the standing wave. In this regard, a uniform-diameter resonator is extremely undesirable, because its higher resonant modes occur at frequencies that are exact integer multiples of the fundamental. In this situation, nonlinear effects drive resonances, and hence the harmonic content of the wave is high. These nonlinear effects, such as the $(\mathbf{v}\cdot\nabla)\mathbf{v}$ term in the momentum equation (neglected elsewhere in this article), generate oscillations at integer multiples of the operating frequency. The resonance frequencies of the first few modes of the resonator of Fig. 5 are not integer multiples, and so higher-mode resonances are avoided.

Choice of sphere diameter in Fig. 5 was a compromise between size/weight and dissipation: A smaller sphere experiences larger pressure oscillations and requires a longer tube to maintain the desired resonance frequency. The tapered connection between the sphere and the small-diameter section reduces the Reynolds number at the sphere opening, in order to minimize dissipation due to turbulence.

Another typical standing-wave thermoacoustic geometry is essentially half-wavelength (Garrett *et al.*, 1994), with mirror-image stacks near the pressure antinodes at each end of the resonator. The central portion of such a resonator generally has a reduced diameter, to exploit the reduced size, dissipation, and harmonic content described above. Half-wavelength resonators are sometimes bent or coiled to reduce overall size.

With the requirement that $\delta_\kappa \gg$ spacing, traveling-wave systems typically operate at lower frequencies than standing-wave systems, pushing conventional acoustic resonators to impractical lengths. Hence, traveling-wave systems often incorporate a mechanical element into the resonator, providing resonance with solid mass bouncing on a gas spring. Such "free-piston" Stirling machines are fully described elsewhere (Urieli and Berchowitz, 1984; STIRLING ENGINES).

5.3 Electroacoustic Power Transducers

To date, thermoacoustic systems have often used loudspeaker-like transducers, with permanent magnets and coils of wire in relative oscillatory motion. Piezoelectric and magnetohydrodynamic transducers are also candidates.

In Fig. 5, the loudspeaker-like driver was located at a pressure antinode of the standing wave, so that the acoustic power was delivered with high force and small displacement, easing engineering difficulties associated with the flexing portion of the driver. This location also placed it at room temperature, where Joule heat generated in the driver could be removed most efficiently.

Commercial loudspeakers are often poorly matched to thermoacoustic applications, because they are designed to drive a comparatively low acoustic impedance with large bandwidth. For better impedance matching, the loudspeaker in Fig. 5 was modified, with the addition of an aluminum cone and associated flexing metal seal to exert the speaker's force over a small area. With this modification, it converted electric power to acoustic power with approximately 20% efficiency. Further modifications to commercial loudspeakers can achieve efficiencies of over 50%. In the field of Stirling machines, linear motors and linear alternators of 90% efficiency have been demonstrated (Corey and Yarr, 1992), indicative of the performance to be expected when loudspeaker-like transducers are designed specifically for efficient conversion of power at a single frequency.

5.4 Heat Exchangers

Heat exchangers are required in thermoacoustic engines and refrigerators to supply and extract heat at the two ends of the stack or regenerator. The length of each along the direction of the acoustic oscillation is of the order of the local displacement amplitude x_1; transverse dimensions are roughly of the order of those of the adjacent stack or regenerator. Equation (16) can be used to estimate the acoustic power dissipation in the heat exchangers, although entrance effects prevent quantitatively accurate predictions.

In the system shown in Fig. 5(a) and other small thermoacoustic systems, the heat exchangers can simply consist of multiple copper strips spanning the resonator at the stack ends. Larger-diameter, high-power systems require integral pumped-fluid channels, heat pipes, or electric resistance heaters imbedded in the heat exchangers to deliver or extract heat uniformly from the stack ends. In this case, the typical geometry comprises a set of high-conductivity fins extending from pipes (Garrett *et al.*, 1994); the assembly typically has 50–75% of the cross-sectional area open to gas flow.

6. POWER AND EFFICIENCY

A thermoacoustic engine converts heat into acoustic work. More specifically, it absorbs heat Q_H from a heat source at high temperature T_H, rejects heat Q_C to a heat sink at low temperature T_C, and produces work W. The first law of thermodynamics determines that $W + Q_C = Q_H$; the second law shows that the efficiency W/Q_H is bounded above by the Carnot efficiency $1 - T_C/T_H$.

Similarly, a thermoacoustic refrigerator uses acoustic work W to absorb heat Q_C from a heat source at low temperature T_C, rejecting waste heat Q_H to a heat sink at higher temperature T_H. The first law of thermodynamics determines that $W + Q_C = Q_H$; the second law shows that the relevant efficiency, known as the coefficient of performance COP $= Q_C/W$, is bounded above by $\mathrm{COP}_{\mathrm{Carnot}} = T_C/(T_H - T_C)$.

Experience has shown that the power (here, heat per unit time) of standing-wave thermoacoustic devices can be estimated roughly by $p_m a A |p_1/p_m|^2/30$, with A the cross-sectional area of the stack. Thus, high amplitude (as a fraction of mean pressure), high mean pressure, and high sound speed increase power density. Heat flux densities of the order of 1 MW/m^2 are easily achievable in high-pressure helium gas, which has the highest sound speed of the inert gases, and so it is often used, typically at a pressure above 10 bar. Helium's high thermal conductivity, the largest of the inert gases, is an additional advantage, allowing spacings within the stack and heat exchangers to be conveniently large. In today's thermoacoustic systems, $|p_1/p_m|$ ranges from 0.03 to 0.10, chosen as a compromise between the high power density achieved at high amplitude and the high confidence in the quantitative accuracy of calculations (described in the next section) for systems operating at low amplitude.

Calculations show that standing-wave thermoacoustic systems have second-law efficiencies (i.e., efficiencies normalized by the Carnot efficiency) as high as 0.5, considering effects in the stack only. Including resonator, heat exchanger, and transducer losses reduces this efficiency to between 0.15 and 0.35 for large–cross-section systems, for which resonator losses are not a significant fraction of the total power. Small-diameter systems can have even lower efficiencies, as a result of resonator losses, auxiliary equipment (such as circulating liquid loops for heat transfer to air streams), and heat losses through insulation to ambient temperature. Traveling-wave thermoacoustic systems can have higher efficiencies.

To date, the most efficient laboratory standing-wave engine and refrigerator have had second-law efficiencies of 0.2. This is impressive for devices with no moving parts and is comparable to the efficiencies of small, inexpensive commercial equipment. It falls far short of the efficiencies of well-engineered, expensive steam turbines or large-scale vapor-compression refrigeration equipment, for which over 80% of Carnot has been achieved. If future inventions and improvements to basic understanding can improve the efficiency or raise the power density of thermoacoustic engines and refrigerators, without sacrificing their simplicity, they will find more widespread use.

The efficiency of standing-wave thermoacoustic devices falls below Carnot's efficiency because of six major sources of irreversibility, which we call inherent loss, viscous loss, conduction loss, auxiliary losses, transduction loss, and unknown loss:

1. Inherent loss arises from the heat transfer to and from each parcel of gas in the stack as illustrated in Figs. 3 and 4: Whenever heat dq is transferred across a nonzero temperature difference δT, the entropy of the universe increases (Bejan, 1982) by $dq\ \delta T/T^2$. This irreversibility is unavoidable in the standing-wave thermoacoustic process, relying as it does on *imperfect* thermal contact across the thermal penetration depth for the correct phasing between pressure oscillations and thermal expansion/contraction, and on nonzero heat transfer across that imperfect thermal contact for work production or refrigeration.
2. Viscous loss in the stack occurs because work must be expended in overcoming viscous shear forces as the gas oscillates between the plates. The viscous penetration depth is nearly as large as the thermal penetration depth, so that most of the gas in the stack experiences significant viscous shear (with the parcels in Figs. 3 and 4 actually experiencing significant shape distortions).
3. Simple conduction of heat from the hot heat exchanger to the cold heat exchanger through the stack material and the gas reduces system efficiency.
4. The first three losses occur in auxiliary parts of a thermoacoustic system. Viscous and inherent losses in the heat exchangers, and conduction loss in the portion of the resonator case surrounding the stack, are usually the most important auxiliary losses in large systems, while viscous and inherent losses on other surface areas in the resonator are important in small systems.
5. With rare exceptions such as shown in Fig. 1(b), electric power—not acoustic power—is the usual interface to external systems, so that electroacoustic transducers are needed. In principle, these can be 100% efficient; in practice, 90% appears possible, while 55% has been achieved to date in laboratory thermoacoustic systems.
6. For $|p_1/p_m|$ near 0.1, systems built to date have suffered from additional losses of unknown origin (see below).

For many designs with high power density, the first four sources of irreversibility contribute roughly equally to the inefficiency of thermoacoustic devices. Some reasons for this balance are easy to understand. First, thermoacoustic systems have inherent trade-offs between power density and efficiency, due to the inherent losses in the stack. In the inviscid picture described in Secs. 4.1 and 4.2, at the critical temperature gradient there are no inherent losses, but there is no work done or dissipated and no heat transported; the difference between dT_m/dx and ∇T_{crit} controls both power and inherent loss. Thus, for a given temperature difference across which the engine or refrigerator must operate, the choice of the length of the stack is essentially a compromise between power density and efficiency. Often this compromise is made with $dT_m/dx \sim 2\nabla T_{\text{crit}}$ for engines and $\sim \nabla T_{\text{crit}}/2$ for refrigerators. Second, stack location in the standing wave controls the trade-off between viscous losses, which are highest when the stack is near the pressure node, and conduction losses, which are highest near the pressure antinode where ∇T_{crit} is steepest. Usually this trade-off leads to a stack position much closer to the pressure antinode than to the node; the proportions shown in Fig. 5 are typical.

One way to increase efficiency is to use a mixture of helium and a heavier inert gas as the working substance to reduce viscous effects. Kinetic theory predicts that the Prandtl number $\sigma = \mu c_p/\kappa = \frac{2}{3}$ for hard-sphere monatomic gases, and indeed real monatomic gases have values very close to this (e.g., $\sigma = 0.68$ for helium at room temperature). Fortunately, mixtures of a heavy and a light monatomic gas have Prandtl numbers significantly lower than $\frac{2}{3}$. The most efficient thermoacoustic refrigerator mentioned above (Garrett *et al.*, 1993) used 89% helium, 11% xenon, with $\sigma = 0.27$, to achieve its highest efficiency of 20% of Carnot (cf. 17% of Carnot in Fig. 5, for a similar apparatus optimized for pure helium gas). However, with a sound speed less than half that of pure helium, the power density using this gas mixture was reduced.

7. METHODS OF COMPUTATION

Although attempts at theoretical understanding of these phenomena began with Lord Rayleigh 120 years ago, a quantitatively accurate theory of thermoacoustics was not developed until the 1970s, through the efforts of Nicholas Rott and co-workers (Rott, 1980). It is remarkable that such qualitatively simple classical phenomena went without a quantitatively accurate explanation until late in the 20th century.

7.1 Rott's Approach

Quantitative thermoacoustics analysis is based on Rott's wave equation and energy-flux equation. These equations result from the momentum, continuity, and energy equations in the acoustic approximation. The results are valid for arbitrary phasing between p_1 and $\langle u_1 \rangle$, i.e., for both standing-wave and traveling-wave systems.

As with simpler one-dimensional acoustic-wave equations, Rott's wave equation may be written as two coupled first-order differential equations in the oscillatory pressure $p_1(x)$ and the spatially averaged oscillatory velocity $\langle u_1(x) \rangle$. Rott's energy-flux equation may be regarded as a first-order differential equation in mean temperature $T_m(x)$, coupled to the pressure and velocity equations. In this form, displayed in Table 2, Rott's equations are suitable for numerical integration along x.

Table 2. Expressions used for numerical integrations in ideal-gas thermoacoustics. Compare to Eqs. (8) and (15), which are appropriate when $dT_m/dx = 0$.

$$\frac{dp_1}{dx} = -\frac{i\omega\rho_m}{(1 - f_\nu)} \langle u_1 \rangle$$

$$\frac{d\langle u_1 \rangle}{dx} = -\frac{i\omega}{\rho_m a^2} [1 + (\gamma - 1) f_\kappa] p_1 + \frac{(f_\kappa - f_\nu)}{(1 - f_\nu)(1 - \sigma)} \frac{1}{T_m} \frac{dT_m}{dx} \langle u_1 \rangle$$

$$\frac{dT_m}{dx} = \left\{ \frac{\dot{H}_2}{A_{\text{gas}}} - \tfrac{1}{2} \operatorname{Re}\left[p_1 \langle \tilde{u}_1 \rangle \left(1 - \frac{(f_\kappa - \tilde{f}_\nu)}{(1 + \sigma)(1 - \tilde{f}_\nu)} \right) \right] \right\} \left\{ \frac{\rho_m c_p |\langle u_1 \rangle|^2}{2\omega(1 - \sigma^2)|1 - f_\nu|^2} \operatorname{Im}(f_\kappa + \sigma \tilde{f}_\nu) - \kappa - \frac{A_{\text{solid}}}{A_{\text{gas}}} \kappa_{\text{solid}} \right\}^{-1}$$

The equations are based on the acoustic approximation, with the relevant variables written as

$$p = p_m + \mathrm{Re}[p_1(x)e^{i\omega t}], \tag{18}$$

$$u = \mathrm{Re}[u_1(x,y,z)e^{i\omega t}], \tag{19}$$

$$v, w = \text{similar to } u, \tag{20}$$

$$T = T_m(x) + \mathrm{Re}[T_1(x,y,z)e^{i\omega t}], \tag{21}$$

$$\rho, s = \text{similar to } T, \tag{22}$$

$$\mu = \mu(x), \tag{23}$$

$$\kappa, a, c_p, \text{ etc.} = \text{similar to } \mu. \tag{24}$$

We are most interested in T_m, p_1, and $\langle u_1 \rangle$.

For clarity, we consider here only the case of large solid heat capacity ($\epsilon_s = 0$ in Swift, 1988), so that the temperature of the solid material in the stack is simply $T_m(x)$, independent of time, y, and z, and we restrict ourselves to ideal gases.

The expression for dp_1/dx shown in Table 2 is identical to Eq. (8) derived in Sec. 3; the presence of nonzero dT_m/dx has no effect on the acoustic momentum equation. In effect, we regard this approximation to the momentum equation as the origin of pressure gradient in thermoacoustics: The moving gas causes the pressure gradient. If $f_\nu = 0$, the pressure gradient is entirely "inertial," but when $f_\nu \neq 0$ the presence of viscosity and the stationary boundaries adds a resistive component to the pressure gradient and also effectively changes the magnitude of the inertial contribution.

In both the continuity and energy equations an expression for the spatial average over y and z of the oscillatory temperature, $\langle T_1 \rangle$, is required. As in Sec. 3, it is derived from the general equation of heat transfer, for which the acoustic approximation is

$$\rho_m c_p\left(i\omega T_1 + u_1\frac{dT_m}{dx}\right) - i\omega p_1 = \kappa\left[\frac{\partial^2 T_1}{\partial y^2} + \frac{\partial^2 T_1}{\partial z^2}\right] \tag{25}$$

when $dT_m/dx \neq 0$. Following the same procedure as in Sec. 3, we find

$$T_1 = \frac{1}{\rho_m c_p}(1 - h_\kappa)p_1 + \frac{i}{\omega(1 - f_\nu)}\frac{dT_m}{dx}\left(1 - \frac{h_\kappa - \sigma h_\nu}{1 - \sigma}\right)\langle u_1 \rangle \tag{26}$$

and

$$\langle T_1 \rangle = \frac{1}{\rho_m c_p}(1 - f_\kappa)p_1 + \frac{i}{\omega(1 - f_\nu)}\frac{dT_m}{dx}\left(1 - \frac{f_\kappa - \sigma f_\nu}{1 - \sigma}\right)\langle u_1 \rangle \tag{27}$$

[cf. Eqs. (10) and (11)].

Using Eq. (27) in the continuity equation $i\omega\langle \rho_1 \rangle + d(\rho_m\langle u_1 \rangle)/dx = 0$ yields

$$\frac{d\langle u_1 \rangle}{dx} = -\frac{i\omega}{\rho_m a^2}[1 + (\gamma - 1)f_\kappa]p_1 + \frac{(f_\kappa - f_\nu)}{(1 - f_\nu)(1 - \sigma)}\frac{1}{T_m}\frac{dT_m}{dx}\langle u_1 \rangle, \tag{28}$$

which is also shown in Table 2. This expression finds easy physical interpretation as a thermoacoustic approximation to the continuity equation, expressing the fact that $d\langle u_1 \rangle/dx$ is nonzero if and only if there is a density oscillation in the gas between x and $x + dx$. The two terms in Eq. (28) show that such density change can be caused either by pressure or by velocity along the temperature gradient. Consider the pressure term first. If $f_\kappa = 0$, there is no thermal contact between gas and solid, and so the density oscillations are adiabatic; in this case, $\rho_m a^2$ is the correct compressibility. If $f_\kappa = 1$, the thermal contact between gas and solid is perfect, and so the gas is anchored at the local solid temperature. In this case, $\rho_m a^2/\gamma$, the isothermal compressibility, is appropriate. For intermediate thermal contact, an effective compressibility $\rho_m a^2/[1 + (\gamma - 1)f_\kappa]$, intermediate in magnitude and with nontrivial phase, describes the density oscillations in response to pressure oscillations. Next consider the velocity term, in the easily interpreted inviscid limit, with $f_\nu = 0$ and $\sigma = 0$. If $f_\kappa = 0$, there is no thermal contact between gas and solid, the velocity term is zero, and the gas density does not respond to motion along the temperature gradient. In the other extreme, if $f_\kappa = 1$, the gas is always at the local solid temperature, so that as it flows toward higher T_m its density decreases and its velocity increases. In the more interesting, intermediate regime, oscillatory motion of the gas along the temperature gradient leads to complex density oscillations.

At this point, we could combine Eqs. (8) and (28), eliminating $\langle u_1 \rangle$, to obtain a second-order differential equation in p_1, Rott's wave equation:

$$[1 + (\gamma - 1)f_\kappa]p_1 + \frac{\rho_m a^2}{\omega^2}\frac{d}{dx}\left(\frac{1 - f_\nu}{\rho_m}\frac{dp_1}{dx}\right) - \frac{a^2}{\omega^2}\frac{f_\kappa - f_\nu}{1 - \sigma}\frac{1}{T_m}\frac{dT_m}{dx}\frac{dp_1}{dx} = 0. \tag{29}$$

However, for numerical computations, it is easiest to use Eqs. (8) and (28) separately.

Finally, the energy equation yields an expression for dT_m/dx. To lowest order, the total energy flux (Rott, 1980; Swift, 1988) is approximately

$$\begin{aligned}\dot{H}_2 &= A_{\text{gas}}\langle \rho_m \overline{w_1 u_1}\rangle - (A_{\text{gas}}\kappa + A_{\text{solid}}\kappa_{\text{solid}})\frac{dT_m}{dx} \\ &= A_{\text{gas}}\rho_m c_p \langle \overline{T_1 u_1}\rangle - (A_{\text{gas}}\kappa + A_{\text{solid}}\kappa_{\text{solid}})\frac{dT_m}{dx}.\end{aligned} \tag{30}$$

Here w is the enthalpy per unit mass of the gas. Using Eqs. (7) and (26) for u_1 and T_1, respectively, and taking the spatial averages of the products in Eq. (30), we find

$$\begin{aligned}\dot{H}_2 = {} & \frac{A_{\text{gas}}}{2}\text{Re}\left[p_1\langle \tilde{u}_1\rangle\left(1 - \frac{(f_\kappa - \tilde{f}_\nu)}{(1+\sigma)(1 - \tilde{f}_\nu)}\right)\right] \\ & + \frac{A_{\text{gas}}\rho_m c_p |\langle u_1\rangle|^2}{2\omega(1 - \sigma^2)|1 - f_\nu|^2}\text{Im}(f_\kappa + \sigma\tilde{f}_\nu)\frac{dT_m}{dx} \\ & - (A_{\text{gas}}\kappa + A_{\text{solid}}\kappa_{\text{solid}})\frac{dT_m}{dx}.\end{aligned} \tag{31}$$

The time-averaged energy flux $\dot{H}_2$ *along the stack must be independent of* x, because the case surrounding the stack is assumed to be rigid and thermally insulated and the system is in time-averaged steady state. With $\dot{H}_2$ *constant, we solve Eq. (31) for* dT_m/dx as shown in Table 2, using it to predict the evolution of T_m.

Because the first two equations in Table 2 are complex, these three coupled equations represent five real coupled equations in the five variables $\text{Re}[p_1]$, $\text{Im}[p_1]$, $\text{Re}[\langle u_1\rangle]$, $\text{Im}[\langle u_1\rangle]$, and T_m, and as such are easily integrated numerically using, for example, a Runge–Kutta method (see ANALYTIC METHODS; SCIENTIFIC COMPUTING BY NUMERICAL METHODS). These results are the basis of all present quantitative analyses of standing-wave system and are equally valid for traveling-wave systems.

The curves in Fig. 5(b), in reasonable agreement with the data, were calculated using publicly available software (Ward and Swift, 1994) based on this theory. The software combines the thermoacoustic computations with similar acoustic solutions for the other portions of the resonator, using continuity of T_m, p_1, and complex volumetric velocity $A\langle u_1\rangle$ at the junctions between ducts and thermoacoustic components. The calculations shown in Fig. 5(b) had no adjustable parameters; they simply used the geometry of the apparatus and the properties of helium gas.

7.2 Approximate Methods

The thermoacoustic calculation method summarized in the previous subsection is suitable for numerical integration. In this subsection we discuss approximate methods, suitable for making estimates of standing-wave system performance on the blackboard, with a hand calculator, or in a spreadsheet. An assumption common to all such approximate methods (Swift, 1988; Atchley, 1992) is that the stack is short enough and the temperature spanned is small enough that all x- and T_m-dependent variables can be regarded as constant, including dT_m/dx itself. For example, with this approximation the pressure drop across the stack would be estimated by $\Delta p_1 = -i\omega\rho_m\langle u_1\rangle\Delta x/(1 - f_\nu)$, where Δx is the stack length, with ρ_m, $\langle u_1\rangle$, and f_ν evaluated at the stack midpoint. For further simplification, the boundary-layer limit can be used for f_ν and f_κ with little additional loss in accuracy.

An approximate expression for the acoustic power absorbed or produced in the stack can be obtained by following the same procedure as was used to derive Eq. (16), but including the $\langle u_1\rangle$ term in Eq. (28). The result is

$$\frac{d\dot{W}_2}{dx} = \frac{A_{\mathrm{gas}}\omega}{2}\left[\frac{\rho_m|\langle u_1\rangle|^2}{|1 - f_\nu|^2}\,\mathrm{Im}(-f_\nu) + \frac{(\gamma - 1)|p_1|^2}{\rho_m a^2}\,\mathrm{Im}\left(-f_\kappa + \frac{f_\kappa - f_\nu}{(1 - \sigma)(1 - f_\nu)}\,\frac{dT_m}{dx}\,\frac{i\rho_m c_p\langle u_1\rangle}{\omega p_1}\right)\right]. \tag{32}$$

The total stack power $\Delta\dot{W}_2$ can then be obtained approximately by evaluating the right-hand side using values at the stack midpoint and multiplying by the stack length. This equation shows that a modest value of dT_m/dx reduces the power dissipated in the stack and that a large enough value of dT_m/dx changes the sign of $\Delta\dot{W}_2$, so that the stack produces power. For $\mu = 0$ and standing-wave phasing, the crossover occurs at $dT_m/dx = \nabla T_{\mathrm{crit}}$.

Equations (31) and (32) can be further simplified by using either the boundary-layer limit expressions for f_κ and f_ν or exact standing-wave phasing. With both these assumptions simultaneously, simple approximate expressions result:

$$\dot{H}_2 = \frac{A_{\mathrm{gas}}}{4}\,\frac{\delta_\kappa}{r_h}\,\frac{|p_1||\langle u_1\rangle|}{(1 + \sigma)e}\left(1 + \sqrt{\sigma} - \frac{\delta_\nu}{r_h} - \Gamma\,\frac{1 + \sqrt{\sigma} + \sigma}{1 + \sqrt{\sigma}}\right) - (A_{\mathrm{gas}}\kappa + A_{\mathrm{solid}}\kappa_{\mathrm{solid}})\,\frac{dT_m}{dx}, \tag{33}$$

$$\Delta\dot{W}_2 = \frac{A_{\mathrm{gas}}\Delta x}{4r_h}\left[\frac{\rho_m|\langle u_1\rangle|^2\delta_\nu\omega}{e} + \frac{(\gamma - 1)|p_1|^2\delta_\kappa\omega}{\gamma p_m}\left(1 - \frac{\Gamma}{(1 + \sqrt{\sigma})e}\right)\right], \tag{34}$$

where

$$\Gamma = (dT_m/dx)/\nabla T_{\mathrm{crit}}, \tag{35}$$

$$\nabla T_{\mathrm{crit}} = \omega|p_1|/\rho_m c_p|\langle u_1\rangle|, \tag{36}$$

$$e = 1 - \delta_\nu/r_h + \delta_\nu^2/2r_h^2. \tag{37}$$

These expressions are easily used in spreadsheets or for hand calculations.

7.3 Similitude

The most promising route to higher power densities is by increasing $|p_1/p_m|^2$, but doing so takes us farther from the range of applicability of Rott theory, which is based on small oscillatory amplitude. Rott's assumptions include gas displacement amplitude much smaller than the length of the stack and other components, Reynolds number of the oscillations small enough to avoid turbulence, and $|p_1| \ll p_m$. Extension of thermoacoustics theory beyond these assumptions will be challenging. In the meantime, application of similitude to thermoacoustics (Olson and Swift, 1994) has shown how to organize and correlate experimental data outside the range of our current quantitative understanding and allows meaningful experimental study of scale models of thermoacoustic apparatus reminiscent of wind-tunnel models of aircraft.

The similitude analysis shows that the dimensionless variable groups in Table 3 provide a *complete* description of the gas in a thermoacoustic system. (Additional variables can be added to include transducers or solid properties if needed.) The analysis is powerful because it is true even when the thermoacoustic system is operating beyond the assumptions inherent in Rott's method. For example, it "includes" turbulence, even though the Reynolds number is not explicitly present in the table.

Figure 6, from the similitude study (Olson and Swift, 1994), illustrates both the power of similitude analysis and the amplitude dependence of the accuracy of our current un-

Table 3. Dimensionless groups relevant to thermoacoustics. The reference location, indicated by the subscript "ref," can be the room-temperature end of the stack. Of the many dimensions x_j of the apparatus, three are singled out for special attention: the overall length L, the stack area A_{ref} at the reference location, and its hydraulic radius r_h at the reference location. The constants b_μ and b_κ account for temperature dependences of μ and κ: $\mu = \mu_{\mathrm{ref}}(T/T_{\mathrm{ref}})^{b_\mu}$ and similarly for b_κ.

Dimensions	A_{ref}/L^2, r_h/L, x_j/L
Gas properties	γ, σ_{ref}, b_μ, b_κ
Thermophysical lengths	fL/a_{ref}, δ_κ/r_h
Powers	Power$/p_m a_{\mathrm{ref}} A_{\mathrm{ref}}$
Spatially dependent variables	$T(\mathbf{x},t)/T_{\mathrm{ref}}$, $p(\mathbf{x},t)/p_m$, $\mathbf{v}(\mathbf{x},t)/a_{\mathrm{ref}}$

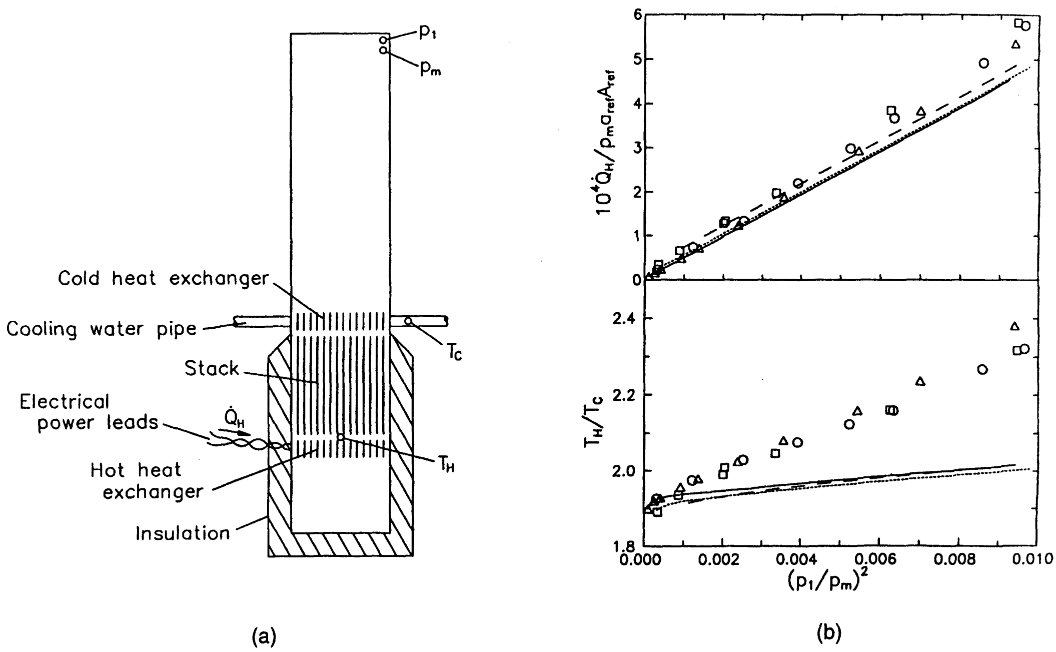

FIG. 6. A recent example of thermoacoustic measurements and calculations. (a) Schematic of apparatus, a standing-wave engine driving no load. Small circles indicate locations of sensors. (b) Heater power $\dot{Q}_H$ and hot temperature T_H as functions of $|p_1|$, all normalized. Points are measurements; lines are calculations. Triangles and solid lines: helium, 0.96 MPa. Circles and dotted lines: neon, 0.70 MPa. Squares and dashed lines: argon, 0.36 MPa.

derstanding of thermoacoustic phenomena. The data shown as points in Fig. 6(b) were obtained with the apparatus sketched in Fig. 6(a), a thermoacoustic engine driving no load. The plots can be interpreted as displaying what heater power $\dot{Q}_H$ *and hot temperature* T_H were required at the hot heat exchanger to maintain steady oscillations at a given pressure amplitude $|p_1|$.

The lines are the results of calculations (Ward and Swift, 1994) based on Rott's theory, the geometry of the apparatus, and the properties of the gases. The calculations agree well with the measurements in the limit of small $|p_1|$, as expected from the assumptions in the theory. However, at $|p_1|/p_m \sim 0.1$, measurements deviate from calculations significantly. The deviations are not surprising, in that they are of the same order as $|p_1|/p_m$, but they are disturbing from a practical point of view, because both $\dot{Q}_H$ *and* T_H deviate from Rott theory in directions that decrease the efficiency.

Three monatomic gases were used in the measurements, with different average pressures selected to make δ_κ the same for all three cases, ensuring similarity. The crux of the similitude analysis is that the only relevant thermophysical length scales are λ, δ_κ, and δ_ν, so that if these are held fixed all other dimensionless groups (such as Reynolds and Mach numbers) will also stay fixed. The data for all three gases do indeed fall along the same curves, demonstrating similarity. Although the similitude analysis does not indicate the cause of the deviations of the measurements from Rott-style calculations, it does allow elimination of some potential suspects, such as gravity-driven convection, resonator vibration, and stack flutter, which are not included in the similitude analysis and would not be expected to scale from gas to gas.

Similitude also permits the building of meaningful thermoacoustic scale models. For example, to model a full-size helium thermoacoustic engine at mean pressure p_m, we can use a half-scale model with argon at $0.79p_m$, the pressure that ensures that δ_κ in the argon is exactly half its value in the full-size helium system. Experiments with the scale model can be easier than those with the full-size system because of its smaller size and because powers are reduced by $(p_m a A)_{\mathrm{Ar}}/(p_m a A)_{\mathrm{He}} = \frac{1}{16}$.

GLOSSARY

Heat Engine: Thermodynamic device that converts heat to work.

Refrigerator: Thermodynamic device that uses work to transfer heat from low to high temperature.

Regenerator: Key heat-exchange element in traveling-wave thermoacoustic device, a porous structure with nonnegligible heat capacity.

Stack: Key heat-exchange element in standing-wave thermoacoustic device, an open structure with nonnegligible heat capacity.

Standing Wave: Wave with oscillatory pressure and oscillatory motion substantially in phase.

Thermoacoustic: With both thermodynamic and acoustic characteristics.

Traveling wave: Wave with oscillatory pressure and oscillatory motion substantially out of phase.

INTRODUCTION

The branch of experimental thermodynamics that deals with changes in enthalpy or energy (both quantities are defined in Sec. 1) associated with chemical reactions is known as thermochemistry. It has practical applications in all branches of science. Thermochemical studies provide valuable information about, for example, the energy to be expected from combustion of fossil fuels; atmospheric pollution; equilibria in geological formations; products and consequences of an accident in a nuclear reactor; chemical effects of enzymes in the physiological milieu; compositions of planetary atmospheres; and strengths of chemical bonds between atoms in molecules. Modern chemical industry is very dependent on thermochemical data for the design of efficient processes, where the concept of "heat balance" comes into play. Thermochemical calculations applied to putative chemical processes may be used to identify reactions that are feasible (but that, ultimately, could be limited by kinetic factors) and those that are not. For example, spontaneous conversion of diamond to graphite is favored thermodynamically but is precluded by kinetic limitations. Put to such uses, thermochemistry can be of great practical and economic value.

It follows, then, that the provision of high-quality thermochemical information is an important scientific pursuit in its own right. High quality implies, above all else, accuracy; a secondary index of merit of thermochemical values is precision, although it, in no way, can be considered to imply accuracy. In fact, those two qualities are quite distinct. Accuracy is related to the closeness with which a particular experimental value approaches the true one, while precision reflects the reproducibility with which experimental results are measured. Thus, a precise result does not necessarily connote an accurate one.

1. BASIC CONCEPTS

1.1 Thermochemistry and the Laws of Thermodynamics

The close relation of thermochemistry with thermodynamics means that the former is subject to the laws of the latter. As to their impact on thermochemistry, it can be said that, of the three laws of thermodynamics, the first is the most significant:

$$\Delta U = q + w + u. \tag{1}$$

Here, ΔU represents the change in internal energy of a system; q, the heat energy; w, the "pressure-volume" work energy; and u, any other energy absorbed or released by the system. If $u = 0$ in a particular experiment, and the volume of the system is kept constant, so that $w = 0$, then

$$\Delta U = q. \tag{2}$$

If, on the other hand, an experiment is performed in which $u = 0$ also, but the pressure is kept constant, then

$$w = -\int p dV = -p \int dV = -p \, \Delta V, \tag{3}$$

where dV denotes an infinitesimal change in the volume of the system. Thus, from Eq. (1),

$$\Delta U = q - p \, \Delta V. \tag{4}$$

It follows that

$$\Delta U + p \, \Delta V = q, \tag{5}$$

and

$$\Delta U + \Delta(pV) = q. \tag{6}$$

In other words,

$$\Delta(U + pV) = q. \tag{7}$$

But, since

$$H = U + pV \tag{8}$$

by definition (see THERMODYNAMICS, EQUILIBRIUM, then

$$\Delta H = q. \tag{9}$$

Thus, depending on experimental conditions, the measured heat is either ΔU (constant volume) or ΔH (constant pressure). Neither U nor H can be determined absolutely, and so, in practice, the difference in those properties between one state and another, denoted by ΔU or ΔH, is measured. Because most thermochemical experiments are performed at constant (atmospheric) pressure, ΔH is reported more frequently than ΔU. When one is dealing with chemical reactions, as we are in the greater part of this article, those quantities are further decorated as $\Delta_r H_m$ or $\Delta_r U_m$, where the subscript r indicates that the change in H or U refers to a chemical reaction and the subscript m denotes a molar quantity. Such changes in energy are customarily measured in a calorimeter, and we discuss several variants of that apparatus in a later section.

An immutable requirement of the first law of thermodynamics is that the initial and final states of systems under investigation must be known precisely, but the path between them need not. Thus, for example, the initial and final temperatures and pressures have to be specified. In the case of chemical reactions, the exact compositions of starting materials and products have to be known as well.

1.2 Second- and Third-Law Calculations

Although, at first sight, the thermochemistry of any chemical change should be amenable to calorimetric study, it is found in practice that many reactions do not occur, or occur very slowly, under normal calorimetric operating conditions of temperature or pressure, and, therefore, other techniques have to be employed to obtain the desired thermochemical information. Of those, two are most common: high-temperature studies of chemical equilibria, and measurements of the potentials of high-temperature electrochemical cells. Although these two approaches may be thought of as having little in common, they are both basically thermodynamic probes of the changes that occur in chemical reactions.

When heated to sufficiently high temperatures, even the most refractory compounds decompose to some extent. Often, only gaseous products are formed:

$$\mathrm{AB(s)} \rightarrow \mathrm{A(g)} + \mathrm{B(g)}. \qquad (10)$$

The equilibrium constant of reaction (10) is given by

$$K = p(\mathrm{A})p(\mathrm{B})/(p^0)^2, \qquad (11)$$

where p denotes the partial pressure of the species, and p^0 is the reference pressure (usually 101.325 or 100 kPa, but we discuss this matter in detail later) and, by convention, the pure solid phase AB is excluded from consideration.

From the second law of thermodynamics, it can be shown that

$$\Delta_r G_m^0 = -RT \ln K, \qquad (12)$$

where $\Delta_r G_m^0$ denotes the standard Gibbs free-energy change for a reaction at the temperature T. (The use of superscript 0 to denote standard state is discussed in Sec. 3.) Clearly, then, an experimental measurement of K can give directly the Gibbs free-energy change of a reaction. At this point, we need to introduce another relation:

$$\Delta_r G_m^0 = \Delta_r H_m^0 - T\,\Delta_r S_m^0, \qquad (13)$$

where $\Delta_r S_m^0$ denotes the change of standard molar entropy S_m^0 for reaction (10). Thus, by combining Eqs. (12) and (13), one obtains

$$\ln K = -\Delta_r H_m^0/RT + \Delta_r S_m^0/R. \qquad (14)$$

In practice, a plot of $\ln K$ against $1/T$ approaches linearity, with the slope of the line corresponding to $-\Delta_r H_m^0/R$. From this operation, $\Delta_r H_m^0$ is obtained at $\langle T \rangle$, the mean temperature of the measurements. This procedure is known as a "second-law" calculation. Values of $\Delta_r H_m^0$ at other temperatures are obtained by application of heat capacity corrections.

As mentioned above, Eq. (12) yields directly a value for the Gibbs free-energy change at $\langle T \rangle$ for a generic reaction

$$\mathrm{A} \rightarrow \mathrm{B} + \mathrm{C}. \qquad (15)$$

This result can be converted to the enthalpy change $\Delta_r H_m^0(T)$ at some other temperature, in practice usually 298.15 K, by a procedure known as the "third-law" method. The fine details of this approach are beyond the scope of this article. Briefly, for each species A, B, and C, numerical values are required for a thermodynamic quantity colloquially referred to as the "Gibbs free-energy function" or the "free-energy function." (Despite lengthy discussions over the past 30 years, international nomenclature bodies have failed to agree on a universally accepted name for this quantity.) For the purpose of this discussion, we shall call the function $\Phi_m^0(T)$; it is equal to $\Delta_0^T S_m^0 - \Delta_{T'}^T H_m^0/T$, where $T' = 298.15$ K. Usually $\Phi_m^0(T)$ is based on measurements of the heat capacity of the solid or liquid or, for gases, is often calculated by means of statistical thermodynamics. In the most favorable cases, reliable values of $\Phi_m^0(T)$ are available for A, B, and C in standard tabulations; however, it is not always so, and estimates often must be made. Mechanically, "third-law" calculations involve the combination of $\Delta_r G_m^0(T)$ with the algebraic sums of $\Phi_m^0(T)$ as follows:

$$\Delta_r H_m^0(298.15\ \mathrm{K}) = \Delta_r G_m^0(T) + T\{\Phi_m^0(\mathrm{B},T) + \Phi_m^0(\mathrm{C},T) - \Phi_m^0(\mathrm{A},T)\}. \qquad (16)$$

In this way, the enthalpy change at $T = 298.15$ K, or any other temperature, may be deduced for a chemical reaction studied at elevated temperatures.

A similar procedure applies to chemical reactions that take place in electrochemical cells. Necessary prerequisites for the validity of such experiments are that the presumed reaction be the true cell reaction and that the electrochemical cell be reversible. In that case,

$$\Delta_r G_m(T) = -nFE(T), \qquad (17)$$

where n denotes the stoichiometric number of electrons in the cell reaction as written, F is the Faraday constant ($F = 96485.3$ $\mathrm{C \cdot mol^{-1}}$), and $E(T)$ is the experimental emf of the cell at the temperature T. Measurements of $E(T)$, combined with a knowledge of n, lead to $\Delta_r G_m(T)$, which, in turn, becomes the starting point for the calculation of $\Delta_r H_m^0(298.15\ \mathrm{K})$ by the "third-law" method, as illustrated in Eq. (16).

1.3 Hess's Law

One statement of the first law of thermodynamics, namely, that the energy of an isolated system remains constant, leads to Hess's law and its application to thermochemical cycles.

Suppose that the chemical reaction W → Z can be broken down into the three simple steps: W → X, X → Y, and Y → Z, which is shown pictorially in Fig. 1. This cycle implies that the reaction of W to form Z is equivalent to the sum of the three consecutive steps: W to form X, X to form Y, and Y to form Z. In other words, one can arrive at Z either directly from W or by the circuitous route from W via X and Y. Hess's law makes a parallel statement to the effect that the enthalpy change in going from W to Z is equal to the sum of the enthalpy changes of the other three individual steps (enthalpy cannot be created or destroyed: it is a "state function"). Thus,

$$\Delta_r H_m^0(1) = \Delta_r H_m^0(2) + \Delta_r H_m^0(3) + \Delta_r H_m^0(4). \tag{18}$$

In thermochemical reasoning and calculations, this law is key. In practice, it means that if $\Delta_r H_m^0$ of the reaction of W to form Z cannot be measured for some reason, or simply has not been determined, it still can be calculated by summing the $\Delta_r H_m^0$'s of the other three reactions. Choice of a four-component cycle is purely arbitrary; in practice, Hess cycles are encountered that comprise many more, but sometimes fewer, component reactions, and the journey from W to Z can encompass many intermediate steps. Needless to say, if even one of the auxiliary $\Delta_r H_m^0$'s is in error, the derived quantity will likewise be in error. The reliability of the calculated $\Delta_r H_m^0(1)$ is no greater than that of any, or all, of the other $\Delta_r H_m^0$'s. Another consequence of Hess's law is that in those cases where $\Delta_r H_m^0$ is known for all components, four as in Eq. (18), then the algebraic sum of the $\Delta_r H_m^0$'s must equal zero within the combined uncertainties of the individual values. Absent that, one of the component values, or some of them or, less likely, all of them, must be in error. This requirement is a powerful diagnostic tool for experimental thermodynamicists and data evaluators alike.

$$\begin{tikzcd} W \arrow[r, "\Delta_r H_m(1)"] \arrow[d, "\Delta_r H_m(2)"'] & Z \\ X \arrow[r, "\Delta_r H_m(3)"'] & Y \arrow[u, "\Delta_r H_m(4)"'] \end{tikzcd}$$

FIG. 1. A thermochemical cycle. The molar enthalpy of reaction is denoted by $\Delta_r H_m$, and $\Delta_r H_m(1) = \Delta_r H_m(2) + \Delta_r H_m(3) + \Delta_r H_m(4)$.

2. STANDARD STATES

Because thermodynamic quantities such as H_m cannot be determined absolutely, they are measured and reported as differences ΔH_m. Clearly, a thermodynamic reference state must be designated for each chemical compound. The standard reference state of a substance at a given temperature is defined as the pure solid or liquid at a specified pressure, or pure gas at a definite fugacity (fugacity may be regarded as a type of corrected pressure; for ideal gases, fugacity and pressure are identical; for real gases, fugacity and pressure approach one another as the pressure approaches zero). For many years, the reference pressure and fugacity had been accepted as 1 atm (1.01325×10^5 Pa), and they are still used by many authors for a variety of reasons. Recently, IUPAC recommended that the standard-state pressure be changed to 1 bar (10^5 Pa), and more and more contemporary studies adhere to that recommendation. Accordingly, investigators are careful to specify the standard pressure that applies to their work. Most modern thermodynamic literature eschews the "atmosphere" and has replaced it with the SI (International System) units of pressure: Pa, kPa, or MPa. Despite those changes, the "normal boiling temperature," of a liquid, for example, still has as its basis the reference pressure 101.325 kPa.

3. STANDARD MOLAR ENTHALPY OF FORMATION

The formation reaction of each substance from the constituent elements is unique, as is the thermodynamic description thereof. For the formation of (solid) ABC from its (solid) reference-state elements,

$$A(s) + B(s) + C(s) \rightarrow ABC(s), \qquad (19)$$

the change of enthalpy has a unique value denoted by the symbol $\Delta_f H_m^0(\mathrm{ABC,s})$, called the standard molar enthalpy of formation of ABC(s). Here, the subscript f shows that the thermochemical quantity refers to a formation reaction, and the superscript 0 specifies that A, B, C, and ABC are all in their standard reference states. The temperature of reaction (19) is necessarily included, as $\Delta_f H_m^0(\mathrm{ABC},s,T)$; frequently, that temperature is 298.15 K (or 25 °C; although in many thermodynamic journals, use of °C now is discouraged). Note that it is essential to designate the physical states (s = solid; l = liquid; g = gas; cr = crystal) of the substances as, for example, in the formation of $CO_2(g)$:

$$\mathrm{C(cr,graphite)} + O_2(g) \rightarrow CO_2(g). \qquad (20)$$

Because carbon can exist as either diamond or *reference-state* graphite (Acheson spectroscopic, to be precise), $\Delta_f H_m^0(\mathrm{CO_2,g})$ must refer to the graphite modification. Note that $\Delta_f H_m^0$ is just a special case of $\Delta_r H_m^0$; thus, $\Delta_r H_m^0(20) \equiv \Delta_f H_m^0(\mathrm{CO_2,g})$.

There is another relation in thermochemistry of great practical importance, because it combines $\Delta_r H_m^0$ and $\Delta_f H_m^0$. For the reaction

$$AB(s) + CD(s) \rightarrow AC(s) + BD(s), \qquad (21)$$

we have

$$\Delta_r H_m^0(21) = \Delta_f H_m^0(\mathrm{AC}) + \Delta_f H_m^0(\mathrm{BD}) - \Delta_f H_m^0(\mathrm{AB}) - \Delta_f H_m^0(\mathrm{CD}). \qquad (22)$$

Thus, if $\Delta_r H_m^0$ is measured, and reliable values of $\Delta_f H_m^0$ for the compounds AC, BD, and AB are available from other sources, then $\Delta_f H_m^0(\mathrm{CD})$ can be deduced without measurement. If, for example, $\Delta_r H_m^0(20)$ is determined experimentally, then

$$\Delta_r H_m^0(20) = \Delta_f H_m^0(\mathrm{CO_2,g}) - \Delta_f H_m^0(\mathrm{C,cr,graphite}) - \Delta_f H_m^0(\mathrm{O_2,g}). \qquad (23)$$

Since the last two quantities in Eq. (23) are for the standard reference states and are, therefore, both zero by definition, the measured standard molar enthalpy of reaction is, in fact, the standard molar enthalpy of formation of $CO_2(g)$.

3.1 Units of Thermochemical Quantities

The fundamental unit of both heat and work is the joule, denoted by the symbol J. Most modern thermochemical quantities are expressed in terms of this unit, although the related *calorie* has not entirely disappeared from the literature (1 cal = 4.184 J). The molar mass of a compound is calculated from the atomic weights of the individual atoms. Thus, for ethene (C_2H_4), the molar mass is $[2(12.011) + 4(1.00794)]\ \mathrm{g \cdot mol^{-1}}$ or $28.054\ \mathrm{g \cdot mol^{-1}}$. Most numerical thermochemical information is given as molar quantities, in units $\mathrm{J \cdot mol^{-1}}$ or $\mathrm{kJ \cdot mol^{-1}}$. Thus, $\Delta_f H_m^0(\mathrm{H_2O,l,298.15\ K}) = -285.83\ \mathrm{kJ \cdot mol^{-1}}$.

4. COMPILATIONS OF THERMODYNAMIC DATA

For day-to-day thermochemical calculations by engineers, scientists, and other users of thermochemical information, the availability of tables of values of $\Delta_f H_m^0$ is essential, because tedious and time-consuming searches of the literature are obviated. Many such tables are accessible; some have as their bases critically evaluated information, others are simply a potpourri of values of frequently marginal reliability that are often not even internally consistent; that is, they do not satisfy Hess's law. All such compilations are available in hard copy, some in electronic versions.

A subset of "key" thermochemical values has been identified by international agreement for simple and frequently encountered molecules and aqueous ions such as O_2, H_2O, HCl, CO_2, SiO_2, $Cl^-(aq)$, and $OH^-(aq)$. In all, a total of 151 species is included. Unlike in some other compilations, numerical values, uncertainties, and the rationale for their selection are recorded (Cox *et al.*, 1989). Extensive and detailed tables of $\Delta_f H_m^0$ and $\Delta_f G_m^0$ (as well as other thermodynamic properties such as heat capacities) that deal mostly, but not exclusively, with inorganic substances are available in the *JANAF Thermochemical Tables* (Chase *et al.*, 1985) and in *Thermodynamic Properties of Individual Substances* (Gurvich *et al.*, 1978 *et seq.*; Russian-language version published as separate volumes at various times, and in an electronic form in English: Gurvich *et al.*, 1993). Sections of this publication are being translated into English, and three volumes have appeared to date (Gurvich *et al.*, 1989, 1991, 1994). Thermochemical properties of organic compounds have been critically evaluated and tabulated by Cox and Pilcher (1970), Pedley (1994), and Frenkel *et al.* (1994), who also include a PC diskette listing of tables.

5. APPARATUS FOR THERMOCHEMICAL STUDIES

The foundations of thermochemistry can been traced back to the end of the 18th century (Domalski, 1979). Shortly before the beginning of the French Revolution, Lavoisier and LaPlace were engaged in pioneering thermochemical studies. Other illustrious names associated with the early history of thermochemistry include Black, Davy, Rumford, and Andrews. The last, for example, measured the energy of combination of hydrogen and oxygen to form water.

In the preceding sections, quantities such as $\Delta_r H_m^0$ and $\Delta_f H_m^0$ figure prominently. Now, we outline how they are determined experimentally. Methods are described for the accurate measurement of $\Delta_r H_m^0$ and $\Delta_r U_m^0$. Apparatus used for that purpose are called calorimeters, and the corresponding branch of science, calorimetry. In essence, we discuss experimental equipment used to quantify the energy or enthalpy changes associated with chemical reactions.

5.1 A Generic Calorimeter

Put simply, a calorimeter for thermochemical experiments frequently consists of a vessel in which the chemical reaction under study takes place, a well-stirred water-filled container in which the vessel sits, and a thermometer. In principle, the energy or enthalpy change of the reaction raises, or lowers, the temperature of the vessel and surrounding water. The thermometer rests in the water, where it measures the resulting change of temperature, which, in turn, is related to the change of energy or enthalpy brought about by the chemical change. General reactions of substances most amenable to calorimetric study have included combustion with an oxidizing gas in a static or flow system, solution in aqueous media or inorganic melts, and direct combination of the component elements at some high temperature. Each approach has special demands and, therefore, requires a calorimeter with its own unique attributes. Several such individual systems are now described.

5.2 Combustion Calorimeters

Thermochemical studies of combustion reactions are most frequently carried out in calorimeters equipped with a combustion bomb, a typical one of which is illustrated in Fig. 2. A bomb is required to confine the high pressure of the oxidizing gas. Let us suppose that the energy of combustion of an organic substance, succinic acid, is to be determined. An accurately weighed pellet of analyzed high-purity succinic acid is placed in the combustion crucible close to the ignition wire. A small quantity of water is pipetted into the bomb, which is then closed by means of the sealing nut and charged with high-purity oxygen to a pressure of ca. 3 MPa. The bomb is then placed in the calorimeter can filled with an accurately known mass of water. This entire assembly sits within a thermostat whose temperature is usually close to 298.15 K. While the water in the can is stirred at a constant rate, the temperature-against-time profile of the calorimeter is recorded, and, when the investigator is satisfied that a steady state has been reached, a measured amount of electrical energy is passed through the ignition circuit, combustion of the succinic acid ensues, and the temperature of the calorimeter increases rapidly. After a steady state has once again been reached, another temperature-against-time profile is recorded, and the experiment is terminated. All being well, the combustion

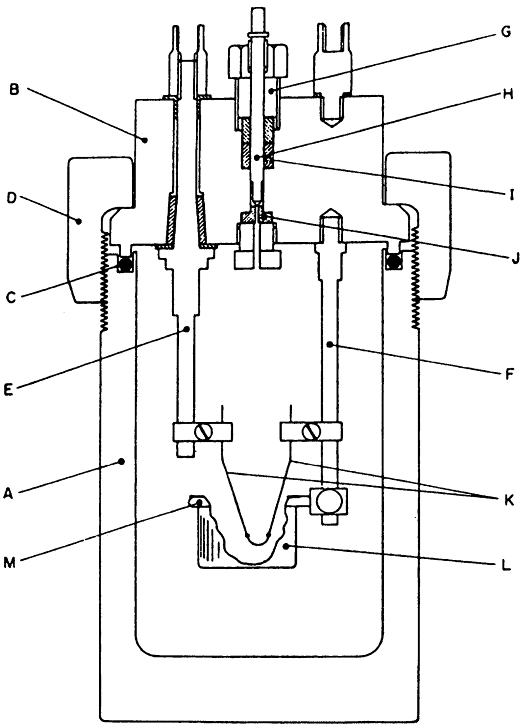

FIG. 2. A typical combustion bomb. A, bomb body; B, bomb head; C, O-ring; D, sealing nut; E, insulated ignition electrode; F, grounded ignition electrode; G, oxygen charging valve; H, valve needle; I, packing gland; J, valve seat; K, ignition wire; L, platinum crucible; M, crucible support ring.

reaction of succinic acid should have proceeded as follows:

$$C_4H_6O_4(cr) + (7/2)O_2(g) \rightarrow 4CO_2(g) + 3H_2O(l). \quad (24)$$

In the most carefully performed determinations, great care would have been expended to ensure that the succinic acid and oxygen were of the highest purity, that the stoichiometrically exact amount of CO_2 had formed, and that by-products such as soot and CO(g) were absent. Recall that, in setting up the experiment, some water was added to the bomb. That was done to ensure that, before the experiment, the gas volume would be saturated with water vapor, which, in turn, would guarantee that all the H_2O produced during the experiment formed as a liquid. In summary, all precautions are taken to make certain that the energy change measured was unequivocally for reaction (24).

Equation (24) represents a relatively straightforward chemical reaction. However, the combustion calorimetry of a molecule containing atoms other than carbon, hydrogen, and oxygen—for example, sulfur, nitrogen, or a halogen (fluorine, chlorine, bromine, or iodine)—is much more complicated. That is illustrated by a recent study by Masuda *et al.* (1994) of the thermochemistry of dimethyl sulfoxide:

$$C_2H_6SO(l) + (9/2)O_2(g) + 113H_2O(l) \rightarrow 2CO_2(g) + H_2SO_4 \cdot 115H_2O(sln). \quad (25)$$

Recall that the first law of thermodynamics dictates that the initial and final states of the system under study be defined precisely. It requires, for reaction (25), not only high-purity dimethylsulfoxide and oxygen as starting materials, but that the concentration of the H_2SO_4 product be known (it is determined by titration) and, moreover, that the H_2SO_4 be at a uniform concentration throughout the combustion bomb. A diagram of one of the first calorimeters designed specifically to fulfill those criteria is shown in Fig. 3 (Hubbard *et al.*, 1954). The equipment is designed in such a way that the bomb rotates while, at the same time, it is also turned "head over heels," thus ensuring that the water in the moving bomb washes all areas of the interior and that, after the combustion has ended, the H_2SO_4 forms a uniform solution. This diagram also illustrates a typical experimental arrangement with the calorimetric can, thermostatted environment, and thermometer.

Oxygen-bomb calorimetry has also been used successfully in studies of organometallic and inorganic compounds. Examples of such applications include the research of Shaulov *et al.* (1969) on tetramethyl germane:

$$Ge(CH_3)_4(l) + 8O_2(g) \rightarrow GeO_2(cr) + 4CO_2(g) + 6H_2O(l); \quad (26)$$

of Mah (1959) on the oxidation of tungsten dioxide:

$$WO_2(s) + (1/2)O_2(g) \rightarrow WO_3(s); \quad (27)$$

and of King and Armstrong (1964) on the combustion of aluminum carbide:

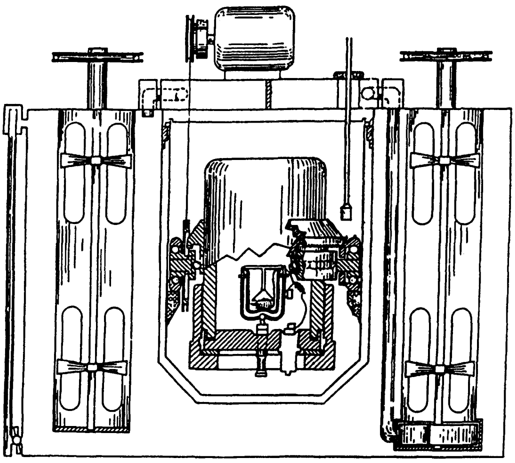

FIG. 3. Rotating-bomb calorimeter for studies of sulfur- and halogen-containing organic compounds. The bomb is similar to that shown in Fig. 2, but it can be rotated and turned head over heels inside the can to bring the aqueous combustion product to a uniform concentration. A chamber filled with stirred water maintained at a constant temperature surrounds the entire assembly.

$$Al_4C_3(s) + 6O_2(g) \rightarrow 2Al_2O_3(s) + 3CO_2(g). \tag{28}$$

Although numerous inorganic substances such as nitrides, carbides, and oxides were found to be responsive to oxygen-bomb calorimetry, it became clear about 35 years ago that many of the emerging technologically important materials could not be studied reliably by this technique. For example, chalcogenides (compounds of a metal with sulfur, selenium, or tellurium) reacted incompletely with high-pressure oxygen, yielding multiple products whose characterization and quantification required heroic efforts in analytical chemistry. In other words, definition of the end states of such systems, as required by the first law of thermodynamics, was very difficult, often nigh impossible. In a nutshell, high-pressure oxygen lacked the requisite oxidizing power, and a more powerful reagent was necessary.

Such considerations led to the invention of fluorine-bomb calorimetry, a detailed description of which was given by Hubbard (1962). Essentially, this technique substitutes fluorine for oxygen as a reagent. That change required a revamping of the traditional oxygen bomb and the incorporation of fluorine-resistant materials of construction such as Monel, lead, gold, and Teflon into the design of the new apparatus.

The great advantage of this method can be illustrated by many examples. Combustion of molybdenum disulfide, MoS_2, with oxygen forms a mixture of molybdenum oxides, sulfur oxides, and, possibly, ternary compounds formed from molybdenum, sulfur, and oxygen, whereas the reaction with fluorine,

$$MoS_2(s) + 9F_2(g) \rightarrow MoF_6(g) + 2SF_6(g), \tag{29}$$

yields well-defined, quantifiable products that require a minimum of analytical characterization. Fluorine-bomb calorimetry has been used successfully to study numerous inorganic substances. Among them are fluorides, oxides, chalcogenides, nitrides, phosphides, silicides, carbides, and borides, as well as individual materials that do not belong in the preceding categories. Developments of the technique over the first 20 years or so were traced by Leonidov and Medvedev (1978), and there is a recent survey of fluorine-bomb calorimetry (O'Hare, 1995).

Although some authors (Kolesov, 1979) have described techniques by means of which vapors of volatile organic liquids are burned in oxygen in a bomb, reactions of gaseous compounds are usually studied by the method of flame calorimetry. Rossini (1931) was a pioneer of such research, and Pilcher and his colleagues at the University of Manchester have also contributed significantly: see Pilcher and Chadwick (1967), for example. Central to this work is the custom-designed burner vessel. It is traditionally made of glass, sits in the calorimeter, and essentially takes the place of the combustion bombs described earlier. It facilitates combination of the reacting gases. A classic example of this procedure is the measurement (Rossini *et al.*, 1931) of the enthalpy of reaction of hydrogen and oxygen:

$$H_2(g) + (1/2)O_2(g) \rightarrow H_2O(l). \qquad (30)$$

Formation of many other simple compounds such as D_2O, CO, SO_2, and HCl has been studied by flame calorimetry.

Just as fluorine-bomb calorimetry was developed as an extension of conventional oxygen calorimetry, fluorine was substituted for oxygen in flame calorimetry for purposes of additional versatility. Because of the aggressive nature of fluorine, Monel, rather than glass, was the main material of construction of the burner. King and Armstrong (1968) used this technique to measure the enthalpies of reaction of $H_2(g)$ with $F_2(g)$, and of $OF_2(g)$ with $H_2(g)$.

5.3 Synthesis Calorimeters

So far, we have described only calorimeters designed for reactions that involve combustion by either gaseous oxygen or fluorine, in which the compound of interest is converted to various products. Some investigators have used an essentially opposite strategy and measured $\Delta_r H_m^0$ for the formation of a substance from its elements,

$$m\mathrm{M}(s) + n\mathrm{N}(s) \rightarrow \mathrm{M}_m\mathrm{N}_n(s), \qquad (31)$$

by means of a synthesis calorimeter.

Such reactions do not, as a rule, occur spontaneously and must usually be initiated by electrical heating or by otherwise encouraging the combination of an intimate mixture of the elements M and N in the calorimeter. The total energy released less the electrical energy input corresponds to $\Delta_r H_m^0$ of reaction (31), in other words, $\Delta_f H_m^0(\mathrm{M}_m\mathrm{N}_n)$.

Among the modern practitioners of this type of calorimetry are Maslov *et al.* (1977), who studied the formation of $MoSi_2$ and other substances, and Vidavskii and Korotkevich (1992), who introduced the pulsed laser as a source of external energy in a determination of $\Delta_f H_m^0$ of the mineral heazlewoodite, Ni_3S_2. Just as in other methods, one must ascertain that only $\mathrm{M}_m\mathrm{N}_n$ is formed; if present, extraneous products and unreacted elements must be corrected for, which oftentimes requires extended analytical procedures and can introduce significant uncertainties in the final $\Delta_f H_m^0(\mathrm{M}_m\mathrm{N}_n)$.

5.4 Calibration of Combustion Calorimeters

Hubbard *et al.* (1956) and other investigators have shown how the corrected temperature change of a calorimeter may be calculated accurately, but that is beyond the scope of this article. The question we wish to address here is how can the measured temperature rise of an experiment be correlated with the energy release that caused it? In other words, how is a calorimeter calibrated?

A few, mostly standardizing, laboratories are equipped to carry out electrical calibrations of combustion calorimeters. Basically, an accurately measured quantity of electrical energy is passed through a resistance heater inserted in the bomb, and the temperature rise of the calorimeter is determined. To calculate the energy equivalent of the calorimetric system, the quantity of electrical energy is divided by the corrected temperature change. Thus, if an input of 12 000 J caused a temperature increase of 1.2 K, the energy equivalent $\epsilon = (12\,000\ \mathrm{J})/(1.2\ \mathrm{K}) = 10\,000\ \mathrm{J \cdot K^{-1}}$. Having established ϵ, one can then know that a temperature rise of 1.23456 K in a combustion experiment, for example, corresponds to an energy release of 12345.6 J.

Most laboratories do not have such facilities and must rely instead on a chemical standard, selected as benzoic acid for combustion calorimetry, by which the unit of electrical energy is essentially transferred from the certifying to the investigator's own laboratory. Thermochemical standard benzoic acid has a certified energy of combustion when reacted with oxygen under specified conditions. Thus, a calorimetrist can calculate precisely how much energy is released by the combustion of a certain mass of the benzoic acid, and the value of ϵ is deduced as if the increase in the temperature of the calorimeter were caused by electrical heating. Thermochemical standard benzoic acid is available from the National Institute of Standards and Technology in the United States (NIST-SRM-39j), from the Russian

Scientific Research Institute of Metrology (sample K-1), and from other sources.

With the calorimeter calibrated, and especially if it is being put into service for the first time, it is important to perform "check" experiments to be sure that no systematic errors are present. Several substances are available whose energies of combustion have been determined by numerous investigators and are, therefore, known with considerable accuracy. Two of those are succinic acid, for combustions of compounds containing carbon, hydrogen, and oxygen, and thianthrene, for combustions of sulfur-containing compounds.

5.5 Solution Calorimeters

Each candidate substance for calorimetric study presents a unique set of challenges to the investigator. Among the most common is the identification of a chemical reaction that yields well-defined products in a reasonable length of time. One might form the impression from the preceding sections that combustion or synthesis calorimetry is applicable to all problems. That is not so; for example, many inorganic compounds do not react completely with high-pressure oxygen or even fluorine, nor can they be readily synthesized directly from the elements. Such substances may, however, dissolve in or combine with aqueous reagents or liquids to form well-defined end products, and, because of that, thermochemical investigations are often carried out in solution calorimeters. A survey of modern solution calorimetry and its applications was published recently (Marsh and O'Hare, 1994).

There are five essential components of a solution calorimeter: the reaction vessel that contains the solvent, a mechanism for introducing the solute into the solvent, a stirrer to promote solution or reaction and to ensure that the product solution is homogeneous, a thermometer, and an electrical calibration heater. We note in passing that almost all modern solution calorimeters, unlike their combustion counterparts, are equipped for electrical calibration.

A typical solution calorimeter is illustrated in Fig. 4. The reaction vessel A is usually constructed of glass for measurements with innocuous solutions; however, aggressive reagents such as aqueous hydrofluoric acid (used in studies of silicates, for example) require platinum, gold, or gold-plated vessels. The electrical heater B and associated equipment are used to calibrate the system. A capsule C, usually constructed of glass or plastic and having thin end windows, contains the substance to be dissolved or reacted, and is held in the tines of the stirrer D. To initiate the reaction, the stirrer is pushed downward, the spike F pierces the windows, the substance is released into the solution, and the reaction begins. The thermometer E measures the temperature of the calorimeter. A metal can G encloses the reaction vessel, and the entire assembly is placed in a thermostatted bath.

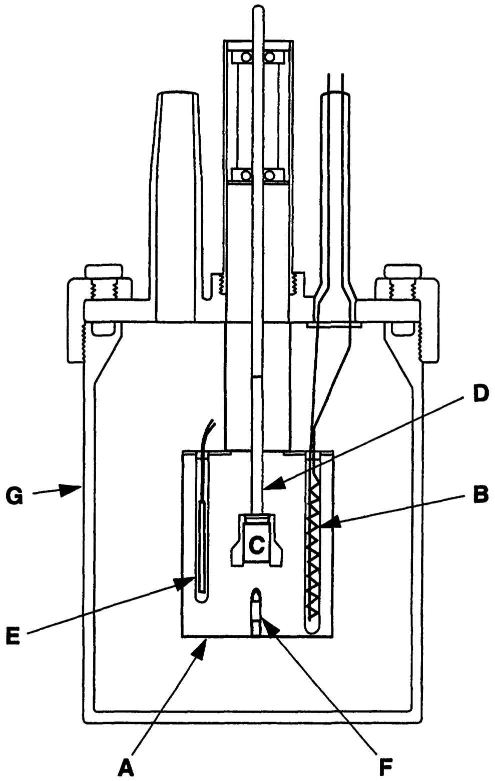

FIG. 4. Diagram of a solution calorimeter. A, reaction vessel filled with solution; B, electrical calibration heater; C, ampoule containing sample to be dissolved or reacted; D, combined stirrer and ampoule holder; E, temperature-measuring device (thermistor, thermometer); F, spike on which ampoule is broken when stirrer is pushed down, thereby introducing sample into solution; G, outer shell of reaction vessel assembly. The entire apparatus shown in this figure sits in a temperature-controlled water bath.

Although the temperature in combustion calorimetric experiments invariably increases (such reactions are called exothermic), decreases in temperature are not uncommon in solution calorimetry. For example, dissolution of crystalline NaCl in water (an endothermic process) would cause the temperature to fall. As in other kinds of calorimetry, careful characterization of the sample under study and the products of reaction are *sine qua non.*

Calorimeters of the kind just described usually are operated at, or within 50 K of, room temperature because vapors of the aqueous solvent at higher temperatures are frequently corrosive. To circumvent that restriction, solution experiments can be, and are, carried out at much higher temperatures, but novel solvents are required. A survey of high-temperature solution calorimetry was given recently by Colinet and Pasturel (1994). They listed a large number of solvents used for different applications, including the liquid metals aluminum, copper, tin, lead, and bismuth. Molten alloys such as $Mn_{0.4}Ni_{0.6}$, and the molten mixed oxides $2PbO \cdot B_2O_3$, $3Na_2O \cdot 4MoO_3$, and $LiBO_2 \cdot NaBO_2$, have also been effective. Colinet and Pasturel (1994) compiled extensive lists of compounds and alloys for which $\Delta_f H_m^0$ has been determined by high-temperature solution calorimetry.

Conventional aqueous solution calorimetry is, as we have mentioned, carried out close to room temperature. Modern advances, however, have led to the construction of equipment that accommodates operating temperatures and pressures much higher than used heretofore. Such apparatus, which revealed unexpected behavior of water as a solvent, among other phenomena, have been described by Smith-Magowan and Wood (1981), Rogers and Pitzer (1981), and Busey *et al.* (1984).

Most of the calorimetric techniques described above consume several grams of substance during a single investigation. Nowadays, however, many compounds of interest (in the pharmaceutical industry, for instance) are extremely expensive, which means that just very small quantities are available for reaction calorimetry (a destructive technique). Accordingly, numerous efforts have been made to design calorimeters capable of accurate measurements on samples with masses of approximately a few milligrams. To reach that goal, the energy equivalent had to be reduced by several factors of 10. A succinct list of about a dozen microbomb calorimeters has been compiled by Månsson (1979).

6. APPLICATIONS OF THERMOCHEMICAL INFORMATION

6.1 Calorimetric Results

Let us suppose that the calorimetric measurements have been completed and all the criteria (purity of substance and reaction, etc.) that we have discussed have been satisfied. How do we proceed from there? We give the following illustrations from the contemporary literature.

6.1.1 Combustion Calorimetry Diogo *et al.* (1993) measured the standard massic energy of combustion $\Delta_c u^0$ of Buckminsterfullerene, C_{60}, with the objective of determining its standard molar enthalpy of formation, that is, the enthalpy of reaction for

$$60C(cr,graphite) \rightarrow C_{60}(cr). \qquad (32)$$

The combustion reaction was shown to proceed entirely as follows:

$$C_{60}(cr) + 60O_2(g) \rightarrow 60CO_2(g), \qquad (33)$$

and the authors found $\Delta_c u^0 = -(35\,924 \pm 16.8)\ J \cdot g^{-1}$, where the quantity after the ± is known as the uncertainty. Although this energy of combustion is the experimental result, it is of limited value *per se* and has to be recast as a molar quantity before further calculations can be performed with it. The molar mass of C_{60} is $720.66\ g \cdot mol^{-1}$, and the molar energy of combustion $\Delta_c U_m^0 = (720.66\ g \cdot mol^{-1})(-35\,923.6 \pm 16.8)\ J \cdot g^{-1} = -(25\,888\,702 \pm 12\,107)\ J \cdot mol^{-1}$ or, more compactly, $-(25\,888.7 \pm 12.1)\ kJ \cdot mol^{-1}$. Next, the molar energy of reaction $\Delta_c U_m^0$ is changed to the molar enthalpy of reaction $\Delta_c H_m^0$ on the basis of the following equation:

$$\Delta_c H_m^0 = \Delta_c U_m^0 + \Delta\nu^g RT, \qquad (34)$$

where $\Delta\nu^g$ represents $\nu(CO_2,g) - \nu(O_2,g)$, ν

denoting the stoichiometric number. It so happens in this example that $\nu(CO_2) = \nu(O_2) = 60$; thus, $\Delta\nu^g = 0$ and, from Eq. (34), $\Delta_c H_m^0 = -(25\,888.7 \pm 12.1)\ kJ\cdot mol^{-1}$. One other piece of information is required: $\Delta_f H_m^0(CO_2,g)$ is found in the critical tabulations mentioned earlier to be $-(393.51 \pm 0.13)\ kJ\cdot mol^{-1}$. Thus, the following are available:

$$C_{60}(cr) + 60O_2(g) \rightarrow 60CO_2(g),\quad \Delta_c H_m^0 = -(25\,888.7 \pm 12.1)\ kJ\cdot mol^{-1}; \tag{35}$$

$$60C(cr,graphite) + 60O_2(g) \rightarrow 60CO_2(g),\quad \Delta_c H_m^0 = 60 \times [-(393.51 \pm 0.13)]\ kJ\cdot mol^{-1}. \tag{36}$$

By appropriate combination of Eqs. (35) and (36), one obtains

$$60C(cr,graphite) \rightarrow C_{60}(cr),\quad \Delta_f H_m^0 = (2278.1 \pm 14.4)\ kJ\cdot mol^{-1}. \tag{37}$$

Note that we have introduced the symbol $\Delta_c H_m^0$ in several places; the subscript c indicates that the thermodynamic quantity refers to a combustion reaction; in other words, $\Delta_c H_m^0$ is another special case of $\Delta_r H_m^0$. This calculation illustrates an application of Hess's law.

Fluorine-combustion calorimetry was discussed in Sec. 5.2. That technique was used (O'Hare *et al.*, 1992) to determine $\Delta_c u^0 = -(37\,943 \pm 8)\ J\cdot g^{-1}$ at $T = 298.15$ K for the following reaction:

$$S(cr,rhombohedral) + 3F_2(g) \rightarrow SF_6(g), \tag{38}$$

the rhombohedral form being the standard reference state of sulfur. Taking the molar mass of S as 32.066 $g\cdot mol^{-1}$, one calculates $\Delta_c U_m^0 = [-(37\,943 \pm 8)\ J\cdot g^{-1}] \times (32.066\ g\cdot mol^{-1}) = -(1\,216\,680 \pm 257)\ J\cdot mol^{-1} = -(1216.7 \pm 0.3)\ kJ\cdot mol^{-1}$. For reaction (38), $\Delta\nu^g = 1 - 3 = -2$; thus $\Delta\nu^g RT = -2 \times (8.314\,51\ J\cdot K^{-1}\cdot mol^{-1}) \times (298.15\ K) = -5\ kJ\cdot mol^{-1}$. Therefore, $\Delta_c H_m^0 = -(1216.7 \pm 0.3)\ kJ\cdot mol^{-1} - 5\ kJ\cdot mol^{-1} = -(1221.7 \pm 0.3)\ kJ\cdot mol^{-1}$. Since Eq. (38) also represents the formation of $SF_6(g)$ in its standard state from the elements in their standard states, $\Delta_f H_m^0(SF_6,g,298.15\ K) = -(1221.7 \pm 0.3)\ kJ\cdot mol^{-1}$.

6.1.2 Solution Calorimetry

The choice of a calorimetric method, where more than one is accessible, or seems to be, is usually dictated by the straightforwardness of the chemical reactions available. Thus, for example, a determination of $\Delta_f H_m^0(BaO,cr)$ appears, at first sight, to be a candidate for combustion calorimetry in oxygen. However, barium metal, Ba, could well form BaO_2 as well as BaO, thus presenting the kind of difficult challenge in analytical chemistry to which we alluded earlier. Furthermore, low-melting metals such as Ba tend not to react cleanly in combustion calorimetry. They melt as the oxidation proceeds, splatter over the interior surface of the bomb, and thereby cause premature quenching of the reaction. Although the analytical problems in this example would probably not be insuperable, solution calorimetry presents a much more attractive alternative, because BaO dissolves readily in dilute mineral acids.

Cordfunke *et al.* (1990) took advantage of that behavior. They performed two sets of measurements: of the enthalpies of reaction of Ba and of BaO with dilute (≈1 $mol\cdot dm^{-3}$) hydrochloric acid, HCl(aq):

$$Ba(cr) + 2HCl(aq) \rightarrow BaCl_2(aq) + H_2(g),\quad \Delta_r H_m^0 = -(535.29 \pm 1.72)\ kJ\cdot mol^{-1}; \tag{39}$$

$$BaO(cr) + 2HCl(aq) \rightarrow BaCl_2(aq) + H_2O(aq),\quad \Delta_r H_m^0 = -(273.08 \pm 0.24)\ kJ\cdot mol^{-1}. \tag{40}$$

Subtracting Eq. (40) from Eq. (39) yields

$$Ba(cr) + H_2O(l) \rightarrow BaO(cr) + H_2(g),\quad \Delta_r H_m^0 = -(262.21 \pm 1.74)\ kJ\cdot mol^{-1}. \tag{41}$$

Next, Eq. (41) and the following are combined:

$$H_2(g) + (1/2)O_2(g) \rightarrow H_2O(l),\quad \Delta_r H_m^0 = -(285.83 \pm 0.04)\ kJ\cdot mol^{-1}, \tag{42}$$

to yield

$$Ba(cr) + (1/2)O_2(g) = BaO(cr),\quad \Delta_r H_m^0 = -(548.04 \pm 1.74)\ kJ\cdot mol^{-1}. \tag{43}$$

The $\Delta_r H_m^0$ for Eq. (42), identical to $\Delta_f H_m^0(\mathrm{H_2O,l})$, was obtained from standard reference sources cited earlier. Note, also, that $\Delta_r H_m^0$ for reaction (43) is identical to $\Delta_f H_m^0(\mathrm{BaO,cr,298.15\ K})$.

6.1.3 A "Third-Law" Calculation of $\Delta_f H_m^0$ Binary silicides are usually thought of as refractory substances, but at sufficiently high temperatures, they are known to break down. A thermodynamic study of one such material, pentatungsten trisilicide ($\mathrm{W_5Si_3}$), has been described by Kematick (1993). Heated to temperatures in the vicinity of 2000 K, it decomposes as follows:

$$\mathrm{W_5Si_3(s) \rightarrow 5W(s) + 3Si(g)}. \qquad (44)$$

Kematick determined the equilibrium vapor pressure of Si(g) as a function of temperature for the preceding reaction, and from it, as outlined in Eqs. (11) and (12), deduced the relation

$$\Delta_r G_m^0/(\mathrm{kJ\cdot mol^{-1}}) = 1447.2 - 0.4077(T/\mathrm{K}). \qquad (45)$$

At the mean experimental temperature, therefore, $\Delta_r G_m^0(1900\ \mathrm{K}) = 672.6\ \mathrm{kJ\cdot mol^{-1}}$. As outlined in Eq. (16), the following relation holds for reaction (44):

$$\begin{aligned}\Delta_r H_m^0(298.15\ \mathrm{K}) = {}& \Delta_r G_m^0(1900\ \mathrm{K}) \\ &+ 1.9[5\Phi_m^0(\mathrm{W,s,1900\ K}) \\ &+ 3\Phi_m^0(\mathrm{Si,g,1900\ K}) \\ &- \Phi_m^0(\mathrm{W_5Si_3,s,1900\ K})\}.\end{aligned} \qquad (46)$$

We take, from compilations mentioned earlier, values of 58.99 $\mathrm{J\cdot K^{-1}\cdot mol^{-1}}$ for $\Phi_m^0(\mathrm{W})$; 189.52 $\mathrm{J\cdot K^{-1}\cdot mol^{-1}}$ for $\Phi_m^0(\mathrm{Si,g})$; and 431.6 $\mathrm{J\cdot K^{-1}\cdot mol^{-1}}$ for $\Phi_m^0(\mathrm{W_5Si_3})$. Therefore, $\Delta_r H_m^0 = (1493 \pm 32)\ \mathrm{kJ\cdot mol^{-1}}$ for reaction (44) at $T = 298.15$ K, or

$$\mathrm{5W(s) + 3Si(g) \rightarrow W_5Si_3(s)}, \quad \Delta_r H_m^0 = -(1493 \pm 32)\ \mathrm{kJ\cdot mol^{-1}}. \qquad (47)$$

Standard compilations give for the sublimation reaction at $T = 298.15$ K

$$\mathrm{3Si(s) \rightarrow 3Si(g)}, \quad \Delta_r H_m^0 = 3 \times (450 \pm 8)\ \mathrm{kJ\cdot mol^{-1}}. \qquad (48)$$

By combining reactions (47) and (48), one obtains

$$\mathrm{5W(s) + 3Si(s) \rightarrow W_5Si_3(s)}, \quad \Delta_r H_m^0 = -(143 \pm 40)\ \mathrm{kJ\cdot mol^{-1}}. \qquad (49)$$

In other words, $\Delta_f H_m^0(\mathrm{W_5Si_3,s,298.15\ K}) = -(143 \pm 40)\ \mathrm{kJ\cdot mol^{-1}}$. This example shows how thermodynamic properties at room temperature or, indeed, any other temperature can be deduced from high-temperature studies.

GLOSSARY

Chemical Equilibrium: The reaction A + B $\rightleftarrows$ C + D is said to be in equilibrium when the rate of the forward reaction between A and B is equal to the rate of the reverse reaction between C and D.

Electrochemical Cell: There are two types of electrochemical cell. Spontaneous chemical reactions occur within the galvanic cell, while in the electrolytic cell, reactions result from an external potential difference.

Enthalpy: The enthalpy H of a system is defined as $H = U + pV$, where U is the energy (or internal energy) and pV denotes the pressure–volume work energy.

Entropy: The difference in entropy S between the states a and b of a system is given by $\Delta S = \int_a^b dq_{\mathrm{rev}}/T$. Thus, to compute ΔS, imagine moving the system from state a to state b via a reversible path, and for each infinitesimal step, computing dq/T, the sum of which is ΔS.

Equilibrium Constant: In a reaction $a\mathrm{A(g)} + b\mathrm{B(g)} \rightarrow c\mathrm{C(g)} + d\mathrm{D(g)}$ in which all the gases are at thermodynamic equilibrium, the equilibrium constant is given by $K = p(\mathrm{C})^c p(\mathrm{D})^d / p(\mathrm{A})^a p(\mathrm{B})^b$.

Fugacity: The molar Gibbs energy of a real gas G_m is related to the standard Gibbs energy G_m^0 by $G_m = G_m^0 + RT\ln(f/p^0)$, where the fugacity is denoted by f and the standard pressure by p^0. As the pressure of a system approaches zero, the gas approaches ideal behavior, and the fugacity approaches the pressure. Thus, in the limit of zero pressure, $p = f$. Units of f and p are the same.

Molar Quantity: A thermodynamic quantity for 1 mol of substance.

Pressure–Volume Work Energy: Work performed in the expansion or compression of a substance, given by the product of the pressure and the change in volume.

INTRODUCTION

Thermodynamics is the science of heat: its transformations and the relations among the various physical quantities ("thermodynamic functions") that arise in its definition and study. It is built upon two laws of nature—the first and second laws of thermodynamics—both of universal validity so far as is now known. Additional properties of the functions that arise in the second law, beyond those properties implied by that law itself, are also recognized and are often referred to as the "third law," or, as in this article, as the "Nernst heat theorem." Sometimes one speaks also of the "zeroth" law, which is a recognition of the existence of temperature as a measure of "degree of hotness." It is an important concept but one that will here be taken as primitive—not requiring definition. Our account of thermodynamics begins with it.

1. THE FIRST LAW

1.1 Temperature

We recall that there are elementary devices—thermometers, such as the familiar mercury-in-glass thermometer—that measure degree of hotness, or temperature, and express that measure on an empirical temperature scale such as the centigrade (Celsius) or Fahrenheit scale. When two bodies of different temperatures are put in intimate thermal contact, the temperature of the warmer body falls and that of the cooler body rises until the temperatures become equal, and then they no longer change. By analogy with the flow of water between two communicating vessels, equalizing the height of the water in the two and then ceasing, one says that "heat," thought of as a caloric fluid, flows from a warmer body to a cooler one with which it is in contact, the flow ceasing only when the respective temperatures have become equal. But that is just a colloquialism; there is no such fluid. One of the accomplishments of thermodynamics is to have given an objective definition of the heat that flows from warmer to cooler bodies and causes their temperatures to become equal.

A *system* (i.e., any object of interest, everything else constituting the *surroundings* of that system) may be thermally insulated from its surroundings, so as to have no tendency to reach temperature equality with

them on practical time scales. Then "no heat flows" into or out of the system. Any changes that occur within the system or any processes to which the system is subject under such conditions are said to be *adiabatic.*

1.2 Work

One (i.e., the surroundings) may do work on a system or a system may do work on its surroundings. Work may be of many kinds: it may be pressure–volume work, in which a volume changes against an opposing pressure, or stress–strain work, or mass × the difference of gravitational potential between two heights, or electric field × electric polarization, or magnetic field × magnetization, etc. Of these, pressure–volume (p-V) work is representative and is what is mostly referred to here for illustrating general principles.

We adopt the convention of saying that w is the work done on a system by its surroundings and that at the same time the work done on the surroundings by the system is $-w$; so that if $w > 0$, work is in fact done on the system, while if $w < 0$, work is in fact done by the system.

In general when a system undergoes any process, as when it does work or has work done upon it or when heat flows into or out of it, its state, or condition, changes. There are conceptually important processes that are said to be *reversible.* In such a process—which is an idealization that may be closely approached in practice but not rigorously achieved—if at any moment the process were interrupted and the system were thermally and mechanically isolated from its surroundings, no further changes would occur in the system: it would be in a state of equilibrium. Thus, in undergoing a reversible process a system passes through states of equilibrium and is at every moment in such a state. It is because in undergoing reversible processes a system would be always in a state of equilibrium that such idealized processes play an important conceptual role in equilibrium thermodynamics.

(Sometimes one uses the term "quasistatic" to denote a process in which a system passes through a sequence of equilibrium states and reserves the word "reversible" for a process that can be reversed so as to return both the system and its surroundings to their initial states, but in this article we are not so formal and simply use "reversible" to mean either or both as the occasion requires.)

The work done on or by a system in a reversible process may be represented graphically. When an isotropic fluid undergoes a reversible expansion or compression, for example, its pressure p is well defined at each moment, and no distinction need be made between the internal and external pressure, so that the variation of p with V in the process may be represented by a curve in the p-V plane, as illustrated in Fig. 1. The work $-w$ done by the system in expanding from the volume V_A to the volume V_B is

$$-w = \int_{V_A}^{V_B} p dV \tag{1}$$

and is therefore the area under the curve, indicated by the shading in the figure.

This work $-w$ is the sum (integral) of the infinitesimal increments of work done during all the infinitesimal volume changes dV that occur between V_A and V_B. This infinitesimal element of reversible work is

$$đw_{\text{rev}} = -pdV; \tag{2}$$

the reason for the line drawn through the stem of the d in $đw_{\text{rev}}$ will be apparent presently.

For any process, even a reversible one, the work w that is done depends not only on the

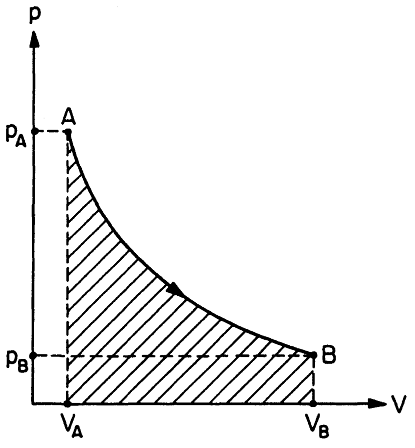

FIG. 1. Expansion from state A to state B, represented by a curve in the pressure (p)–volume (V) plane.

initial and final states of the system but also on the details of the process. For example, the same change from the system state A to state B pictured in Fig. 1 could also be brought about by an alternative reversible process represented by a different curve connecting A and B, the area under which could differ from that in Fig. 1.

A process in which a system ends in the same state in which it started is termed *cyclic.* A reversible cyclic process is represented by a closed curve in the p-V plane, as illustrated in Fig. 2. If the system traverses the cycle clockwise, the work *it does* along the upper part of its path is the area under that part, while the work *done on it* along the lower part is the area under that part; so the net work $-w$ done by the system is the area enclosed by the cycle:

$$-w = \oint p\,dV = \text{area enclosed}. \tag{3}$$

If the cycle is traversed counterclockwise, that area is the net work w done *on* the system. These relations apply even for paths of more complicated shape than that in Fig. 2, as long as they are closed curves.

1.3 Energy and Heat

An *adiabatic* process, one resulting in an adiabatic change in the state of a system, was defined at the end of Sec. 1.1. In Sec. 1.2 it was remarked that the work w done on a system depends, in general, not merely on the initial and final states of the system in the process the system undergoes but also on the details of that process. The *first law of thermodynamics* is the universally verified observation that the work w_{ad} done on a system in an adiabatic process does indeed depend *only* on the initial and final states of the system and is otherwise independent of the details of the process.

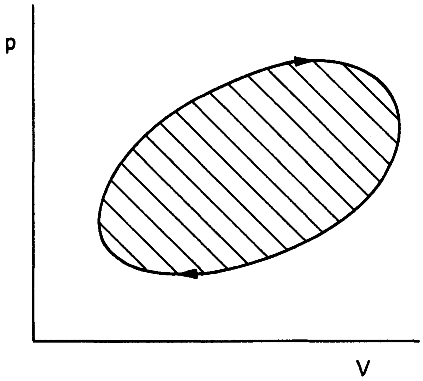

FIG. 2. A reversible cyclic process in which the cycle is traversed clockwise. The work $-w_{\mathrm{rev}}$ done by the system is the area enclosed by the curve, shown shaded.

Thus, there is a function of the system's state—we call it the system's *energy* and symbolize it by U—such that

$$w_{\mathrm{ad}} = U_{\mathrm{B}} - U_{\mathrm{A}} = \Delta U, \tag{4}$$

where U_{B} and U_{A} are the energies of the system in its final state B and initial state A, respectively. The symbol Δ means "change in"; ΔU is the change in the system's energy when the system undergoes an adiabatic process in which work w_{ad} is done on it (or when it does work $-w_{\mathrm{ad}}$). The same change in state, A → B, with, therefore, the same change ΔU in the system's energy, may be brought about by processes that are not adiabatic. The work w done on the system is then not in general equal to ΔU. The difference between w and ΔU is now the *definition* of the *heat* q absorbed by the system during the process:

$$\Delta U = q + w; \tag{5}$$

i.e., q is the difference between the work that *would* have been done on the system in changing its state from A to B *had* that change been brought about by an adiabatic process, and the work w that actually *was* done. If the process is adiabatic, then $w = w_{\mathrm{ad}}$ and $q = 0$. When $q > 0$, one says that the system has absorbed heat q, or that there has been a flow of heat q into the system from its surroundings; when $q < 0$, one says that heat q was evolved, or flowed from the system to the surroundings. With this view, Eq. (4) is a law of nature—the first law of thermodynamics—while Eq. (5) is the definition of heat.

Since w depends not only on the initial and final states of the system but also on the details of the process in which the system's state changes, while ΔU depends only on the initial and final states and not on the details of the process, q, too, must depend on the details of the process. The net work w in a process is the sum (integral) of the infinitesimal increments of work $\text{đ}w$ in each infinitesimal part of the process, where, as in Eq. (2), we put a line through the stem of the d in $\text{đ}w$; and likewise the net heat absorbed, q, is the sum of the infinitesimal increments of absorbed heat, $\text{đ}q$:

$$w = \int_A^B \text{đ}w, \qquad q = \int_A^B \text{đ}q. \tag{6}$$

The symbols đ indicate *inexact* differentials: the integrals depend not only on the initial and final states A and B but also on the details of the process. That, we saw, is true even for reversible processes, for which $\text{đ}w$ is given by Eq. (2): pdV is an *inexact* differential in the two variables p and V. This is to be contrasted with the *exact* differential dU, which is such that

$$\Delta U = U_B - U_A = \int_A^B dU \tag{7}$$

independently of the details of the path between the initial and final states A and B. The inexactnesses in $\text{đ}w$ and $\text{đ}q$ cancel in the combination

$$dU = \text{đ}w + \text{đ}q. \tag{8}$$

When the only work considered is p-V work, if the system's volume is fixed, the system is essentially mechanically isolated from its surroundings, and $w = 0$ in any process it then undergoes. Thus,

$$\Delta U = q \quad \text{(constant volume).} \tag{9}$$

We define another function of the state of the system—the *enthalpy* H—by

$$H = U + pV. \tag{10}$$

If a system is confined under a fixed pressure p then $w = -p\Delta V = -\Delta(pV)$, and so, from Eqs. (5) and (10),

$$\Delta H = q \quad \text{(constant pressure).} \tag{11}$$

2. THE SECOND LAW

2.1 Spontaneous Processes

One recognizes many processes in nature that occur spontaneously, i.e., without the intervention of an outside agency, so that they would occur even in a system that was thermally and mechanically isolated from its surroundings. One example is the spontaneous flow of heat from a warmer to a cooler body already referred to. Another is the diffusion of a substance from a region in which it is present at high concentration to a region in which its concentration is lower. Any such process is characterized by an inexorable drive to a condition of equilibrium, when the process then ceases.

In each of the processes carried out as described, no work is done by the system on its surroundings, but the same change in the system's state may be made to occur indirectly in such a way as to be a source of work. In the first example referred to above, let the two bodies ("heat reservoirs") be kept apart so that heat does not flow directly from one to the other. Then immerse in the warmer reservoir a system ("engine") consisting of a gas in a cylinder fitted with a movable piston and initially at a temperature between that of the two reservoirs (Fig. 3). The gas is allowed to expand as it warms, and the moving piston, mechanically coupled to the surroundings, may do work. The cylinder

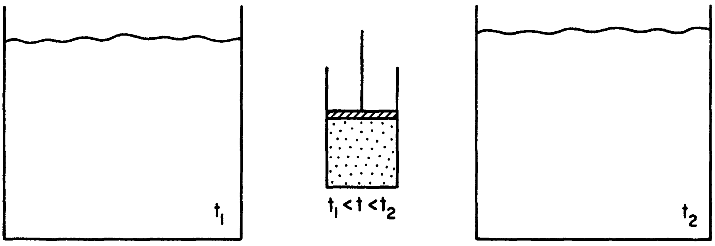

FIG. 3. Heat reservoirs at temperatures $t_1 < t_2$ and a gas confined in a cylinder at an intermediate temperature t.

is then removed from the warmer reservoir and immersed in the cooler, where the gas is allowed to contract, while the now receding piston (the sense of the coupling having in the meantime been switched) again does work. Once the cylinder and gas have been cooled to their initial temperature and the piston is back to its original position, the engine is removed from the cooler reservoir.

There has been no net change in the state of the engine; the only net changes have been the absorption of heat from the warmer reservoir, thus lowering its temperature, the conversion of some of that heat into work on the environment, and the discharge of heat into the cooler reservoir, thus warming it. The spontaneous tendency of heat to flow from high to low temperatures was taken advantage of to do work, but it was at the expense of the respective temperatures' being now closer to equality, i.e., of a spontaneous process's having run part way down.

That work can be done only at the expense of spontaneous processes' running down is a universally observed principle: the second law of thermodynamics.

2.2 Absolute Temperature

In the example in Sec. 2.1 in which the spontaneous flow of heat from high to low temperature was made to do work, it was essential, in restoring the engine to its initial state in the final stage, that it be cooled at the lower temperature. According to the second law it would have been impossible for the engine to have undergone such a cyclic process, the only result of which was the absorption of heat from the higher-temperature reservoir and its conversion to work, without some heat's having also been conducted to the lower-temperature reservoir. From this observation alone one may follow a classic route to the concepts of entropy and absolute temperature.

The argument, which may be found in standard references (see Further Reading), typically proceeds via the consideration of a particular reversible cyclic process called a *Carnot cycle,* represented in the *p*-*V* plane in Fig. 4. Adiabatic steps BC and DA alternate with isothermal steps AB at the constant temperature t_1 and CD at the constant temperature t_2. No heat is absorbed—$q = 0$—in the adiabatic steps. The heats absorbed in the isothermal steps are q_{t_1} on AB and q_{t_2} on CD, and are opposite in sign. The figure (although not the principle to be derived) assumes a system with positive coefficient of thermal expansion, in which case t_1 is a higher temperature than t_2, and in traversing the cycle clockwise, as in the figure, the system absorbs heat $q_{t_1} > 0$ at the higher temperature and evolves heat $-q_{t_2} > 0$ at the lower temperature. In traversing the cycle once in the indicated sense, the system does positive work $-w$ given by

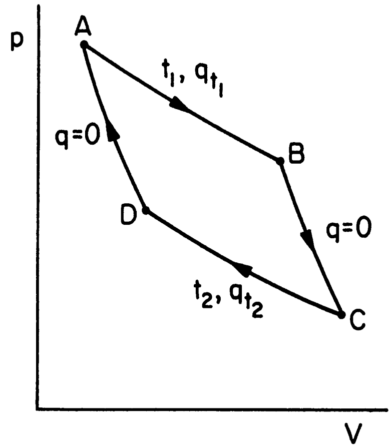

FIG. 4. A reversible Carnot cycle represented in the pressure–volume plane. Adiabatic ($q = 0$) steps BC and DA alternate with isothermal steps AB and CD at the constant temperatures t_1 and t_2, respectively. The heats q_{t_1} and q_{t_2} absorbed in the isothermal steps are opposite in sign.

$$-w = q_{t_1} + q_{t_2} = q_{t_1} - (-q_{t_2}). \tag{12}$$

In classical thermal engineering one defines the *efficiency e* of this Carnot cycle as the fraction of the heat absorbed at the higher temperature that is converted to work:

$$e = \frac{-w}{q_{t_1}} = \frac{q_{t_1} - (-q_{t_2})}{q_{t_1}} = 1 - (-q_{t_2})/q_{t_1}. \tag{13}$$

This is always less than 1 because some heat $-q_{t_2} > 0$ must be discharged at the lower temperature, and it is always greater than 0 because $-w$ and q_{t_1} are both positive. The argument then proceeds by showing that the efficiency *e* depends *only* on the two temperatures t_1 and t_2; two systems undergoing reversible Carnot cycles between the same two temperatures t_1 and t_2 must have the same efficiency. The main idea is that if it were not so, one could run the more efficient process clockwise and the less efficient one counterclockwise in such a way as to absorb heat at the higher temperature and convert all of it to work, with no net heat discharged at the lower temperature—which would violate the second law.

Let t_0 now be an arbitrary fixed reference temperature. Then by the principle just discussed, and from (13), when t_0 and any other temperature t are the two temperatures in a reversible Carnot cycle, $|q_t/q_{t0}|$ depends only on t, and so does any fixed constant multiple c of $|q_t/q_{t0}|$. Any such multiple, with arbitrary choices of t_0 and c, may be defined to be the *absolute* temperature $T(t)$ at the (empirical) temperature t:

$$T(t) = c|q_t/q_{t0}|. \tag{14}$$

For fixed t_0 and c this is then a function of t alone, independently of the system undergoing the cycle. The arbitrary constant $c = T(t_0)$ determines the sign of T and the size of the "degree" on this temperature scale.

Taking t_0 to be the triple point of water that has the isotopic composition of ocean water, and $c = 273.16$, defines the Kelvin scale of absolute temperature, the size of the degree on which is the same as that on the empirical Celsius scale. With that same t_0, the choice $c = (9/5) \times 273.16 = 491.69$ defines the Rankine scale of absolute temperature, the size of the degree on which is the same as that on the empirical Fahrenheit scale. Temperatures T_K and T_R on the Kelvin and Rankine scales are then related to temperatures $t_{°C}$ and $t_{°F}$ on the Celsius and Fahrenheit scales by the empirical rules

$$\begin{aligned} T_K &= t_{°C} + 273.15 \\ T_R &= t_{°F} + 459.68 \end{aligned} \tag{15}$$

(since the triple point of water lies 0.0075 °C or 0.0135 °F above the 1-atm freezing point).

By tradition c, hence T, is chosen positive, although it need not have been. Throughout this account the traditional choice is made without further comment. Some inequalities to be derived later would have had their sense reversed if absolute temperature had been chosen to be negative instead of positive.

2.3 Entropy

If T_1 and T_2 are the absolute temperatures in the two isothermal steps of a reversible Carnot cycle, and if q_{T_1} and q_{T_2} are the heats absorbed in those two steps, one of these being positive and one negative, then from the definition of the absolute temperature in Eq. (14),

$$q_{T_1}/T_1 + q_{T_2}/T_2 = 0. \tag{16}$$

One next considers a general reversible cycle in the p-V plane such as that in Fig. 2, now in Fig. 5. The plane may be imagined filled with infinitely closely spaced adiabats, such that for each point C on the cycle there is another point D on it accessible from C by a reversible adiabatic process, and likewise for the pair of points A and E on the cycle, close to C and D. These two adiabats may then be connected by the short isothermal segments DF and BC, as shown in the figure. BCDF is then a reversible Carnot cycle, which we allow the system to traverse in the same sense in which it traverses its original cycle.

The classical argument then proceeds by showing that in the limit in which the grid of adiabats in the p-V plane is made infinitely fine, the two ratios q_{AC}/q_{BC} and q_{DE}/q_{DF} both approach 1. But, since q_{BC} and q_{DF} are the heats absorbed in the two isothermal

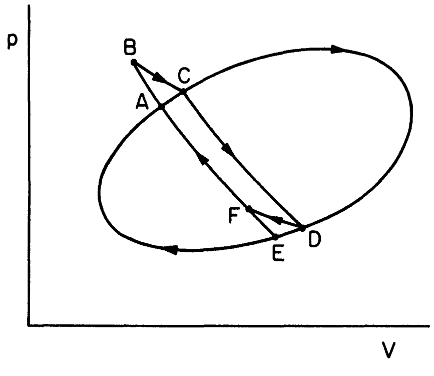

FIG. 5. A general reversible cycle on which are superimposed two closely spaced adiabats CD and EB connected by segments of isotherms BC and DF, so that BCDF is a Carnot cycle.

steps of a reversible Carnot cycle, they satisfy (16). Therefore, so do q_{AC} and q_{DE}:

$$q_{AC}/T_C + q_{DE}/T_D = 0, \tag{17}$$

where T_C is the absolute temperature of the system in the state C (or in any state infinitesimally distant from C, such as A) and T_D is that in state D.

The same relation holds for all such pairs of points C and D around the whole cycle, each such pair lying on an adiabat. Each of the corresponding terms q_{AC}/T_C is of the form $đq_{rev}/T$, where $đq_{rev}$ is the infinitesimal heat absorbed by the system in that infinitesimal part of the reversible cycle and T is the system's absolute temperature at that point. Thus, summing over the whole cycle,

$$\oint \frac{đq_{rev}}{T} = 0. \tag{18}$$

Now let $(PQ)_1$ and $(PQ)_2$ be any two distinct reversible paths connecting two states P and Q. Then form (18),

$$\underset{\text{(on path 1)}}{\int_P^Q \frac{đq_{rev}}{T}} + \underset{\text{(on path 2)}}{\int_Q^P \frac{đq_{rev}}{T}} = 0 \tag{19}$$

because following path 1 from P to Q and path 2 from Q to P constitutes a reversible cycle. Changing the direction in which a reversible path is traversed changes the sign of the heat $đq_{rev}$ absorbed along each infinitesimal element of the path, so (19) is equally well

$$\underset{\text{(on path 1)}}{\int_P^Q \frac{đq_{rev}}{T}} = \underset{\text{(on path 2)}}{\int_P^Q \frac{đq_{rev}}{T}}. \tag{20}$$

But paths 1 and 2 are *any* two reversible paths connecting states P and Q. Therefore, (20) implies that

$$\int_P^Q \frac{đq_{rev}}{T} \tag{21}$$

is independent of the path; it depends only on the initial and final states P and Q. It is therefore the change ΔS in some function S of the state of the system:

$$\Delta S = \int \frac{đq_{rev}}{T}, \tag{22}$$

where the integral extends from the initial to the final state and is independent of the path that connects them.

The state function S is the entropy. The second law of thermodynamics has thus been seen to imply the existence of two functions of the state of a system, absolute temperature and entropy, of which the former is a function only of the system's (empirical) temperature and not of any other variable defining the system's state.

Since ΔS depends only on the initial and final states of the system, its value is independent of the nature of the process by which the change in state is effected and, in particular, is independent of whether the process is reversible or not. The meaning of (22) is that the difference in entropy $\Delta S = S_Q - S_P$ between two specified equilibrium states P and Q of a system, while independent of the nature of the process P → Q, may be calculated by Eq. (22), with $đq_{rev}$ the infinitesimal heat the system *would* absorb during an infinitesimal stage of a *hypothetical reversible* process that takes it from P to Q, and T is what the system's absolute temperature *would* be in that stage of the process.

Since ΔS is independent of the path, Eq. (22) implies that $T^{-1}đq_{rev}$ is an exact differential, dS:

$$\Delta S = \int dS, \qquad dS = \frac{1}{T}\,đq_{rev}. \tag{23}$$

In mathematical terms, $1/T$ is an integrating factor for the inexact differential $đq_{rev}$. When the only work done is pressure–volume work, so that $đw_{rev} = -pdV$, we have from (8) and (23)

$$đq_{rev} = dU + pdV = TdS; \tag{24}$$

i.e., $1/T$ is an integrating factor for the inexact differential $dU + pdV$, where the pressure $p = p(U,V)$ is some function of the system's state as defined by U and V. Mathematically, a differential in two variables always has an integrating factor, and in this case it would then have been some function of U and V; but the second law goes beyond this mathematical statement to assert that the integrating factor $1/T$ is not merely some function of the system's state as defined, for example, by the two variables U and V but is more specifically a function of only one variable, the system's temperature. When there is more than one reversible work term, the inexact differential $đq_{\text{rev}}$ ($= dU - đw_{\text{rev}}$) is a differential in more than two variables, and then mathematics alone no longer guarantees the existence of an integrating factor, while thermodynamics still asserts that there is one, and that it is $1/T$, a function only of the system's temperature. The second law is a law of nature, not of mathematics.

If a process is both adiabatic and reversible, then $đq = đq_{\text{rev}} = 0$, and so $dS = 0$; i.e., such a process is isentropic. A reversible adiabat, such as BC and DA in Fig. 4 and CD and EB in Fig. 5, is an isentrope.

2.4 Entropy of an Isolated System

Let A be a constrained equilibrium state of an isolated system. An example is an isolated system—a system thermally and mechanically isolated from its surroundings—consisting of two subsystems at different temperatures but thermally insulated from each other, so that there is no heat flow between the subsystems and their respective temperatures do not equalize. Another example is a thermally and mechanically isolated mixture of chemical substances that are potentially capable of reacting with each other but only in the presence of a catalyst, which is absent, so that no reaction takes place. Let B be a state obtained from A by the relaxation of one or more of the constraints while the system as a whole is still isolated. In the first example above, the subsystems may be put in thermal contact, so that heat flows between them and their temperatures approach equality. In the second example, introduce the catalyst so that reaction occurs and the system approaches chemical equilibrium.

As these examples show, each time a constraint is removed a spontaneous (hence irreversible) process A → B occurs in this otherwise isolated system, and the system's state becomes more nearly one of unconstrained equilibrium. In Fig. 6 there is indicated schematically, by hatch marks, such a spontaneous change from state A to state B of an isolated system. Then, with the system in state B, put it in contact with its surroundings and allow it to undergo a reversible adiabatic change to a state C, and then a reversible isothermal change from C to a state D that lies on the same reversible adiabat as state A, so that the reversible adiabatic process D → A then completes a cycle (Fig. 6).

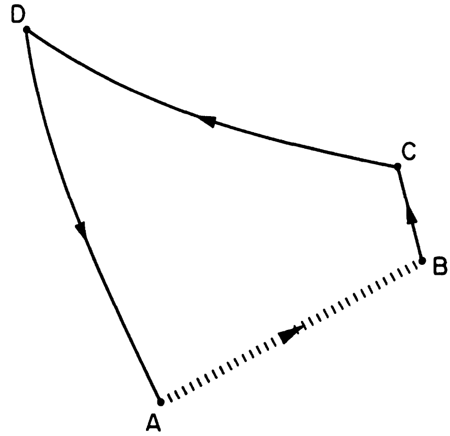

FIG. 6. A system, while isolated, undergoes an irreversible process A → B from a state of constrained equilibrium A to a less constrained or unconstrained state B; while B → C and D → A are reversible adiabatic processes and C → D is a reversible isothermal process at the temperature T.

In the original irreversible change from A to B, the system is isolated so that $q_{\text{AB}} = w_{\text{AB}} = 0$. No heat is absorbed in the adiabatic changes B → C and D → A, and so $q_{\text{BC}} = q_{\text{DA}} = 0$, and these are reversible adiabatic changes, hence isentropic, and so $\Delta S_{\text{BC}} = \Delta S_{\text{DA}} = 0$ as well. Let T be the constant absolute temperature in the reversible isothermal process C → D, so that $\Delta S_{\text{CD}} = q_{\text{CD}}/T$. This q_{CD} is the only heat absorbed or evolved by the system in the entire cycle. From this picture and principles already annunciated, one may conclude that the second law would be violated unless q_{CD} and the equivalent work $-w(=q_{\text{CD}})$ done by the system in the cycle were both negative, and that therefore the entropy change ΔS_{AB} for the process A → B were positive:

$$\Delta S_{\text{AB}} > 0. \tag{25}$$

The principle expressed in (25) is that as constraints in an isolated system are relaxed and the system then approaches equilibrium by irreversible processes occurring in it, its entropy increases. As a corollary, the condition that a process occurring in an isolated system be spontaneous is that, as a result of the process, the system's entropy increase. An isolated system at full, unconstrained equilibrium then already has its maximum possible entropy, so that $dS = 0$ for any virtual infinitesimal change that would occur in it while it remains isolated.

2.5 $S = S(U,V,M_1,M_2,\ldots)$

The volume V of a system is the sum of the volumes of its parts; V is then said to be an extensive variable. The mass M of a system is likewise the sum of the masses of its parts, and so M is also an extensive variable, and the same is true, too, of each of the separate masses M_1, $M_2, \ldots$ of the different chemical substances 1, 2, . . . of which the system is composed. The energy U is also extensive: the net heat (positive or negative) absorbed by a system from its surroundings and net work (positive or negative) done on the system by its surroundings, in any process, is the sum of the heats absorbed from the surroundings by, and work done by the surroundings on, the component subsystems, so that ΔU for the system is the sum of the ΔU's of the system's component parts. (The heat absorbed by one subsystem from another and the work done by one on another need not be considered in this arithmetic because their net contribution to the sum of the energy changes suffered by all the subsystems together is nil.) Similarly, the entropy S is extensive: $đq_{\text{rev}}$ in (22) is the sum of the infinitesimal reversible heats absorbed from (or evolved to) the surroundings by the system's component parts.

When the only work is p-V work, so that $đw_{\text{rev}} = -pdV$, a system's equilibrium state is fixed by specifying its energy, its volume, and its chemical composition. (These are the variables that would be conserved if the system were isolated; the constancy of V would be a consequence of the mechanical isolation, which would be achieved by rigid container walls, ensuring that no p-V work is done on or by the system.) The entropy, which depends on the state of the system, may then be taken to be a function of those same variables: $S = S(U,V,M_1,M_2,\ldots)$. (The composition is specified by the masses M_1, $M_2, \ldots$ of as many *independent* chemical components as there are. What one means by independent components is stated more precisely and illustrated later, in connection with the discussion of chemical equilibrium at the end of Sec. 3.3.)

If there were more than one kind of work possible, there would be additional extensive variables analogous to V required to define the state, and S would be a function of those also. Every system has its own $S(U,V,M_1,M_2,\ldots)$ expressing its equilibrium entropy as a function of its energy, volume, and chemical composition. The relation

$$S = S(U,V,M_1,M_2,\ldots) \tag{26}$$

may be said to be that system's equation of state (thus extending somewhat the more traditional use of that term).

We cannot deduce a system's equation of state from thermodynamics alone (that is the domain of statistical mechanics), but we can, from general principles, deduce an important property of the function $S(U,V,\ldots)$. Let A and B be two equilibrium states of a system Σ. Take a sample $\Sigma_{\alpha,\mathrm{A}}$ of the system Σ in its state A, this sample consisting of a fraction α of the original system in state A, so that all the extensive functions S, U, V, $M_1, \ldots$ of the sample are equal to the same fraction α of those variables in the original system. Let $\Sigma_{1-\alpha,\mathrm{B}}$, likewise, be a fractional sample of Σ in state B, the fraction now being $1 - \alpha$. Consider the composite system consisting of $\Sigma_{\alpha,\mathrm{A}}$ and $\Sigma_{1-\alpha,\mathrm{B}}$, and isolate it. If these two subsystems are not in contact, the entropy of the composite system, by extensivity, is $\alpha S(U_\mathrm{A},V_\mathrm{A},\ldots) + (1 - \alpha)S(U_\mathrm{B},V_\mathrm{B},\ldots)$, where $S(U,V,\ldots)$ is the entropy of the original system Σ as a function of its energy U, volume V, etc. If these subsystems are now put into contact with each other and the (isolated) composite system allowed to come to equilibrium, its entropy will increase, by the principle deduced in Sec. 2.4. But this equilibrated entropy is now that of the original system Σ in a new state C in which, because of the isolation of the composite system during its equilibration, $U_\mathrm{C} = \alpha U_\mathrm{A} + (1 - \alpha)U_\mathrm{B}$, etc. Thus, by the inequality just alluded to,

$$S[\alpha U_A + (1-\alpha)U_B, \ldots] > \alpha S(U_A, \ldots) + (1-\alpha)S(U_B, \ldots). \qquad (27)$$

This is true whatever the fraction α.

In mathematical terms, (27) says that $S(U,V,M_1,M_2,\ldots)$ is a *concave* (downward) function of its arguments U, V, M_1, M_2, ... At fixed V, M_1, ..., for example, the entropy $S(U)$ as a function of the remaining variable U will be as depicted in Fig. 7: for all U between U_A and U_B the curve $S = S(U)$ lies above the chord that connects U_A, S_A to U_B, S_B. The curve is pictured with positive slope at all U to be in accord with the usual convention of taking absolute temperatures $T > 0$ and with $\partial S/\partial U = 1/T$ from (24). More generally, the curve $S = S(U)$ in Fig. 7 would be a surface or hypersurface $S = S(U,V,M_1,M_2,\ldots)$ and the chord AB a corresponding plane or hyperplane intersecting it, and within the region of the intersection, the former would lie above the latter.

The downward concavity of $S(U,V,M_1, M_2,\ldots)$ requires that the eigenvalues of the symmetric matrix of second derivatives (Hessian matrix) of S,

$$\begin{pmatrix} \dfrac{\partial^2 S}{\partial U^2} & \dfrac{\partial^2 S}{\partial U \partial V} & \cdots \\ \dfrac{\partial^2 S}{\partial U \partial V} & \dfrac{\partial^2 S}{\partial V^2} & \cdots \\ \vdots & \vdots & \end{pmatrix}, \qquad (28)$$

be all negative. This implies, in particular, that the elements of the principal diagonal, $\partial^2 S/\partial U^2$, etc., are all negative:

$$\frac{\partial^2 S}{\partial U^2} < 0, \quad \frac{\partial^2 S}{\partial V^2} < 0, \quad \frac{\partial^2 S}{\partial M_1^2} < 0, \cdots. \qquad (29)$$

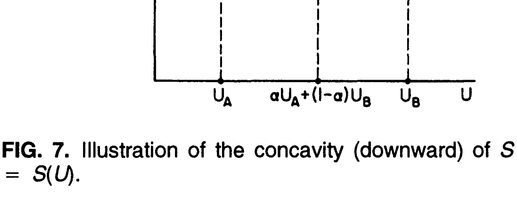

FIG. 7. Illustration of the concavity (downward) of $S = S(U)$.

While the conditions (29) are consequences of the concavity of $S(U,V,M_1,M_2,\ldots)$ they are not the totality of such consequences since the negativity of all the eigenvalues implies restrictions on the mixed second derivatives $\partial^2 S/\partial U \partial V$, etc., as well.

A necessary qualification of some of these statements should be noted. If the "states" A and B in (27) are two different phases in equilibrium (a liquid and its equilibrium vapor, for example), the inequality becomes an equality. To allow for such exceptional cases the "greater than" sign in (27) should be replaced by $\geq$, meaning "not less than." In the case of such phase equilibrium a portion of the entropy surface is a ruled surface, i.e., consists of straight line segments, at each point of which one of the eigenvalues of the Hessian matrix is then zero rather than strictly negative. Where three phases are in equilibrium, two of the eigenvalues are zero; etc. The associated eigenvectors, however, are not in general in the direction of any of the coordinate axes, so the inequalities (29) remain true.

Until now the systems considered have, implicitly, been closed systems, i.e., those in which no material substances enter or leave so that the variables M_1, M_2, ... are fixed. For such a system there need be no explicit reference to these composition variables, and one may take $S = S(U,V)$ with fixed M_1, M_2, ... understood. When such a system undergoes an infinitesimal change in its equilibrium state, the accompanying infinitesimal changes dS, dU, and dV in the entropy, energy, and volume are not independent but are related to each other by (24). We will use the conventional thermodynamic partial-derivative notation according to which $(\partial S/\partial U)_V$, for example, means the rate of change of S with U at fixed V and, implicitly, fixed M_1, M_2, ... as well. From (24) we then have the two thermodynamic identities (the first of these having already been noted)

$$\left(\frac{\partial S}{\partial U}\right)_V = \frac{1}{T}, \quad \left(\frac{\partial S}{\partial V}\right)_U = \frac{p}{T}. \qquad (30)$$

The ratio of the heat absorbed by a system in an infinitesimal process to the infinitesimal temperature rise dT that accompanies the absorption of that heat is called the *heat capacity* of the system; the greater the heat capacity the smaller the temperature rise for a given amount of heat absorbed. If the absorption of heat occurs at constant volume, this defines the constant-volume heat capacity, C_V. Since by (9) the infinitesimal heat absorbed is then dU, we have the thermodynamic identity

$$C_V = \left(\frac{\partial U}{\partial T}\right)_V . \tag{31}$$

This is clearly a result of the first law alone; the temperature occurs in (31) only as the difference dT, and so could be any empirical temperature. From the first of Eqs. (30), however, we have $(\partial S/\partial T)_V = T^{-1}(\partial U/\partial T)_V$, and so from (31),

$$C_V = T\left(\frac{\partial S}{\partial T}\right)_V . \tag{32}$$

This is a result of the second law. Note that the temperature appears in it not merely as the difference dT, which could be measured on any empirical scale, but also as the multiplying factor T, where it is explicitly the absolute temperature.

From the concavity condition $\partial^2 S/\partial U^2 < 0$, which is one of the inequalities (29), together with (31) and the first of Eqs. (30), we have $0 > (\partial T^{-1}/\partial U)_V = -(T^2 C_V)^{-1}$, and so

$$C_V > 0. \tag{33}$$

The inequality (33) is the first of several such—often called thermodynamic stability conditions—that we shall obtain. Indeed, as was seen above, the concavity of S implies more conditions than just $\partial^2 S/\partial U^2 < 0$, and there are then derivable more stability conditions than just that in (33). Some of these will be derived later by a different route.

If one now explicitly recognizes the dependence of S on chemical composition and allows that composition itself to be variable (so considering now an *open* rather than a closed system), one must add to $dS = (1/T)dU + (p/T)dV$ [Eq. (24)], which gives the change in S due to changes in U and V at fixed composition, the further contributions to dS that would arise from infinitesimal changes dM_1, dM_2, ... Thus, this fundamental differential identity now becomes

$$dS = \frac{1}{T}dU + \frac{p}{T}dV - \frac{\mu_1}{T}dM_1 - \frac{\mu_2}{T}dM_2 - \cdots , \tag{34}$$

where μ_1, μ_2, . . .—called the *chemical potentials* of the substances 1,2, . . . in the system—are by definition

$$\mu_i = -T\left(\frac{\partial S}{\partial M_i}\right)_{U,V,\text{ all } M_{j(\neq i)}} . \tag{35}$$

The partial derivative, as indicated, is with respect to the mass of substance i holding fixed the total energy of the system, the volume, and the masses M_j of all the *other* independent chemical components.

(Chemical potentials are often defined with respect to the numbers of moles or molecules rather than the masses of the several components, but then when thermodynamic functions are calculated for specific molecular models, the molecular basis is obscured by the molecular weights' not appearing explicitly in the results. With the present definition the molecular basis of such applications is manifest in the explicit appearance of the molecular weights. This important didactic point was made by Gibbs; see Gibbs, 1961.)

Since $S(U,V,M_1,M_2, \ldots)$ is an extensive function of extensive arguments, $S(\alpha U, \alpha V, \ldots) \equiv \alpha S(U,V, \ldots)$ for all α; i.e., S is homogeneous of the first degree in its extensive arguments. According to Euler's theorem on homogeneous functions, if a function $f(\alpha x, \alpha y, \ldots) \equiv \alpha^n f(x,y, \ldots)$, so that f is homogeneous of degree n in x, y, . . . , then $nf = x\partial f/\partial x + y\partial f/\partial y + \cdots$. By this theorem, with $n = 1$, it follows from (35) that

$$S = \frac{1}{T}U + \frac{p}{T}V - \frac{\mu_1}{T}M_1 - \frac{\mu_2}{T}M_2 - \cdots , \tag{36}$$

an important thermodynamic identity.

3. FREE ENERGY

3.1 Legendre Transforms; Free Energies F and G

The fundamental differential identity (34) may be rewritten

$$dU = TdS - pdV + \mu_1 dM_1 + \mu_2 dM_2 + \cdots, \tag{37}$$

and equivalently, from the definition of the enthalpy in (10),

$$dH = TdS + Vdp + \mu_1 dM_1 + \mu_2 dM_2 + \cdots. \tag{38}$$

Defining

$$F = U - TS, \qquad G = H - TS = F + pV, \tag{39}$$

one has also

$$\begin{aligned} dF &= -SdT - pdV + \mu_1 dM_1 + \mu_2 dM_2 + \cdots, \\ dG &= -SdT + Vdp + \mu_1 dM_1 + \mu_2 dM_2 + \cdots. \end{aligned} \tag{40}$$

The transformations from (37) to (38) and (40) replace one or both of V and S as independent variables by their respective conjugates $-p$ and T. Mathematically, these are Legendre transformations. The Legendre-transformed energy H is the enthalpy; the Legendre-transformed energies F and G defined by (39) are called free energies, the former that of Helmholtz and the latter that of Gibbs. Just as S, U, V, M_1, $M_2, \ldots$ are extensive quantities, so also are the transformed energies H, F, and G.

As alternatives to the definition of the chemical potential μ_i in (35), one now has, from (37), (38), and (40), four additional expressions for μ_i, the two most useful of which are those from (40),

$$\mu_i = \left(\frac{\partial F}{\partial M_i}\right)_{T,V,\ \text{all}\ M_{j(\neq i)}} = \left(\frac{\partial G}{\partial M_i}\right)_{T,p,\ \text{all}\ M_{j(\neq i)}}. \tag{41}$$

Likewise, as analogs of the identities (30), in which fixed M_1, $M_2, \ldots$ is understood, one has from (37), (38), and (40) eight additional identities, of which the four most useful are again those from (40),

$$\left(\frac{\partial F}{\partial T}\right)_V = \left(\frac{\partial G}{\partial T}\right)_p = -S, \quad \left(\frac{\partial F}{\partial V}\right)_T = -p, \quad \left(\frac{\partial G}{\partial p}\right)_T = V. \tag{42}$$

From (39) one has $G = U - TS + pV$, and so from (36), which was a consequence of the extensivity of the entropy as a function of the extensive variables U, V, M_1, $M_2, \ldots$, one has

$$G = \mu_1 M_1 + \mu_2 M_2 + \cdots. \tag{43}$$

On substituting (43) for G on the left-hand side of the second of Eqs. (40), one obtains

$$M_1 d\mu_1 + M_2 d\mu_2 + \cdots = -SdT + Vdp, \tag{44}$$

which is called the *Gibbs–Duhem equation.* It is the result of having replaced, by Legendre transformation, all the extensive independent variables S, V, M_1, $M_2, \ldots$ on the right-hand side of (37) by their conjugates T, $-p$, μ_1, $\mu_2, \cdots$. Replacing by Legendre transformation all but the volume V leads to the ("grand canonical") free energy $\Omega(T,V,\mu_1,\mu_2,\ldots) = -Vp(T,\mu_1,\mu_2,\ldots)$, just proportional to V, with $d\Omega = -pdV - SdT - M_1 d\mu_1 - \cdots$.

3.2 Equilibrium and Convexity

Imagine a very large isolated system containing in its interior a much smaller subsystem the volume V and chemical composition M_1, $M_2, \ldots$ of which are fixed. The rest of the entire, isolated system will be referred to as the heat bath or the thermostat in which the smaller subsystem is immersed. The smaller subsystem is the system of interest. It is imagined to be at first in a state of constrained equilibrium at the temperature T of the thermostat; but then the constraint is removed and the subsystem spontaneously (hence irreversibly) approaches a state of complete internal equilibrium in which its temperature is again T. The thermostat, because of its much larger size, is scarcely perturbed by this process and so may be taken to be always in a state of equilibrium at the fixed temperature T; that *defines* a heat bath or thermostat. Then any heat q (positive or negative) absorbed by the subsystem during its equilibration is lost by the thermostat reversibly, and so the entropy change suffered by the thermostat is $-q/T$, where T is its constant temperature as well as the initial and final temperature of the subsystem. The entropy change suffered by the subsystem—the system of interest—during its equilibration is some ΔS, and so, by extensivity, that of the entire system is $\Delta S - q/T$. The whole system is isolated so this net entropy change is positive: $\Delta S - q/T \geq 0$ (the = sign holding only if the subsystem was in complete internal equilibrium at the temperature T to begin with).

Since the volume V of the subsystem is fixed, the heat q it absorbs is equal to the change in its energy, ΔU, by (9), and so this inequality is $\Delta S - \Delta U/T \geq 0$; or, from the definition of F in (39), and the usual convention for the sign of T, it is

$$\Delta F \leq 0 \qquad (\text{at fixed } T, V, M_1, M_2, \ldots). \tag{45}$$

Thus, when a spontaneous process takes place in a system of fixed T, V, M_1, $M_2, \ldots$ the Helmholtz free energy F of the system decreases, and correspondingly the condition of equilibrium in such a system is that its free energy be minimal for the given T, V, M_1, $M_2, \ldots$.

By a similar argument one shows that

$$\Delta G \leq 0 \qquad (\text{at fixed } T, p, M_1, M_2, \ldots); \tag{46}$$

i.e., that at fixed T, p, M_1, $M_2, \ldots$ the Gibbs free energy G spontaneously approaches a minimum and so is minimal at equilibrium.

Just as the extremal condition on the entropy led, in Sec. 2.5, to the concavity (downward, or convexity upward) of $S(U, V, M_1, M_2, \ldots)$ as a function of its extensive arguments U, V, M_1, $M_2, \ldots$, so also do (45) and (46) require that *$F(T,V,M_1,M_2,\ldots)$ at fixed T* be a convex (downward, or concave upward) function of its *extensive* arguments V, M_1, $M_2, \ldots$, and a concave downward function of T at fixed V, $M_1, \ldots$; and that *$G(T,p,M_1,M_2,\ldots)$ at fixed T and p* be a convex (downward, or concave upward) function of its *extensive* arguments M_1, $M_2, \ldots$, and a concave downward function of T and p at fixed M_1, $M_2, \ldots$. If all but one of the extensive variables is replaced by its conjugate by Legendre transformation (as with the free energy Ω, for example, defined at the end of Sec. 3.1), the resulting function is neither concave nor convex in the remaining extensive variable but simply proportional to it.

The convexity of F and G lead to further useful stability conditions analogous to (33) for C_V. The isothermal compressibility χ is defined as the fractional rate of decrease of volume with increasing pressure at fixed temperature (and, it is understood, at fixed M_1, $M_2, \ldots$ as well),

$$\chi = -\frac{1}{V}\left(\frac{\partial V}{\partial p}\right)_T. \tag{47}$$

As the analog of the inequalities (29) (now with > instead of < because we have convexity instead of concavity), we have $\partial^2 F/\partial V^2 > 0$, etc. Then from the third of the equalities (42) and the definition of χ in (47), we have the stability condition

$$\chi > 0. \tag{48}$$

Likewise, from $\partial^2 F/\partial M_i^2 > 0$ and the first of the equalities (41),

$$\left(\frac{\partial \mu_i}{\partial M_i}\right)_{T,V,\text{ all } M_{j(\neq i)}} > 0. \tag{49}$$

Similarly, from $\partial^2 G/\partial M_i^2 > 0$ and the second of the equalities (41),

$$\left(\frac{\partial \mu_i}{\partial M_i}\right)_{T,p,\text{ all } M_{j(\neq i)}} > 0. \tag{50}$$

The inequalities (33) and (48)–(50) are only a selection of the full set derivable from the convexity–concavity conditions but are the most generally useful.

3.3 Potentials, Fields, and Densities

The functions $S(U,V,M_1,M_2,\ldots)$, $F(T,V,M_1,M_2,\ldots)$, $G(T,p,M_1,M_2,\ldots)$, and $p(T,\mu_1,\mu_2,\ldots)$, of just those specified arguments, are examples of what one may call *thermodynamic potentials*, by which is meant that from any of those functions of those arguments one may obtain all other thermodynamic functions of the system by differentiations alone, no integrations with their attendant unknown constants of integration being required. In the case of the last of those mentioned, $p(T,\mu_1,\mu_2,\ldots)$, one obtains densities—U/V, S/V, M_1/V, etc.—and their derivatives, and not the extensive functions V, U, S, $M_1, \ldots$ themselves, but that is a minor difference. [One may instead consider the extensive potential $\Omega(V,T,\mu_1,\mu_2,\ldots) \equiv -Vp(T,\mu_1,\mu_2,\ldots)$ introduced at the end of Sec. 3.1, which is then on the same footing as the others.] Those thermodynamic functions that are the coefficients of the differentials (37), (40), and (44) (the latter after division by V) are immediately the first derivatives of the thermodynamic potentials, and all other thermodynamic properties are obtained by (at most) further differentiations with respect to those same independent variables. That is not to say that one may not, for example, contemplate p as a function of T, M_1/V, $M_2/V, \ldots,$ for p is indeed determined when the values of those variables are specified; but as a function of *those* variables, p is not a thermodynamic potential as defined above.

The pressure p and the variables T, μ_1, $\mu_2, \ldots,$ the differentials of which occur in the Gibbs–Duhem equation (44), are termed *fields* (Griffiths and Wheeler, 1970). (The name derives from the subject of magnetism, where the magnetic field is the thermodynamic conjugate of the extensive magnetization.) After division by V in (44), the coefficients of those differentials are the *densities* S/V, M_1/V, etc. More generally, the term density is used to denote the ratio of any pair of extensive variables. Fields and densities are *intensive,* in the sense that their values in a homogeneous system at equilibrium are the same everywhere; they reflect the intrinsic properties of such a system and are independent of the system's size. But the fields, unlike the densities, also have uniform values in an inhomogeneous system at equilibrium. (The pressure is sometimes an exception. When the interfaces between different phases in contact are curved, the pressure has unequal values in the phases; but when the interfaces are planar, the pressure at equilibrium is the same in all the phases.) The uniformity of the fields may be derived as consequences of the conditions of equilibrium found earlier—(25), (45), or (46), with the inequalities holding as equalities—by considering the flow of heat, volume, or matter between the subsystems of a composite system. The distinction between extensive and intensive variables—when the latter are densities—is often superficial or trivial but that between fields and densities is fundamental.

From an argument similar to that by which one derives uniformity of chemical potential as a necessary condition for equilibrium, one may also derive the condition of equilibrium with respect to chemical reaction. Any balanced chemical equation is of the form

$$aA + bB + \cdots \rightleftharpoons xX + yY + \cdots, \tag{51}$$

where $A, B, \ldots, X, Y, \ldots$ are the chemical formulas of the various substances that take part in the reaction as reactants or products while $a, b, \ldots, x, y, \ldots$ are the stoichiometric coefficients giving the relative numbers of molecules (or moles) of those substances used up or formed in the reaction. (Such stoichiometry, which is central in chemistry, is an intrinsically molecular notion. It is the first occurrence of a molecular model in this account and so, in accord with a parenthetical remark made in Sec. 2.5, it will be the first instance in which the molecular weights of chemical substances appear in a fundamental formula. That will not happen again until Sec. 5). One may then derive, as the condition of equilibrium with respect to reaction (51),

$$am_A\mu_A + bm_B\mu_B + \cdots = xm_X\mu_X + ym_Y\mu_Y + \cdots, \tag{52}$$

where m_A, etc., are the molecular weights (as they are known colloquially, but more properly, molar masses) of the various substances. Note that (52) is homogeneous in the molecular weights $m_A, \ldots$ and so is independent of the molecular-weight scale—as expected, since any such scale is of relative masses only.

It is now possible to answer the question raised in Sec. 2.5 about how one counts the number of independent chemical components. Pure water, for example, is a single component. (For simplicity, we ignore the matter of isotopic composition. If that were variable, it would indeed alter the count but would not require any new principles.) Because of hydrogen bonding one may imagine there to be distinct molecular species $(H_2O)_n$

with $n = 1, 2, \ldots$, but at equilibrium one has $2H_2O \rightleftharpoons (H_2O)_2$, etc. Thus, however many species one recognizes in pure water, there is that number minus one independent equilibrium conditions (52), and there then remains only one independently variable chemical potential; hence the conclusion that pure water is a one-component system. One might choose to consider separately the H and O components of H_2O, but then the stoichiometric constraint $n_H = 2n_O$ on the relative numbers of moles or atoms of H and O again reduces the number of independent components to one. The general rule is that the number of independent chemical components is the number of species minus the number of constraints, which may be either of equilibrium or of stoichiometry.

3.4 Further Identities

Many useful identities in addition to those already derived follow from (39)–(44).' The Gibbs–Duhem equation, (44), for example, may be rewritten

$$dp = s\,dT + \rho_1 d\mu_1 + \rho_2 d\mu_2 + \cdots \tag{53}$$

where $s = S/V$ is the entropy density and $\rho_i = M_i/V$ is the mass density of component i. Then from the thermodynamic potential $p(T,\mu_1,\mu_2,\ldots)$, as anticipated earlier, one obtains

$$s = \left(\frac{\partial p}{\partial T}\right)_{\mu_1,\mu_2,\ldots}, \qquad \rho_i = \left(\frac{\partial p}{\partial \mu_i}\right)_{T,\ \text{all}\ \mu_j(\neq i)}. \tag{54}$$

From (39), (43), and (44) the Gibbs–Duhem equation may be written in still another form,

$$d\frac{p}{T} = -u\,d\frac{1}{T} + \rho_1 d\frac{\mu_1}{T} + \rho_2 d\frac{\mu_2}{T} + \cdots, \tag{55}$$

where $u = U/V$ is the energy density; so

$$u = -\left(\frac{\partial(p/T)}{\partial(1/T)}\right)_{\mu_1,\mu_2,\ldots}. \tag{56}$$

From (39) and (42) there follow the *Gibbs–Helmholtz equations*,

$$\left(\frac{\partial(F/T)}{\partial T}\right)_V = -\frac{U}{T^2}, \qquad \left(\frac{\partial(G/T)}{\partial T}\right)_p = -\frac{H}{T^2} \tag{57}$$

or, equivalently,

$$\left(\frac{\partial(F/T)}{\partial(1/T)}\right)_V = U, \qquad \left(\frac{\partial(G/T)}{\partial(1/T)}\right)_p = H. \tag{58}$$

Heat capacity was defined in Sec. 2.5, and that led to the identities (31) and (32) for the constant-volume heat capacity C_V. If the heating process that defines the heat capacity occurs at constant pressure instead of at constant volume, the ratio of heat absorbed to temperature rise is then the constant-pressure heat capacity C_p. Then from (11) and (37) one has as the analogs of (31) and (32),

$$C_p = \left(\frac{\partial H}{\partial T}\right)_p = T\left(\frac{\partial S}{\partial T}\right)_p. \tag{59}$$

Likewise, as an analog of the isothermal compressibility χ defined in (47), one defines the coefficient of thermal expansion α as the fractional rate of increase of volume with increasing temperature at fixed pressure,

$$\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_p. \tag{60}$$

Unlike χ, which is always positive [inequality (48)], α may be of either sign. For liquid water at 1 atm, for example, which has its maximum density at 4 °C, α is negative below 4° and positive above. Related to α and χ is the thermal pressure coefficient $(\partial p/\partial T)_V$,

$$\left(\frac{\partial p}{\partial T}\right)_V = \frac{\alpha}{\chi}, \tag{61}$$

which has the sign of α. These quantities C_V, C_p, α, χ, and $(\partial p/\partial T)_V$ occur in the further identities that follow.

From the equalities of mixed second derivatives $\partial^2 F/\partial V\partial T = \partial^2 F/\partial T\partial V$ and $\partial^2 G/\partial p\partial T = \partial^2 G/\partial T\partial p$, one obtains from (40), (61), and the definition of α in (60)

$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial p}{\partial T}\right)_V = \frac{\alpha}{\chi}, \qquad \left(\frac{\partial S}{\partial p}\right)_T = -V\alpha. \tag{62}$$

These are *Maxwell relations*. From these and (37) and (38) one obtains the important formulas for the volume dependence of the energy and the pressure dependence of the enthalpy, at fixed temperature:

$$\left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_V - p = -\left(\frac{\partial(p/T)}{\partial(1/T)}\right)_V$$
$$\left(\frac{\partial H}{\partial p}\right)_T = V(1 - T\alpha). \tag{63}$$

That T occurs multiplicatively in the formulas (63) shows that these are consequences of the second law even though the quantities U, H, V, p, and α, as well as the temperature differences implicit in the temperature derivatives, are recognizable from the first law alone.

From (32) and (62) for the temperature and volume derivatives of the entropy, it follows that in any infinitesimal change in the thermodynamic state of a system (at fixed M_1, M_2, . . .), the infinitesimal changes in S, V, and T are related by $dS = (C_V/T)dT + (\alpha/\chi)dV$. This holds, in particular, when the change occurs at constant pressure; and so, with the expression (59) that relates $(\partial S/\partial T)_p$ to C_p and the definition of α in (60),

$$C_p = C_V + TV\alpha^2/\chi. \tag{64}$$

This important identity relates the two principal heat capacities C_p and C_V. Since $\chi > 0$ we note that C_p is the greater of the two. (For liquid water at 1 atm and 4 °C, the two heat capacities are the same because then $\alpha = 0$). That T occurs multiplicatively on the right-hand side of (64) shows that this formula, too, is a consequence of the second law in spite of the fact that all the other quantities in it (including the temperature differences implicit in the derivatives defining C_V and C_p in terms of U and H) are definable from the first law alone. Since $C_p \geq C_V$ it follows *a fortiori* from the stability condition $C_V > 0$ in (33) that $C_p > 0$.

The last of the identities to be derived here relates the isentropic (i.e., adiabatic and reversible) rate of change of pressure with volume, $(\partial p/\partial V)_S$, to the isothermal rate of change, $(\partial p/\partial V)_T$; or equivalently, by the definition (47), relates the isentropic to the isothermal compressibility. From the mathematical identities

$$\left(\frac{\partial p}{\partial V}\right)_S = -\frac{\left(\frac{\partial S}{\partial V}\right)_p}{\left(\frac{\partial S}{\partial p}\right)_V} = -\frac{\left(\frac{\partial S}{\partial T}\right)_p\left(\frac{\partial T}{\partial V}\right)_p}{\left(\frac{\partial S}{\partial T}\right)_V\left(\frac{\partial T}{\partial p}\right)_V}$$
$$= \frac{\left(\frac{\partial S}{\partial T}\right)_p}{\left(\frac{\partial S}{\partial T}\right)_V}\left(\frac{\partial p}{\partial V}\right)_T \tag{65}$$

and the thermodynamic identities (32) and (59), one obtains

$$\left(\frac{\partial p}{\partial V}\right)_S = \frac{C_p}{C_V}\left(\frac{\partial p}{\partial V}\right)_T. \tag{66}$$

If the isothermal compressibility χ defined by (47) is written χ_T to distinguish it from the isentropic $\chi_S = -V^{-1}(\partial V/\partial p)_S$, then (66) is

$$\chi_S = \gamma^{-1}\chi_T, \qquad \gamma = C_p/C_V. \tag{67}$$

Since $C_p \geq C_V > 0$ we have $\gamma \geq 1$ and $\chi_S \leq \chi_T$. From (66) it follows that when isentropes and isotherms in the p-V plane intersect—for example, at A, B, C, and D in Fig. 4 (since reversible adiabats are isentropes)—the isentrope has a steeper (more negative) slope at the point of intersection than the isotherm does.

Equation (67) has an application in acoustics in a formula for the speed of sound, c. From acoustic theory one has $c^2 = dp/d\rho$, the rate of change of pressure with density in the medium in which the sound is traveling, the derivative to be evaluated for the conditions under which the sound propagates. Any practical sound frequency is so great that in the short time of one period negligible heat is transported into or out of any element of the medium of length equal to the wavelength of the sound wave, so that the sound propagation is effectively adiabatic; and at frequencies below that at which there is significant dispersion—which means, typically, below ultrasonic frequencies—the periodic expansions and compressions are effectively also reversible. Thus, over a great range of frequencies, the sound propagation is both adiabatic and reversible, hence isentropic; so $dp/d\rho$ here means $(\partial p/\partial \rho)_S$. Since $\rho = (\text{mass})/V$, we have for a fixed mass $(\partial p/\partial \rho)_S = -(V/\rho)(\partial p/\partial V)_S$. Then from (67) and the formula for c^2 quoted above,

$$c = \sqrt{\gamma/\rho\chi_T}. \tag{68}$$

For example, for dry air at 1 atm and 20 °C one has $\rho = 1.205 \times 10^{-3}$ g/cm^3, $\gamma = 1.40$, and $\chi_T = 1.00$ atm^{-1} = 9.87×10^{-7} cm s^2/g, so $c = 3.43 \times 10^4$ cm/s = 343 m/s. For liquid water at its triple point one has $\rho = 1.000$ g/cm^3, $\gamma = 1.001$, and $\chi_T = 5.089 \times 10^{-5}$ bar^{-1} = 5.089×10^{-11} cm s^2/g, so $c = 1.402 \times 10^5$ cm/s = 1402 m/s (Rowlinson and Swinton, 1982).

4. PHASE EQUILIBRIUM

4.1 Phase Rule

The (Gibbs) phase rule states how many of a system's field variables (variables such as pressure, temperature, and chemical potential; Sec. 3.3) may be independently varied when the system consists of some number C of independent chemical components (defined in Sec. 3.3) and some number P of coexisting phases. This number, f, of independently variable fields is termed the number of degrees of freedom in the system. It is the number of field variables remaining to be specified in order that all the fields then have prescribed values. It is equivalently the dimensionality of the thermodynamic field space, in which a thermodynamic state of the P-phase, C-component system is represented by a point. Because only fields but not densities are specified, the thermodynamic state so represented is one in which only the intensive properties of each of the P phases present are determined but not their amounts (i.e., not the masses or volumes of the phases).

The pressure $p^{(\alpha)}$ in each of the phases $\alpha = 1, \ldots, P$ separately is some function $p^{(\alpha)}(T^{(\alpha)}, \mu_1^{(\alpha)}, \ldots, \mu_C^{(\alpha)})$ of the temperature $T^{(\alpha)}$ and the chemical potentials $\mu_i^{(\alpha)}$ of the C components in that phase (Sec. 3.3). The arguments $T^{(\alpha)}$, $\mu_1^{(\alpha)}, \ldots, \mu_C^{(\alpha)}$ of these P functions together constitute $P(C + 1)$ variables that one would need to specify to fix the states of all P phases if the phases were independent; but if the phases are in equilibrium with each other, the temperature T and the C chemical potentials μ_i must each have the same value in every phase (Sec. 3.3); and so also must the pressure p (assuming planar interfaces). These equilibrium conditions

$$\begin{aligned} T^{(1)} &= \cdots = T^{(P)} \\ \mu_1^{(1)} &= \cdots = \mu_1^{(P)} \\ &\vdots \\ \mu_C^{(1)} &= \cdots = \mu_C^{(P)} \\ p^{(1)} &= \cdots = p^{(P)} \end{aligned} \tag{69}$$

constitute $(P - 1)(C + 2)$ constraints on the values of the $P(C + 1)$ fields $T^{(\alpha)}$, $\mu_1^{(\alpha)}, \ldots, \mu_C^{(\alpha)}$, leaving only $f = P(C + 1) - (P - 1)(C + 2)$ of them independently variable. That is the phase rule:

$$f = C - P + 2. \tag{70}$$

According to this rule a C-component, one-phase system has $C + 1$ degrees of freedom so that its states may be represented by points in a $(C + 1)$-dimensional thermodynamic space; the P-phase states constitute $(C - P + 2)$-dimensional submanifolds in that space.

When two or more phases are in equilibrium, the field variables in the system necessarily have the values given by the coordinates of a corresponding point on one of the lower-dimensional phase-equilibrium manifolds in the $(C + 1)$-dimensional field space, but the converse is not true: for reasons that will be explained in the following section, one cannot, in the laboratory, impose phase equilibrium by fixing field variables alone. It will transpire that for two-phase equilibrium one must fix at least one density, for three-phase equilibrium at least two densities, etc.

4.2 Phase Diagrams

Phase diagrams tell us what may be the equilibrium phases that are present in any given thermodynamic state. A phase diagram may be displayed in a space of fields, of densities, or of mixed fields and densities, and may be of any dimensionality $\leq C + 1$. Most often it is presented as two-dimensional, so that in a system of $C > 1$ components it is then either a section of the full $(C + 1)$-dimensional space in which $C - 1$ fields are fixed or else a projection from that space onto the plane of two of the variables.

A schematic solid (S)–liquid (L)–vapor (V) phase diagram of a one-component system in a space of the two fields p and T is shown in Fig. 8. The one-phase regions are labeled S, L, and V, showing which is the stable

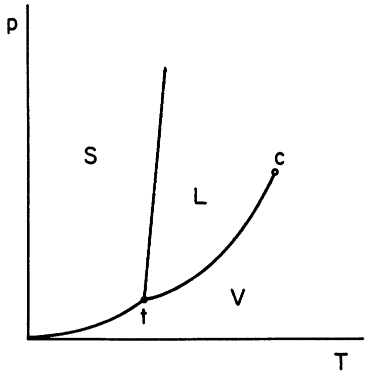

FIG. 8. *p,T* phase diagram of a one-component system with solid (S), liquid (L), and vapor (V) phases. The triple point is marked t and the liquid–vapor critical point *c*.

phase in each region. The boundaries between regions are the two-phase lines of SV, SL, and LV equilibria, and the three lines and three regions come together at the triple point, marked *t*.

The LV coexistence line is the vapor-pressure curve, giving the vapor pressure *p* of the liquid as a function of the temperature *T*. It is also the boiling-point curve, giving the temperature *T* at which the liquid boils under an external pressure *p*. The SL line is the melting-point or freezing-point line, giving the equilibrium melting point *T* of the solid or equilibrium freezing point *T* of the liquid as a function of the pressure *p*. The SV line is the vapor-pressure curve of the solid, giving its vapor pressure *p* as a function of the temperature *T* or its sublimation temperature *T* as a function of the pressure *p*.

The liquid–vapor curve ends in a critical point, marked *c*, where the previously distinct liquid and vapor phases become identical. Only a single homogeneous fluid phase is present at the critical point, but one must not then take the phase rule (70) to read $f = 1 - 1 + 2 = 2$. On the contrary, at the critical point one must take for the number of phases *P* the number of previously distinct phases, 2, and then subtract an additional 1 from the number of degrees of freedom *f* to account for the additional constraint of the two phases' being identical. Hence, $f = 1 - 2 + 2 - 1 = 0$: a critical point in a one-component system is a single, uniquely determined state. In a two-component system, where the liquid–vapor states constitute a surface in the three-dimensional field space, that surface is terminated by a whole line (curve) of critical points; etc.

When the LV curve in Fig. 8 is crossed from the liquid to the vapor side or the reverse, at any point, there is a discontinuity in the properties of the fluid: the density ρ, for example, of the liquid and vapor are different even when they are in equilibrium at the same *p* and same *T*. However, because the LV line ends in a critical point, it is possible to pass continuously, with no sudden change of properties, from what is clearly a liquid state on the liquid side of the LV line to what is clearly a vapor state on the vapor side, by following a path in the *p,T* plane that goes around the end of the LV line instead of crossing it. This is the principle of the continuity of the liquid and vapor states of Andrews and van der Waals, and implies that there is no fundamental distinction between a liquid and a vapor.

The same phases and phase equilibria that are seen in the *p,T* phase diagram in Fig. 8 for a one-component system are shown in a mixed field (*T*) and density (ρ) phase diagram in Fig. 9. What had been lines of two-phase equilibria in Fig. 8 are now regions filled with horizontal tie-lines. The values of ρ at the two ends of each tie-line are the densities of the separate coexisting phases at that temperature.

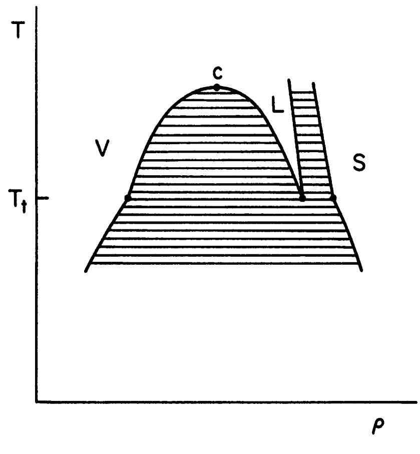

FIG. 9. *T,ρ* phase diagram of a one-component system with solid (S), liquid (L), and vapor (V) phases. The triple-point temperature is T_t; the liquid–vapor critical point is at *c*.

When two phases coexist, the average density in the system lies between that of the separate phases; a point ρ,T in any of the three two-phase regions in Fig. 9 represents that average density at the temperature T, and the exact location of that point on the tie-line determines the relative amounts of the two phases. If $\rho^{(\alpha)}$ and $\rho^{(\beta)}$ with $\rho^{(\alpha)} < \rho^{(\beta)}$ are the densities of the separate phases at some temperature T, and ρ is the mean density in the system, then the point ρ, T divides the tie-line into a segment of length $\rho - \rho^{(\alpha)}$ and one of length $\rho^{(\beta)} - \rho$. If the masses and volumes of the two phases are $M^{(\alpha)}$, $V^{(\alpha)}$ and $M^{(\beta)}$, $V^{(\beta)}$ then $\rho^{(\alpha)} = M^{(\alpha)}/V^{(\alpha)}$ and $\rho^{(\beta)} = M^{(\beta)}/V^{(\beta)}$. The total mass and volume of the system are $M = M^{(\alpha)} + M^{(\beta)} = \rho^{(\alpha)}V^{(\alpha)} + \rho^{(\beta)}V^{(\beta)}$ and $V = V^{(\alpha)} + V^{(\beta)}$, while $\rho = M/V$. From these relations it follows that

$$V^{(\alpha)}/V^{(\beta)} = (\rho^{(\beta)} - \rho)/(\rho - \rho^{(\alpha)}), \tag{71}$$

expressing the relative amounts (volumes) of the two coexisting phases in terms of the relative lengths of the two segments into which the point ρ,T divides the tie-line. Thinking of the tie-line as a lever and the point ρ,T as the position of a fulcrum on which the lever rests, with $V^{(\alpha)}$ and $V^{(\beta)}$ the "weights" at the two ends at the respective distances $\rho - \rho^{(\alpha)}$ and $\rho^{(\beta)} - \rho$ from the fulcrum, we have (71) as the condition of balance; hence the name *lever rule* for that relation. If the "density" variable had been the specific volume $v = 1/\rho$ instead of the mass density ρ, the rule would have been $M^{(\alpha)}/M^{(\beta)} = (v - v^{(\beta)})/(v^{(\alpha)} - v)$, expressing the relative amounts of the two phases as the ratio of their masses rather than of their volumes.

If in this one-component system one tried, in the laboratory, to create a two-phase state by fixing p and T (or any other pair of field variables) at values corresponding to a point on one of the two-phase lines in Fig. 8, the attempt would fail for reasons both of practice and of principle. As a practical matter it would fail because one cannot fix laboratory variables with infinite precision and so cannot force the system's state to be exactly on the coexistence line; inevitably, it would be slightly to one side or the other, in one of the one-phase regions. As a matter of principle it would fail because if only field variables and no density variable were fixed, only that phase that had the lower free energy of contact with the container walls would be present, since if both phases were present there would be both a less favorable (more positive) free energy of contact with the wall and an additional positive free energy (interfacial tension) of contact of the two phases with each other. It is seen in Fig. 9 how by specifying a field and a density instead of two fields one may now impose the coexistence of two phases. One need only specify, with practical laboratory precision, that the temperature T and overall average density ρ in the system lie somewhere in the now two-dimensional two-phase *region*, and at equilibrium there will then be two phases with an interface between them.

The same phases and phase equilibria in this one-component system are depicted again, in Fig. 10, now in the plane of two densities—the mass density ρ and energy density u in this illustration. The two-phase regions are again filled with tie-lines connecting the densities $u^{(\alpha)}$, $\rho^{(\alpha)}$ and $u^{(\beta)}$, $\rho^{(\beta)}$ of coexisting phases, while the triple point—a *point* in Fig. 8 and a *line* in Fig. 9—is now a two-dimensional *region;* it is the triangle in the middle of the figure. The coordinates of the vertices of the triangle are the energy and mass densities $(u^{(\alpha)},\rho^{(\alpha)})$, $(u^{(\beta)},\rho^{(\beta)})$, and

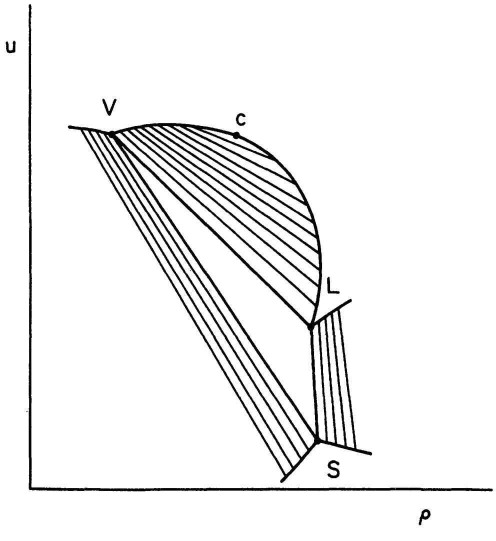

FIG. 10. u,ρ phase diagram of a one-component system with solid (S), liquid (L), and vapor (V) phases. The triangle is the region of the three-phase coexistence (triple point); the liquid–vapor critical point is at *c*.

$(u^{(\gamma)},\rho^{(\gamma)})$ of the three coexisting phases α, β, and γ. Neither by specifying two fields, as in Fig. 8, nor one field and one density, as in Fig. 9, could one have imposed three-phase coexistence; but by imposing two densities—requiring that the overall average energy and mass densities u,ρ in the system lie somewhere within the three-phase triangle in Fig. 10—the system at equilibrium would be required to consist of three coexisting phases. Wherever in the three-phase triangle the imposed u,ρ lies, i.e., as long as all three phases are present in equilibrium, the system will automatically adjust its pressure and temperature to be exactly the unique triple-point p,T in Fig. 8. The location of the point u,ρ in the three-phase triangle determines the relative amounts of the three phases by the three-phase analog of the lever rule (71):

$$\frac{V^{(\alpha)}}{V^{(\beta)}} = \frac{\begin{vmatrix} u - u^{(\beta)} & u^{(\gamma)} - u \\ \rho - \rho^{(\beta)} & \rho^{(\gamma)} - \rho \end{vmatrix}}{\begin{vmatrix} u^{(\alpha)} - u & u^{(\gamma)} - u \\ \rho^{(\alpha)} - \rho & \rho^{(\gamma)} - \rho \end{vmatrix}}, \text{ etc.} \qquad (72)$$

For a lever rule like (71) to hold when ρ is a density in a general sense, it is necessary that ρ be of the form X/Z where each of X and Z is an extensive function whose value in a *heterogeneous* system is the sum of its values in the separate phases. (U, V, and M are such extensive functions while V^2/M is not, even though in a *homogeneous* system it is proportional to the system's size.) Then (71) is more generally a formula for $Z^{(\alpha)}/Z^{(\beta)}$. This was illustrated in (71) itself with $\rho = M/V$ and subsequently with the "density" $v = V/M$. For the tie-lines in the two-phase regions of figures like Fig. 10 to be linear, i.e., for the overall average u,ρ to lie on the line connecting $u^{(\alpha)}$, $\rho^{(\alpha)}$ and $u^{(\beta)}$, $\rho^{(\beta)}$, and for the three-phase analog (72) of the lever rule (71) to hold, it is necessary that the "densities" u,ρ be of the compatible form $u = Y/Z$ and $\rho = X/Z$, where X, Y, and Z are all extensive in the specific sense defined above. The energy and mass densities $u = U/V$ and $\rho = M/V$ are such a compatible pair, as are the specific energy and volume $u' = U/M$ and $v = V/M$, while u',ρ and u,v are both incompatible pairs.

Where two phases coexist in a one-component system, as in any of the three two-phase regions in Fig. 9, the composite system's constant-pressure heat capacity C_p, compressibility χ, and coefficient of thermal expansion α are all infinite: If a small amount of heat is added to the system at fixed pressure, then a proportional amount of phase change (S → V, S → L, or L → V in the example in Fig. 9) occurs, the absorbed heat being just the enthalpy change ("latent heat") that is required to accompany the transition; and, because in the two-phase region the temperature is fixed by the pressure (Fig. 8), there is no accompanying increase in temperature; hence, $C_p = \infty$. Likewise, if for a fixed mass the volume of the two-phase system is decreased isothermally, all that happens is that some of the less dense phase transforms into some of the more dense phase, but the pressure remains unchanged; hence $\chi = \infty$. Meanwhile, $\alpha = V^{-1}(\partial V/\partial T)_p = -V^{-1}(\partial p/\partial T)_V(\partial V/\partial p)_T = \chi(\partial p/\partial T)_V$; and in the two-phase region $(\partial p/\partial T)_V$ is just dp/dT, the (nonzero) slope of the corresponding equilibrium curve in Fig. 8 at that point; so $\alpha = \infty$, too.

The constant-volume heat capacity C_V, by contrast, is finite in the two-phase region. This, too, is clear from Fig. 9: if heat is added at constant volume (fixed ρ), there is again a proportionate amount of phase change, but it is now accompanied by a proportionate temperature rise, and so C_V is finite. That C_p, χ, and α are infinite in the two-phase region is still true at the liquid–vapor critical point (point c in Fig. 9), which is the limit point of that two-phase coexistence. Remarkably, as one knows from statistical-mechanical theory and experiment, C_V is also infinite at the critical point—although it diverges to ∞ very slowly as the critical point is approached, and so at moderate distances from the critical point is not very large, as befits there having been no thermodynamic necessity for it to diverge there at all. At three-phase coexistence, on the other hand, C_V is necessarily infinite, as one may visualize in Fig. 10: adding a small amount of heat at fixed overall density ρ increases u and causes the relative amounts of the three phases to change in accordance with (72), but there is no accompanying rise in temperature, which remains fixed at that of the triple point.

It is seen in Fig. 8 that the angles between the three two-phase equilibrium lines where they meet at the triple point are all less than

180°. This illustrates the "180° rule." The $\alpha\beta$ equilibrium line in the p,T plane, including the extension of that line beyond the triple point, is defined by $\mu^{(\alpha)}(p,T) = \mu^{(\beta)}(p,T)$. If the angle occupied by the α phase, say, in the diagram, were greater than 180°, this extension of the $\alpha\beta$ line, on which $\mu^{(\alpha)} = \mu^{(\beta)}$, would lie in the α region. But since this is the region in which α is supposed to be the stable phase, one must have $\mu^{(\alpha)} < \mu^{(\beta)}$ at every point p,T in this region; so in fact the supposition that the angle occupied by the α phase could be greater than 180° is inadmissible. That is likewise true for the other two angles: the extension of any of the two-phase lines $\alpha\beta$ must lie in the region of stability of the third phase γ. On the extension of the $\alpha\beta$ equilibrium line beyond the triple point into the region of stability of the γ phase, the phases α and β may still be in equilibrium with each other, but they are then unstable with respect to γ, to which they would ultimately transform irreversibly. There are more rigorous derivations of the 180° rule that do not make reference to metastable extensions of the equilibrium lines (Wheeler, 1974; Fisher, 1990; Teubner, 1991).

The 180° rule in a two-dimensional field space such as the p,T plane of Fig. 8 has its analog in a density space such as that in Fig. 10, where it is known as Schreinemakers' rule. First, the angles formed by the tangents to the boundaries of the one-phase regions at each vertex of the three-phase triangle (the angles labeled S, L, V in Fig. 10) must each be less than 180°. Second, when the two tangent lines forming any of those angles are continued beyond their intersection, they must either both go inside the three-phase triangle (as at L in Fig. 10) or both go outside (as at V and at S in the figure) but not one inside and the other outside. There are analogous conditions for the mixed field and density diagram of Fig. 9, but these are less often referred to.

The transitions that occur across the two-phase lines in Fig. 8 are said to be of first order, and with the appropriate constraints (Figs. 9 and 10) may be associated with phase coexistence, as discussed. In Fig. 11 is a schematic version of the p,T phase diagram of ^{4}He. The regions II and I are superfluid and nonsuperfluid liquid. There is no solid–liquid–vapor triple point. The curves separating solid from liquid (I or II) and liquid from vapor in Fig. 11 are loci of ordinary first-order transitions, but the line between liquids I and II is not. The I–II transition is said to be of second order; even if densities were prescribed instead of fields, the liquid phases I and II could not be made to coexist as two separate phases with an interface between them. The I–II–V and I–II–S junctions are therefore not triple points.

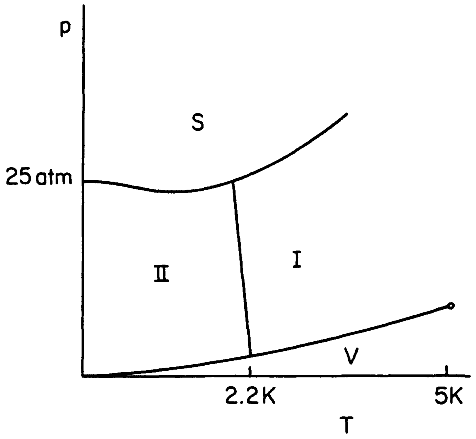

FIG. 11. Phase diagram of ^{4}He (schematic), showing solid (S), vapor (V), superfluid liquid (II), and nonsuperfluid liquid (I) regions. The boundary between I and II is a line of second-order transitions.

In general, a first-order transition is accompanied by discontinuities in densities u, ρ, etc., but at a second-order transition the densities are continuous: at the I–II boundary in Fig. 11 the two liquids have the same entropy, energy, and mass densities. The slopes of the vapor–liquid and solid–liquid phase boundaries are continuous at the respective junctions I–II–V and I–II–S: the angle between the I–V and II–V boundaries and that between the I–S and II–S boundaries are 180°, which is thus a limiting case of the 180° rule. Instead of discontinuities in the densities at the I–II transition line, there are now singularities in C_p, χ, and α that are much like the divergence in C_V at a liquid–vapor critical point that was remarked above. Because of a fancied resemblance to the letter "lambda" of a plot of C_p against T, such second-order transitions are often called lambda points; the I–II boundary in Fig. 11 is a locus of such points.

4.3 Clapeyron Equations

The Gibbs–Duhem equation in the form (53) relates to each other the infinitesimal changes in the fields p, T, $\mu_1, \ldots$ that result from an infinitesimal change in the state of a system. When two phases are in equilibrium and an infinitesimal change is made in the two-phase state, each of the phases must undergo the same infinitesimal change in its pressure because this has to have the same value in both phases after as well as before the change (assuming planar interfaces). Thus, if the two phases be called α and β, one has from (53)

$$0 = (s^{(\alpha)} - s^{(\beta)})dT + (\rho_1^{(\alpha)} - \rho_1^{(\beta)})d\mu_1 + \cdots, \tag{73}$$

relating to each other the changes dT, $d\mu_1, \ldots$ in the other field variables. In a one-component system (73) gives the slope of the two-phase equilibrium curve in the μ,T plane in terms of the differences $s^{(\alpha)} - s^{(\beta)}$ and $\rho^{(\alpha)} - \rho^{(\beta)}$ in the entropy and mass densities of the two phases:

$$\frac{d\mu}{dT} = -\frac{s^{(\alpha)} - s^{(\beta)}}{\rho^{(\alpha)} - \rho^{(\beta)}}. \tag{74}$$

The same Gibbs–Duhem equation (53) could have been rewritten to express dT in terms of dp, $d\mu_1, \ldots$ or $d\mu_1$ in terms of dp, dT, $d\mu_2, \ldots$, etc., and so in a C-component system there are $C + 2$ equations of the form of (73), each one relating the infinitesimal changes in $C + 1$ of the field variables to each other when an infinitesimal change is made in a two-phase equilibrium. Another $C + 2$ equations of the same general form as (73) follow when the Gibbs–Duhem equation is taken in the form (55) with p/T, $1/T$, $\mu_1/T, \ldots$ as the field variables. All of these, in a one-component system, reduce to a relation like (74), expressing the slope of the two-phase equilibrium curve in some two-dimensional field space in terms of the ratio of differences of "densities," with "density" understood in a general sense.

For example, if we represent specific entropy and volume by $\sigma = s/\rho$ and $v = 1/\rho$, then another form of the Gibbs–Duhem equation (53) for a one-component system is $d\mu = vdp - \sigma dT$, so that an alternative to (74), giving the slope of the equilibrium curve in the p,T plane, is

$$\frac{dp}{dT} = \frac{\sigma^{(\alpha)} - \sigma^{(\beta)}}{v^{(\alpha)} - v^{(\beta)}}. \tag{75}$$

All the relations of the form of (73) in a multicomponent system or their special cases like (74) and (75) in a one-component system may collectively be called Clapeyron equations. Of these, (75) is the most familiar and most used, but none is more fundamental than another.

The phase change $\beta \rightarrow \alpha$ at a point on the $\alpha\beta$ equilibrium curve in the p,T plane may be made to occur reversibly, with the phases in equilibrium at every stage and with p and T both fixed. The heat ("latent heat") absorbed or evolved in the process is then both the change in the system's enthalpy, ΔH (because p is constant), and T times the change in its entropy, ΔS (because the process is isothermal and reversible). Therefore $\Delta H = T\Delta S$ in the process; so the difference $\sigma^{(\alpha)} - \sigma^{(\beta)}$ in the specific entropies (entropies per unit mass) of the two phases is also $(h^{(\alpha)} - h^{(\beta)})/T$, where $h = H/M$ is specific enthalpy. Then (75) is equally well

$$\frac{dp}{dT} = \frac{h^{(\alpha)} - h^{(\beta)}}{T(v^{(\alpha)} - v^{(\beta)})}, \tag{76}$$

another frequently used form of the Clapeyron equation for a one-component system.

Heat is usually absorbed in the melting of a solid (an interesting exception being helium at very low temperatures), and always in the evaporation of a liquid or solid, and so for those transformations $\beta \rightarrow \alpha$ the differences $h^{(\alpha)} - h^{(\beta)}$ and $\sigma^{(\alpha)} - \sigma^{(\beta)}$ are both positive. The volume increases in the evaporations so that $v^{(\alpha)} - v^{(\beta)}$ is then also positive, implying positive slope dp/dT for the SV and LV equilibrium lines in Fig. 8. The difference $v^{(\alpha)} - v^{(\beta)}$ on melting may be positive or negative depending on whether the liquid or the solid is the denser. More often the solid is, and so if, as is usual, it is also of lower entropy and enthalpy, then dp/dT is again positive on the melting line, as in Fig. 8. An important exception is water, for which the density of the liquid is greater than that of the solid, and so in the analog of Fig. 8 for water the SL equilibrium line has negative rather than positive slope; and another exception, for the reason already stated, is helium at very low temperatures, as seen in the schematic Fig. 11.

The infinite values that the constant-pressure heat capacity C_p and compressibility χ have at two-phase coexistence (Sec. 4.2) are both $+\infty$, by the stability conditions $C_p > 0$ (Sec. 3.4) and $\chi > 0$ (Sec. 3.2). Then since $\chi = (\partial \ln \rho/\partial p)_T$ [from the definition of χ in (47), with $\rho = M/V$] and $C_p = (\partial H/\partial T)_p = (\partial S/\partial \ln T)_p$ [Eq. (59)], it follows that at a two-phase line in a p,T phase diagram the phase that lies in the direction of increasing T as the transition line is crossed has both the greater entropy and the greater enthalpy of the two, while the phase that lies in the direction of increasing p as the line is crossed has the greater density (smaller specific volume). These rules are consistent with the sign of dp/dT as implied by (76).

Density variables such as the entropy, energy, and mass densities $s = S/V$, $u = U/V$, $\rho_1 = M_1/V, \ldots$, the specific entropy and energy S/M and U/M, and the mass fractions M_1/M, $M_2/M, \ldots$ of the several components, where V and M are the total volume and mass of a phase, all generally have different values in coexisting phases. Those differences occur in the general Clapeyron equations like (73) or in the special cases of those equations like (74)–(76). When, exceptionally, a density variable has the same value in different phases at equilibrium, the event is called an *azeotropy*.

Each azeotropic constraint such as $\rho^{(\alpha)} = \rho^{(\beta)}$ decreases by one the number of degrees of freedom of a system, and so in a one-component system such states can only occur as isolated points on the two-phase equilibrium lines in the system's thermodynamic plane (its p-T plane, for example). Figure 12 is a schematic representation of the phase diagram of elemental carbon, showing the regions of stability of graphite (gr), diamond (dia), and liquid (liq) in the p-T plane (Bundy, 1989). The region of stability of the vapor is invisible on this scale. There is a gr–dia–liq triple point, marked t on the diagram. The liquid always has a greater entropy and enthalpy than either solid, the graphite in particular; so by the Clapeyron equation for a one-component system, (75) or (76) (or by the principle that the denser phase is the one that lies in the direction in which p increases as the two-phase line is being crossed), at any point on the gr–liq equilibrium curve at which $dp/dT > 0$, the graphite is the denser phase, whereas where $dp/dT < 0$, the liquid is the denser. Where $dp/dT = \pm\infty$ ($dT/dp = 0$), the two densities are equal: $v^{(\mathrm{gr})} = v^{(\mathrm{liq})}$. That is an azeotropy. It must thus occur at a temperature extremum ($dT = 0$) in this representation and is seen here to be at a temperature maximum, at the point marked az in the figure.

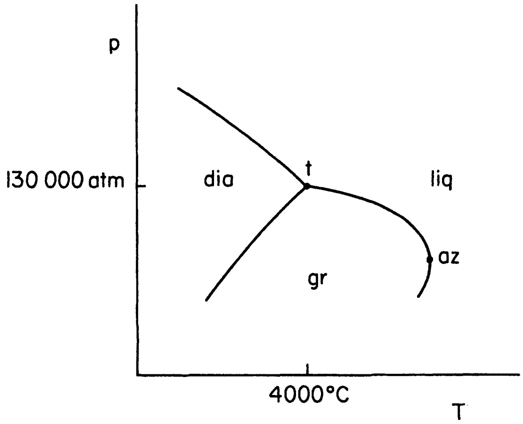

FIG. 12. Phase diagram of carbon showing regions of stability of graphite (gr), diamond (dia), and liquid (liq). The gr–dia–liq triple point is marked t; the azeotropic point on the gr–liq equilibrium curve is marked az.

Azeotropes are more commonly found in multicomponent systems because in a mixture of $C > 1$ components azeotropes occur as whole $(C - 1)$-dimensional manifolds of states instead of as isolated points. Higher-order azeotropies, where some density has equal values simultaneously in more than two coexisting phases, or where, in a two-phase equilibrium, one has $\rho_i^{(\alpha)} = \rho_i^{(\beta)}$ for more than one density i, occur on manifolds of correspondingly lower dimensionality and are therefore more difficult to achieve and are of rarer occurrence.

The *simultaneous* equalities $\rho^{(\alpha)} = \rho^{(\beta)}$ and $s^{(\alpha)} = s^{(\beta)}$ (or $u^{(\alpha)} = u^{(\beta)}$) in a *one*-component system (as at the λ-line in liquid ^{4}He; Sec. 4.2) define a second-order transition; they are not associated with the coexistence of distinct phases and so are not an azeotropy in the usual sense.

5. DILUTE SYSTEMS

Any relation among thermodynamic functions that is specific to the system and not a mere thermodynamic identity may be called an equation of state, a term that was used before for the expression of S as a function of $U, V, M_1, \ldots$ in (26). Such equations of state are determined by experiment or by the methods of statistical mechanics, which lie beyond classical thermodynamics. These equations often refer to the molecular constitution of the system. When the equation is that for a thermodynamic potential such as $S = S(U,V,M_1,M_2,\ldots)$ or $p = p(T,\mu_1,\mu_2,\ldots)$, all the thermodynamic properties of the system (in the latter case, all the intensive properties) are derivable from it (Sec. 3.3).

An example is the expression for p as a function of $T, \mu_1, \mu_2, \ldots$ for an *ideal gas,*

$$p = RT \sum_i c_i^0(T) \exp(m_i\mu_i/RT), \tag{77}$$

where m_i is the molecular weight of constituent i and $c_i^0(T)$ is some function of the temperature alone, with the dimensions of a molar concentration (moles per unit volume), characteristic of that constituent. The gas constant R is a universal constant, $R = 8.315$ J/mol·K. In molecular terms $R = N_0k$, where $N_0 = 6.022 \times 10^{23}$/mol is Avogadro's number and $k = 1.381 \times 10^{-23}$ J/K is Boltzmann's constant, but (77) itself is a relation among macroscopic quantities only. It holds accurately for real gases only when these are dilute. It is derivable as the equation of state of a gas of noninteracting molecules from statistical mechanics, which also allows the explicit calculation of the functions $c_i^0(T)$ characteristic of each species i.

From (54) and (77) one finds the density ρ_i of component i, or equivalently its molar concentration $c_i = \rho_i/m_i$,

$$c_i = c_i^0(T) \exp(m_i\mu_i/RT), \tag{78}$$

so that

$$\mu_i = \frac{RT}{m_i} \ln \frac{c_i}{c_i^0(T)}. \tag{79}$$

From (79) one sees that the chemical potential of any constituent of an ideal gas depends logarithmically on its concentration and, at any fixed T, is independent of the concentrations—indeed, independent of the presence or absence—of any other species. The molecular origin of this independence is the near absence of interactions among the molecules of a dilute gas.

From (77) and (78),

$$p = RT \sum_i c_i = nRT/V, \tag{80}$$

where $n = n_1 + n_2 + \cdots$ is the total number of moles of gas. Equation (80) is the "ideal-gas law." The pressure p as given by (80) is an example of a *colligative* property: it expresses p at any T as being proportional to the total molar concentration n/V of the gas whatever its chemical constitution. Thus, every molecule makes the same average contribution to p (at given V and T) whatever its nature. There are analogous colligative properties of dilute solutions, as will be noted later.

From (80) and the definitions (47) and (60), together with (61), one has for an ideal gas

$$\chi = \frac{1}{p}, \quad \alpha = \frac{1}{T}, \quad \left(\frac{\partial p}{\partial T}\right)_V = \frac{p}{T} = \frac{nR}{V}. \tag{81}$$

From (80) and (63) one finds $(\partial U/\partial V)_T = 0$ and $(\partial H/\partial p)_T = 0$; i.e., the energy and enthalpy of an ideal gas depend on temperature alone, and for fixed temperature are then constant, independent of the gas's state of compression. From the identities (31) and (59) the same is then also true of the heat capacities C_V and C_p; and from (64) and (81) one has for their difference

$$C_p - C_V = nR, \tag{82}$$

depending only on the total number of moles of gas and neither on the chemical species nor on the temperature.

From (80), the equation of an isotherm (T = const.) in the p-V plane of an ideal gas is pV = const. (Boyle's law). One may obtain a corresponding equation of an isentrope (reversible adiabat). From the definition of the isentropic compressibility χ_S that appears in (67), and from that equation and the first of Eqs. (81), one has as a differential equation for an isentrope in the p-V plane of an ideal gas, $d \ln p + \gamma d \ln V = 0$ with $\gamma = C_p/C_V$

now a function of the temperature alone. While the difference $C_p - C_V$ of the principal heat capacities is a constant for an ideal gas [Eq. (82)], their ratio γ, in general, depends on the temperature and so varies along the isentrope, but it is often nearly enough constant so that to a good approximation the differential equation may be integrated to yield pV^γ = const. as the explicit equation of the isentrope in the p-V plane. From (80), the corresponding equations in the T-V and p-T planes are then $TV^{\gamma-1}$ = const. and $T^\gamma/p^{\gamma-1}$ = const., respectively.

The ideal-gas law combined with the Clapeyron equation (76) leads to an important approximation for the liquid–vapor and solid–vapor equilibrium lines in Fig. 8. Let α in (76) be the vapor and β the liquid or solid. Then, except near the critical point on the liquid–vapor line, $v^{(\alpha)} \gg v^{(\beta)}$; and the vapor is typically dilute enough to be a nearly ideal gas, so that by (81), $mv^{(\alpha)} = RT/p$, the molar volume of the vapor, where m is the molecular weight of the *vapor*. Thus, from (76),

$$\frac{d\ln p}{dT} = \frac{m\Lambda}{RT^2}, \qquad \frac{d\ln p}{d(1/T)} = -\frac{m\Lambda}{R}, \tag{83}$$

where $\Lambda = h^{(\alpha)} - h^{(\beta)}$ is the heat of vaporization per unit mass. It is significant that the molecular weight m is that of the vapor, not of the liquid or solid, for the molecular weight of a condensed phase, especially of a liquid of strongly associating molecules like water, is often a meaningless concept, whereas the molecular weight of a dilutely dispersed species, where the molecules are separated by large distances and essentially noninteracting, is well defined.

Equation (83), called the Clausius–Clapeyron equation, is frequently applied to estimate p at one temperature when it is known at another and m and Λ are known: if Λ is nearly constant over the temperature range T_0 to T, then $p = p_0 \exp[-(m\Lambda/R)(1/T - 1/T_0)]$, where p and p_0 are the vapor pressures at T and T_0, respectively. This is an approximate equation of the vapor-pressure curve, p vs T, parametrized by the two parameters $p_0 \exp(m\Lambda/RT_0)$ and $m\Lambda$.

The ideal-gas law (80) is no longer accurate when the gas is not dilute. Corrections to it are often expressed as power series in the density called *virial series*. For a one-component gas one has

$$p = \frac{nRT}{V}\left[1 + B(T)\frac{n}{V} + C(T)\left(\frac{n}{V}\right)^2 + \cdots\right], \tag{84}$$

where $B(T)$, $C(T)$, . . . , which are functions of the temperature alone characteristic of the substance, are called the second, third, . . . *virial coefficients*. This reduces to the ideal-gas law in the limit of vanishing density, $n/V \to 0$.

A typical plot of the second virial coefficient B as a function of T is shown schematically in Fig. 13. B is negative at low temperatures and becomes rapidly more negative as the temperature decreases, while it is positive at high temperatures and then increases only slowly with increasing temperature. The temperature T_B at which $B(T) = 0$ is called the Boyle temperature: it is the unique temperature at which the deviation of pV/nRT from 1 is proportional to the second rather than the first power of n/V at low densities, and so the temperature at which Boyle's law pV = const. remains accurate to the highest densities. Negative values of $B(T)$ are manifestations mainly of the attractive forces that molecules exert on each other when they are separated by moderate distances, while the positive $B(T)$ are manifestations mainly of the strong intermolecular repulsions at short distances. At $T = T_B$ the intermolecular attractions that tend to decrease the pressure p and the repulsions that tend to increase it

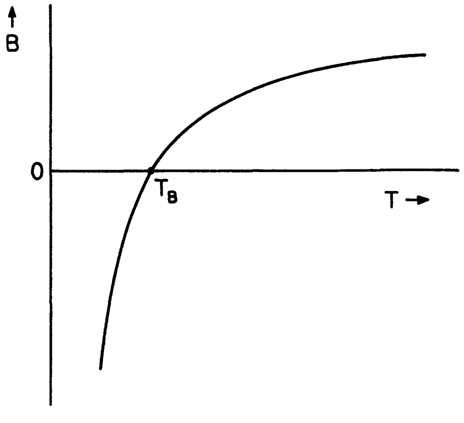

FIG. 13. Second virial coefficient $B(T)$ as a function of T, with T_B the Boyle temperature.

are roughly in balance. The Boyle temperatures of helium (^{4}He), hydrogen ($^1H_2$), and nitrogen (N_2) are 21, 110, and 327 K, respectively.

While U and H of an ideal gas depend only on the temperature and are independent of the state of compression, that is no longer true when the correction terms in (84) are significant. From the virial expansion (84) and the identities (63), with the coefficient of thermal expansion α defined in (60), one finds, to leading order in n/V,

$$\left(\frac{\partial U}{\partial V}\right)_T = RT^2\frac{dB}{dT}\left(\frac{n}{V}\right)^2 + O\left[\left(\frac{n}{V}\right)^3\right],$$
$$\left(\frac{\partial H}{\partial p}\right)_T = n\left[\frac{d(B/T)}{d(1/T)} + O\left(\frac{n}{V}\right)\right]. \tag{85}$$

When a gas expands into an evacuated, thermally insulated space (Joule expansion), no work is done or heat absorbed, $w = q = 0$, so that $\Delta U = q + w = 0$: the expansion is at constant energy. The rate of change of temperature with volume in such an expansion is then

$$\left(\frac{\partial T}{\partial V}\right)_U = -\frac{1}{C_V}\left(\frac{\partial U}{\partial V}\right)_T, \tag{86}$$

by (31). Then from the first of Eqs. (85) and the positivity of C_V, one sees that for a dilute gas the sign of this quantity is opposite that of dB/dT, hence negative (Fig. 13): the gas cools in the expansion.

When, instead, the gas is forced through a porous plug from a region of a constant high pressure p_1, where it occupies a volume V_1 initially, to a region of a constant low pressure p_2, where it occupies a volume V_2, but with the whole apparatus thermally insulated so that $q = 0$, the net work w done on the system is $p_1V_1 - p_2V_2$ and the net energy change is then $\Delta U = q + w = p_1V_1 - p_2V_2$. Then the enthalpy change is $\Delta H = \Delta U + \Delta(pV) = \Delta U + p_2V_2 - p_1V_1 = 0$. This expansion, called a Joule–Thomson expansion, is thus isenthalpic. The rate of change of temperature with pressure in such an expansion is then

$$\left(\frac{\partial T}{\partial p}\right)_H = -\frac{1}{C_p}\left(\frac{\partial H}{\partial p}\right)_T, \tag{87}$$

by the first of Eqs. (59). This quantity is called the Joule–Thomson coefficient. From the second of Eqs. (85) and the positivity of C_p, one sees that for a dilute gas its sign is opposite that of $d(B/T)/d(1/T)$, hence the same as that of $d(B/T)/dT$. From Fig. 13 one sees that since B increases only very slowly with increasing T at high temperatures, B/T vs T has positive slope for temperatures up to some T_i that is greater than T_B and negative slope for $T > T_i$. Thus, a dilute gas undergoing a Joule–Thomson expansion ($dp < 0$) cools ($dT < 0$) when $T < T_i$ and warms ($dT > 0$) when $T > T_i$. The temperature T_i is called the Joule–Thomson inversion temperature. For nitrogen $T_i = 633$ K, or about twice the Boyle temperature, which is typical.

When the intermolecular forces are of very long range, such as Coulomb forces, the deviations from ideality are no longer of the form (84). From the Debye–Hückel theory applied to a fully ionized gas (a plasma), analogous to the D–H theory of an electrolyte solution, one knows that the leading term in $pV/nRT - 1$ is proportional not to n/V, as in (84), but to $(n/V)^{1/2}$, and so the deviations from ideal-gas behavior begin at much lower densities than in gases whose molecules interact with short-range forces.

Another important class of dilute systems comprises liquid or solid mixtures in which one component (the "solvent") is present in large excess while all the other components (the "solutes") are dilutely dispersed in the solvent. When the solution is so dilute that the solute molecules interact very little with each other, we have the analog of the ideal gas, now called an ideal-dilute solution. Both from statistical-mechanical theory and from experiment one learns that the chemical potential μ_i of solute species i in such a solution is again given by (79), as in an ideal gas,

$$\mu_i = \frac{RT}{m_i}\ln\frac{c_i}{c_i^0}, \tag{88}$$

independently of the concentrations (or of the presence or absence) of any other solute species in the solution; but now c_i^0 not only depends on the chemical nature of the solute i and on the temperature, as in (79), but also depends on the nature of the solvent and on the pressure p. Equation (88) for the solute species i is called Henry's law. From (88) and the Gibbs–Duhem equation in the form

(53) one finds that the chemical potential μ_{solv} of the solvent depends on the total molar concentration $c = \Sigma_i c_i$ of all the solutes, according to

$$\mu_{\text{solv}} - \mu^0_{\text{solv}} = -RTc/\rho^0_{\text{solv}}, \tag{89}$$

where ρ^0_{solv} and μ^0_{solv} are the mass density and chemical potential of the pure solvent at the temperature T and pressure p of the solution. This is called Raoult's law.

The molar concentration c_i is conventionally called the molarity. An alternative measure of solute concentration, called molality, is the number of moles of solute per unit mass of solvent. In a dilute solution, which is almost all solvent, the ratio c/ρ^0_{solv} that appears in (89) is then the total solute molality.

All the properties of ideal-dilute solutions are derivable from (88) and (89). In particular, one may derive a group of colligative properties, which, analogously to the ideal-gas law, are properties that are proportional to the number of moles or molecules (the molar concentrations) of the dilute solute species but independent of their kind. By measuring any such colligative property one may determine the molecular weight m of the solute, since the measurement itself then leads to a knowledge of the solute's molar concentration c while the mass density ρ of the solute is known from how the solution was prepared, and then $m = \rho/c$. Since the solute species in question is dilute, its molecules, and so its molecular weight, are well defined—unlike those of the solvent. [Compare with the similar remark made in connection with the Clausius–Clapeyron equation, Eq. (83).]

The colligative properties of dilute solutions include the lowering of the solvent's vapor pressure, the elevation of the boiling point by nonvolatile solutes, and the depression of the freezing point when the solid that separates from the freezing solution is pure solid solvent.

Another colligative property of a dilute solution is its osmotic pressure. When a solution in one compartment is separated from pure solvent in another by a membrane that is freely permeable to solvent but impermeable to the solutes (which may be large polymer molecules, for example—too large to pass through the pores in the membrane), solvent will flow spontaneously from the pure solvent into the solution, to dilute it and thus tend to equalize the chemical potentials on the two sides. The process is called osmosis. The flow may be reversed by pressing on the solution with a pressure sufficiently in excess of that on the pure solvent; this is reverse osmosis. At one value of the excess pressure—termed the osmotic pressure, π—the chemical potential of the solvent will be the same on both sides of the membrane, and there will be no flow of solvent in either direction. This condition, with the dilute-solution law (89) and the known pressure dependence of the Gibbs free energy as given by (42), yields

$$\pi = RTc. \tag{90}$$

This is the law of van 't Hoff. It says that the osmotic pressure of a dilute solution of some total solute concentration is the same as the pressure of an ideal gas of that same concentration [Eq. (80)]. As with any other colligative property, as noted above, it may be used to determine the molecular weight of the dilute species. Measurement of the osmotic pressure is one of the principal methods of determination of the molecular weights of both synthetic and biological macromolecules in solution. According to (90) a solution of a polymer of molecular weight 50 000 g/mol at a concentration of 20 g/L would have an osmotic pressure at 25 °C of a hundredth of an atmosphere. That is a pressure of 10 cm of water, which is easily measurable.

6. THE THIRD LAW

The "third law of thermodynamics," unlike the first and second laws, does not introduce any new functions of state but rather asserts a universal behavior of the entropy at low temperatures. The most useful form of the third law is the Nernst "heat theorem."

Suppose a system undergoes a change in its thermodynamic state at a fixed temperature T (isothermal change) and that the accompanying entropy change is ΔS_T. The change could be a chemical reaction, a change of physical state (melting, for example, or transformation between two different crystalline forms), an isothermal expansion or compression, etc. We ask only that the system in both its initial and final states be in a condition of (complete or constrained) equilibrium so that it would be possible in principle to carry out the process reversibly, however it may actually be carried out, and so that the system has well-defined values of its thermodynamic functions both initially and finally. At the low temperatures of interest here the relevant processes are almost always those in which the system is a solid in both its initial and final states. Helium below 25 atm is an exception; see Fig. 11.

The third law of thermodynamics asserts as an empirical fact that as the temperature T at which such an isothermal process occurs approaches 0, so does the accompanying entropy change ΔS_T:

$$\lim_{T\to 0} \Delta S_T = 0. \tag{91}$$

This is the Nernst heat theorem. It says that the entropies in the initial and final states become equal at $T = 0$. This is true whether the change be merely one of physical state (crystal structure or density) or a change of chemical identity (chemical reaction). For all such states that are in principle transformable one into the other by a reversible process, physical or chemical, one may arbitrarily assign a value of the entropy in one of them at $T = 0$, and then, by (91), that will also be the value of the entropy in all the others at $T = 0$. By a generally accepted convention, that universal value of the entropy at $T = 0$ is taken to be 0. For substances that are not transformable into each other by chemical reaction that convention may be, and is, applied separately to each. Thus, one arrives at the statement that the entropies of substances in internal equilibrium, i.e., in well-defined thermodynamic states, are all 0 at $T = 0$, but it should be understood that the "0" for the value of the entropy is an arbitrary convention, not a law of nature. The law of nature is (91), which is a law about entropy changes. Only such differences are measurable physical quantities.

While the Nernst heat theorem is about entropy, it is an additional principle not derivable from the second law. It is understood from statistical mechanics to have its origin in the relative sparseness of the quantum mechanical energy levels of a macroscopic system in the neighborhood of its ground state.

An illustration of the third law may be seen in Fig. 11. According to the Clapeyron equation (75) the slope dp/dT of the solid–liquid-II equilibrium line in the p-T plane equals the ratio of entropy to volume changes that accompany that phase transition. The densities of those two equilibrium condensed phases approach limiting values, different from each other, as $T \to 0$, and so the volume difference has a nonvanishing limit; while the entropy difference, by (91), vanishes in that limit, implying that the slope dp/dT of the equilibrium line must then also vanish as $T \to 0$, as it is seen to do.

(That the slope of the vapor–liquid-II equilibrium line also vanishes at $T = 0$ is not an illustration of the third law. That slope vanishes because the specific volume of the equilibrium vapor rapidly becomes infinite as $T \to 0$. Because of the vanishing density of the vapor, the third law is not applicable to it.)

On the scale on which the entropy of a pure crystalline substance is taken to be 0 at $T = 0$, the entropy of that substance in any other physical state at any temperature and pressure may be identified with the entropy change that accompanies the transformation of the substance from a crystal at $T = 0$ to the state in question. This may be determined from measurements of heat capacities [by integrating C_p/T with respect to T at fixed p, for example, according to (59)] and the latent heats $\Delta H (= T\Delta S)$ of equilibrium phase transformations.

One may similarly obtain the enthalpy in that same state, hence also the Gibbs free energy $G = H - TS$ at that point, by (39). That, per unit mass, is the substance's chemical potential μ in that state, by (43). In this way, for example, one would have determined the c_i^0 characteristic of the substance i that appears in (79) or (88).

When the concentrations of the various species in equilibrium in a chemical reaction in a dilute system are then calculated from (52) with (79) or (88) and with the c_i^0's that are obtained from the third law of thermodynamics in the way just outlined, and are then also determined by direct measurement—by chemical analysis of equilibrium mixtures, for example—they are found to agree. These constitute important experimental verifications of the third law.

ACKNOWLEDGMENTS

GLOSSARY

Azeotropy: The circumstance of a density variable's having, exceptionally, the same value in coexisting phases.

Carnot Cycle: A reversible cycle consisting of alternating isothermal and adiabatic steps.

Colligative Property: Property proportional to the number but not the kind of molecules responsible for it.

Density (Variable): Ratio of two extensive variables.

Efficiency: Fraction of the heat absorbed at the higher temperature that is converted to work in a Carnot cycle.

Exact Differential: A quantity the integral of which depends only on the limits but not on the path of integration.

Field (Variable): Variable such as temperature or chemical potential that has a uniform value even in a heterogeneous system.

Heat Capacity: Ratio of heat absorbed to temperature rise.

180° Rule: Rule restricting the angles with which two-phase lines may meet at a triple point.

Joule Expansion: Expansion of a gas into an insulated space without its doing work (isoenergetic expansion).

Joule–Thomson Coefficient: Isenthalpic rate of change of temperature with pressure.

Joule–Thomson Expansion: Expansion of a gas through a plug from a constant high pressure to a constant low pressure (isenthalpic expansion).

Latent Heat: Enthalpy change (heat absorbed or evolved) in a phase transition.

Lever Rule: Rule giving the relative amounts (volumes, masses, etc.) of two phases in equilibrium.

Nernst Heat Theorem: The useful form of the third law of thermodynamics.

Osmotic Pressure: Excess pressure one must exert on a solution to prevent the spontaneous flow of solvent into it.

Schreinemakers' Rules: Density-space analogs of 180° rule.

Virial Series, Virial Coefficients: Expansion of the pressure in a series of powers of the density; the coefficients in that expansion.

INTRODUCTION

The preceding article (Thermodynamics, Equilibrium) contains the thermodynamics of equilibrium systems. In classical thermodynamics, the changes of entropy are generally evaluated by considering idealized *reversible* processes that connect the initial and final equilibrium states. For reversible transformations, the change in entropy is $dS = dQ/T$ in which dQ is the heat exchanged and T is the absolute temperature. Since changes in entropy depend only on the initial and final states, the entropy changes that occur in nature as a result of irreversible processes can be computed using the idealized reversible processes. This approach does not relate the rate of change of entropy to *irreversible* processes such as heat conduction, diffusion, and chemical reactions. A formalism that relates entropy to irreversible processes (Prigogine, 1947, 1967) begins with the recogni-

tion that dS is a sum of two parts (see Fig. 1):

$$dS = d_iS + d_eS, \quad d_iS \geq 0, \tag{1}$$

in which d_iS is the entropy change due to irreversible processes within the system and d_eS is the change in entropy due to exchange of matter and energy with the exterior, both occurring in a time dt. For a closed system, $d_eS = dQ/T$, where dQ is the heat exchanged with the exterior in a time dt. For idealized reversible processes $d_iS = 0$; we then have the classical result $dS = dQ/T$. The formulation of thermodynamics presented here relates d_iS explicitly to irreversible processes and encompasses both equilibrium and nonequilibrium systems.

Irreversible processes can be characterized by *thermodynamic forces,* which we shall denote by X_α, and *thermodynamic flows,* J_α. A gradient of temperature, for example, is the thermodynamic force that causes the flow of heat. Explicit expressions for the forces and flows in nonequilibrium systems are given below (see Sec 1.4). A basic quantity in nonequilibrium thermodynamics is the entropy production per unit volume, σ, which, as shown below, is a bilinear function in the forces and flows:

$$\sigma = \sum_\alpha J_\alpha X_\alpha. \tag{2}$$

Nonequilibrium systems may be classified into two regimes: the linear regime, which is characterized by a linear relationship between the forces and flows, and the nonlinear regime, in which the flows are nonlinear functions of the forces. In the linear regime, general results, such as the Onsager reciprocal relations and the theorem of minimum entropy production, are valid. In the nonlinear regime, we encounter instability and spontaneous transition to organized states called *dissipative structures.*

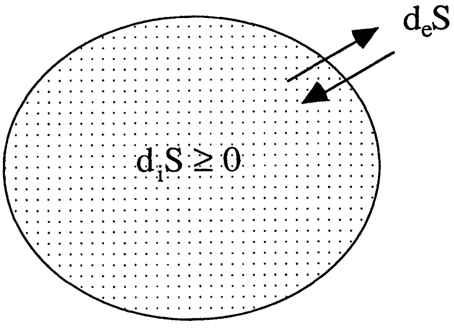

FIG. 1. The change of entropy of a system $dS = d_iS + d_eS$, in which d_iS is the change due to irreversible processes and d_eS is the change due to exchange of energy and matter with the exterior.

1. FORMULATION OF NONEQUILIBRIUM THERMODYNAMICS BASED ON THE ASSUMPTION OF LOCAL EQUILIBRIUM

1.1 Local Thermodynamic Variables

This formulation of nonequilibrium thermodynamics is based on the assumption that the temperature $T(x,t)$ in a nonequilibrium system, though not uniform, is a well-defined, measurable quantity at each point x and time t. Furthermore, it is assumed that in every elemental volume to which a definite temperature may be assigned, thermodynamic variables such as entropy and chemical potential may be defined, and that all the equilibrium relationships remain valid for these variables. It is assumed that, in spite of the existence of gradients of temperature, concentration, or other variables, the equilibrium relations between local variables remain valid. This is the *assumption of local equilibrium.* It has been shown that this assumption is valid whenever the local velocity distribution is nearly Maxwellian (Prigogine, 1949); a detailed discussion of this point may be found in Chapter IX of De Groot and Mazur (1969). Systems that are not locally in equilibrium are exceptional; for these systems, no general thermodynamic theory exists.

In accordance with the assumption of local equilibrium the following local variables are defined:

$$s = \text{entropy per unit mass,} \tag{3}$$

$$u = \text{total internal energy per unit mass,} \tag{4}$$

$$\rho_k = \text{mass per unit volume of component } k, \tag{5}$$

$$\rho = \sum_k \rho_k, \text{ mass per unit volume,} \tag{6}$$

$$\omega_k = \rho_k/\rho, \text{ the mass fraction of component } k, \tag{7}$$

$$\nu = \text{the specific volume.} \tag{8}$$

As in the case of equilibrium systems, it is assumed that s is a function of u, ν, and ω_k,

$$s = s(u,\nu,\omega_k), \tag{9}$$

and that

$$Tds = Td_is + Td_es = du + pd\nu - \sum_k \mu_k d\omega_k, \tag{10}$$

in which d_is and d_es are the entropy production and entropy exchange, respectively, p is the pressure, and μ_k is the chemical potential of component k. The total internal energy U and the total entropy S of a system of volume V are given by

$$U = \int_V \rho u dV, \tag{11}$$

$$S = \int_V \rho s dV. \tag{12}$$

The entropy production per unit volume

$$\sigma \equiv \frac{d_is}{dt}\rho \tag{13}$$

is derived incorporating the law of conservation of mass, momentum, and energy into Eq. (10).

1.2 The Conservation of Mass

The classical nonrelativistic mass is conserved in all physical and chemical processes. In any volume, the change in mass can only be due to flow through the surface enclosing the volume. In fluids, if $v(x,t)$ is the velocity at the location x at time t, the conservation of mass is expressed in the differential form

$$\frac{\partial \rho}{\partial t} = -\nabla\cdot(\rho\mathbf{v}). \tag{14}$$

For each component (or compound) k, on account of chemical reactions there is a "source" term that produces or consumes it. If the reaction rate (or velocity) of reaction j is v_j, and the flow velocity of the component is $\mathbf{v}_k$, the mass balance equation for k is

$$\frac{\partial \rho_k}{\partial t} = -\nabla\cdot(\rho_k\mathbf{v}_k) + \sum_j \nu_{jk}v_j, \tag{15}$$

in which $\nu_{jk} = M_k\nu'_{jk}$, where ν'_{jk} is the stoichiometric coefficient of component k in reaction j, and M_k is the molecular mass of k. The flow $\rho_k\mathbf{v}_k$ can be separated into the center-of-mass or barycentric velocity $\mathbf{v}$ and the flow $\mathbf{J}_k$ with respect to the center of mass, called the "diffusional flow." $\mathbf{v}$ and $\mathbf{J}_k$ are defined by

$$\mathbf{v} = \sum_k \rho_k\mathbf{v}_k/\rho, \tag{16}$$

$$\mathbf{J}_k \equiv \rho_k(\mathbf{v}_k - \mathbf{v}), \quad \sum_k \mathbf{J}_k = 0. \tag{17}$$

Substitution of (17) into (15) gives

$$\frac{\partial \rho_k}{\partial t} = -\nabla\cdot\mathbf{J}_k - \nabla\cdot(\rho_k\mathbf{v}) + \sum_j \nu_{jk}v_j. \tag{18}$$

In order to look at the time derivatives in the center-of-mass reference frame, the following "barycentric time derivative" may be introduced:

$$\frac{d}{dt} = \frac{\partial}{\partial t} + \mathbf{v}\cdot\nabla. \tag{19}$$

Using Eqs. (14)–(19), it can be shown that the mass balance of component k in the center-of-mass reference frame can be written as

$$\rho\frac{d\omega_k}{dt} = -\nabla\cdot\mathbf{J}_k + \sum_j \nu_{jk}v_j. \tag{20}$$

1.3 Conservation of Momentum and Energy

The rate of change of the center-of-mass momentum at a point x is given by

$$\frac{\partial \rho\mathbf{v}}{\partial t} = -\nabla\cdot(\rho\mathbf{v}\mathbf{v} + \mathsf{P}) + \sum_k \rho_k\mathbf{F}_k, \tag{21}$$

in which $\mathbf{vv}$ is a dyadic product, P is the pressure or stress tensor, and F_k is the force per unit mass acting on the component k. In terms of the Cartesian components of the vectors and the tensors,

$$\frac{\partial \rho v_\alpha}{\partial t} = -\sum_\beta \frac{\partial}{\partial x_\alpha}(\rho v_\alpha v_\beta + P_{\alpha\beta}) + \sum_k \rho_k(\mathbf{F}_k)_\alpha, \quad \alpha, \beta = 1, 2, 3. \tag{22}$$

A conservative force $\mathbf{F}_k$ is a gradient of a potential energy ψ_k:

$$\mathbf{F}_k = -\nabla\psi_k, \tag{23}$$

in which ψ_k is the interaction energy or potential energy of component k per unit mass. For static fields ψ_k is independent of time. In chemical reactions the potential energy remains unchanged. As a consequence,

$$\sum_k \psi_k \nu_{jk} = 0. \tag{24}$$

Using mass balance equation (15) and Eqs. (17) and (22)–(24), the following equation for the rate of change of the sum of kinetic and potential energy for the center-of-mass motion is obtained:

$$\frac{\partial(\mathbf{v}^2/2 + \psi)\rho}{\partial t} = -\nabla\left((\mathbf{v}^2/2 + \psi)\rho\mathbf{v} + \mathsf{P}\cdot\mathbf{v} + \sum_k \psi_k\mathbf{J}_k\right) + \mathsf{P}:\nabla\mathbf{v} - \sum_k \mathbf{J}_k\cdot\mathbf{F}_k. \tag{25}$$

In the above expression, ψ is the potential energy density defined by

$$\rho\psi \equiv \sum_k \rho_k\psi_k. \tag{26}$$

Equation (25) shows that the sum of the kinetic and potential energies is not conserved. This loss is compensated by a corresponding change in the total internal energy. Only when we include the total internal energy u do we have conservation of energy. The total energy per unit mass, e, may be defined by

$$e = \tfrac{1}{2}\mathbf{v}^2 + \psi + u, \tag{27}$$

in which the potential energy ψ is not considered a part of the internal energy. (One may also define u such that the potential energy is a part of the internal energy). The conservation of energy can now be written as

$$\frac{\partial \rho e}{\partial t} + \nabla\cdot\mathbf{J}_e = 0, \tag{28}$$

in which $\mathbf{J}_e$ is the energy current density. A more explicit expression for $\mathbf{J}_e$ is

$$\mathbf{J}_e = \rho e\mathbf{v} + \mathsf{P}\cdot\mathbf{v} + \sum_k \psi_k\mathbf{J}_k + \mathbf{J}_u. \tag{29}$$

In this expression the term $\mathsf{P}\cdot\mathbf{v}$ represents the energy flow due to mechanical work, while the term $\Sigma_k\psi_k\mathbf{J}_k$ represents the change in potential energy due to the flows. The term $\mathbf{J}_u$ is the flow of internal energy or, as it is sometimes referred to, the "heat flow." Using (25), (27), and (29) in (28), one obtains the following balance equation for the internal energy:

$$\frac{\partial \rho u}{\partial t} + \nabla\cdot(\rho u\mathbf{v} + \mathbf{J}_u) = -\mathsf{P}:\nabla\mathbf{v} + \sum_k \mathbf{J}_k\cdot\mathbf{F}_k. \tag{30}$$

Using (19), the balance equation for the internal energy in the center-of-mass reference frame can be written as

$$\rho\frac{du}{dt} + \nabla\cdot\mathbf{J}_u = -\mathsf{P}:\nabla\mathbf{v} + \sum_k \mathbf{J}_k\cdot\mathbf{F}_k. \tag{31}$$

For thermodynamic considerations, it is necessary to separate the hydrostatic part of the pressure tensor P through the use of the relation

$$\mathsf{P} = p\mathsf{I} + \mathsf{p}, \tag{32}$$

in which p is the hydrostatic pressure, I is the unit tensor, and p is the dissipative part of the pressure tensor because it contains viscous forces. By virtue of (14) and (19), it can be seen that

$$\rho\frac{d\nu}{dt} = \nabla\cdot\mathbf{v}, \tag{33}$$

in which $\nu = 1/\rho$ is the specific volume. Using (33) and (32) in (31), the following balance equation for the internal energy u in the center-of-mass reference frame is obtained:

$$\frac{du}{dt} + v\nabla\cdot\mathbf{J}_u = -p\frac{dv}{dt} - v\mathsf{p}{:}\nabla\mathbf{v} + v\sum_k \mathbf{J}_k\cdot\mathbf{F}_k. \tag{34}$$

1.4 The Entropy-Balance Equation

For the entropy-balance equation, the starting point is the assumption of local equilibrium as expressed in Eq. (10), which is assumed to be valid in the center-of-mass reference frame. For the time derivative of the specific entropy, we have

$$T\frac{ds}{dt} = \frac{du}{dt} + p\frac{dv}{dt} - \sum_k \mu_k \frac{d\omega_k}{dt}. \tag{35}$$

The equations of balance of internal energy, (34), and mass, (20), can now be used in (35) to obtain the following entropy-balance equation:

$$\begin{aligned}\rho\frac{ds}{dt} + \nabla\cdot\left(\frac{\mathbf{J}_u - \sum_k \mu_k\mathbf{J}_k}{T}\right) &= \mathbf{J}_u\cdot\nabla\left(\frac{1}{T}\right)\\ &- \sum_k \mathbf{J}_k\cdot\nabla\left(\frac{\mu_k}{T}\right) + \sum_k\frac{\mathbf{F}_k\cdot\mathbf{J}_k}{T} - \frac{\mathsf{p}{:}\nabla\mathbf{v}}{T} + \sum_j\frac{A_j v_j}{T},\end{aligned} \tag{36}$$

in which A_j is the chemical affinity of the reaction j, defined by

$$A_j = -\sum_k \nu_{jk}\mu_k. \tag{37}$$

Chemical affinity of a reaction is a fundamental concept introduced by De Donder and Van Rysselberghe (1936; see also Prigogine and Defay, 1967) to describe the thermodynamic driving force of chemical reaction. Equation (36) enables us to identify an entropy current $\mathbf{J}_S$ and an entropy production per unit volume σ as

$$\mathbf{J}_S \equiv \frac{1}{T}\left(\mathbf{J}_u - \sum_k \mu_k\mathbf{J}_k\right), \tag{38}$$

$$\begin{aligned}\sigma &\equiv \mathbf{J}_u\cdot\nabla\left(\frac{1}{T}\right) - \sum_k \mathbf{J}_k\cdot\nabla\left(\frac{\mu_k}{T}\right)\\ &+ \sum_k \mathbf{J}_k\cdot\frac{\mathbf{F}_k}{T} - \mathsf{p}{:}\frac{\nabla\mathbf{v}}{T} + \sum_j v_j\frac{A_j}{T}\\ &= \sum_\alpha J_\alpha X_\alpha \geq 0,\end{aligned} \tag{39}$$

in which we have emphasized the positivity of σ in accordance with the second law. Each of the terms in (39) is a product of a thermodynamic flow caused by a thermodynamic force: the gradient of $1/T$ causes the "heat flow" $\mathbf{J}_u$, the gradient of μ_k/T causes the matter flow $\mathbf{J}_k$, and affinities A_j cause the chemical reactions j with velocities v_j. The form of σ is bilinear in the thermodynamic forces and flows, as expressed in (2). Table 1 lists the thermodynamic forces and the corresponding flows. Alternative ways of expressing the entropy production and "heat flow" $\mathbf{J}_u$ can be found in De Groot and Mazur (1969) or Glansdorff and Prigogine (1971). The total entropy production of the system is given by

$$\frac{d_iS}{dt} = \int_V \sigma dV \geq 0. \tag{40}$$

1.5 Rational Thermodynamics

Some authors (Truesdell, 1969) have argued that the traditionally used Clausius inequality $TdS \geq \delta Q$ and other thermodynamic statements are lacking in mathematical rigor. For example, according to Truesdell (1969, p. 3), the reader "is told that dS is a differential, but not of what variable S is a function; that δQ is a small quantity not generally a differential; he is expected to believe not only that one differential can be bigger than another, but even that a differential can be bigger than something that is not a differential." In order to make thermodynamic more rigorous or "rational," an axiomatic approach is taken (Coleman and Noll, 1963; Coleman, 1964; Truesdell, 1969; Noll, 1974). This approach also formally includes systems with memory for which the values of the de-

Table 1. Table of thermodynamic forces and flows.

	Force X_α	Flow $\mathbf{J}_\alpha$
Heat conduction	$\nabla(1/T)$	Heat flow $\mathbf{J}_u$
Diffusion	$-\nabla(\mu_k/T)$	Diffusion current $\mathbf{J}_k$
Conservative force	$-\nabla\psi_k/T = F_k/T$	Current $\mathbf{J}_k$
Chemical reactions	A_j/T	Velocity of reaction v_j
Viscous dissipation	$-\nabla\mathbf{v}$	Stress p

pendent variables depend on the history of the system; i.e., the values of the dependent variables at time t are functionals of the independent variables for all times less than $t' < t$.

In rational thermodynamics, s and T are taken as primitive concepts. No physical or operational interpretation is given to these variables; in other words, how these quantities are related to experimentally measured variables is not made clear at the outset. It is assumed that the variables of the system are in general memory dependent. Furthermore, functions such as s are assumed to be dependent not only the variables such as T and ν but also on the gradient of T and the velocity of the fluid. Thus, for example,

$$s = s(\nu, T, \mathbf{v}, \nabla T). \tag{41}$$

Similarly, other quantities such as the heat flux $\mathbf{J}_q$ are also functionals of the same variables. Such formal relations that express one set of variables as functions of the other are called *constitutive equations*. Forces and energy fluxes are assumed to be such that the balance of momentum and energy are always valid. The conservation of energy (34) includes an additional term ρr due to radiation. The force terms $\mathbf{F}_k$ are assumed to be such that the conservation of momentum is satisfied. Unlike the formulation in Sec. 1.3, rational thermodynamics does not introduce the forces as known functions; the momentum-balance equation is taken to be the definitions of the forces.

The other axioms on which rational thermodynamics is based are the following:

- The constitutive equations should be such that the Clausius–Duhem inequality, stated as

$$\frac{d}{dt}\int_V \rho s dV \geq -\int_a \frac{\mathbf{J}_q \cdot d\mathbf{a}}{T} + \int_V \frac{\rho r}{T} dV, \tag{42}$$

  holds, in which $d\mathbf{a}$ is the area-element vector and $\mathbf{a}$ is the area enclosing the volume V. The second law is incorporated into the theory using this condition or other local forms that can be derived from this basic condition.
- The *principle of equipresence* holds, which states that all independent variables are equally present in the functions that specify the dependent variables except when the Clausius–Duhem inequality is violated.
- The *principle of material frame-indifference* holds, according to which all constitutive equations must be independent of the frame of reference, which undergoes arbitrary time-dependent translations and rotations. That is, equations for quantities such as heat flux should be the same for every frame of reference including arbitrary rotations.

Other more detailed aspects of the formalism can be found in Truesdell (1969).

With the above axioms, it is shown that the specific entropy s and energy u are local functions of ν and T, in agreement with the assumption of local equilibrium. In this formulation the local validity of the Gibbs equation is derived from the axioms, not assumed. Many of the results obtained by the theory that assumes local equilibrium are also obtained in rational thermodynamics, though with more emphasis on mathematical rigor than on applications.

Rational thermodynamics is mostly of formal interest, and its application has been beset with many computational difficulties. The most serious difficulty is the principle of material frame-indifference, which is found not to be valid in kinetic theory of gases, turbulence, rheology, and other subjects (Jou, 1993).

2. EXTENDED THERMODYNAMICS

2.1 The Need to Go Beyond Local Equilibrium

When a system is not in thermodynamic equilibrium, there are flows such as heat flow or diffusion. In general, every part is associated not only with the usual variables such as energy density, specific volume, pressure, and temperature but also with flows, such as heat flow. In view of this, it is natural to ask if quantities such as the entropy density s depend on the flows as well. Indeed, nonequilibrium statistical mechanics does lend support to such a notion. Local-equilibrium formulation assumes that such dependence can be ignored.

Another aspect of local-equilibrium theory is that linear phenomenological laws that can be obtained from the expression for the entropy production, such as the Fourier law of heat conduction and Fick's law of diffusion, imply infinite propagation velocity for heat and matter, which are clearly unphysical. As an example, let us consider heat conduction. According to Fourier's law, the heat flow $\mathbf{J}_q = -\kappa\nabla T$ (κ = heat conductivity) is assumed to be established instantaneously with the temperature gradient. In reality, this is not true because the heat flow $\mathbf{J}_q$ has a relaxation time during which it evolves to the value given by Fourier's law. This relaxation time, τ_q, is very small, of the order of 10^{-13} s (Jou, 1993), but not zero. From a thermodynamic point of view, the relaxation of these flows is itself an entropy-producing process, and hence the entropy depends on the value of these flows. Thus, in dealing with rapid processes in which relaxation times of the flows cannot be ignored, the local-equilibrium approach is inadequate. However, a very large class of phenomena, discussed in later sections of this article, can be described using the local-equilibrium thermodynamics.

The more recently developed *extended thermodynamics* is a formalism that goes beyond the assumption of local equilibrium and finds the explicit dependence of entropy on the flows. It is better suited for describing fast processes and viscoelastic phenomena in which the relaxation time of the flows cannot be ignored. Because of space limitations, we give only a brief outline of this theory. An excellent description of extended thermodynamics and its applications may be found in Jou (1993) and Müller and Ruggeri (1993).

2.2 The Extended Gibbs Equation

In presenting the basic formalism of extended thermodynamics, for simplicity we consider only the heat flow and assume that there are no gradients of velocity. The specific entropy s is then a function of u, ν, and the heat flow $\mathbf{J}_q$:

$$s = s(u,\nu,\mathbf{J}_q), \tag{43}$$

and

$$ds = \left(\frac{\partial s}{\partial u}\right)du + \left(\frac{\partial s}{\partial \nu}\right)d\nu + \left(\frac{\partial s}{\partial \mathbf{J}_q}\right)\cdot d\mathbf{J}_q. \tag{44}$$

A nonequilibrium absolute temperature θ and pressure π may now be defined as

$$\frac{1}{\theta} = \frac{\partial s}{\partial u}, \quad \frac{\pi}{\theta} = \frac{\partial s}{\partial \nu}. \tag{45}$$

To make a connection with the temperature $T(u,\nu)$ and pressure $p(u,\nu)$ of the local equilibrium theory, it is assumed that to the leading order the temperature θ is equal to T, i.e.,

$$1/\theta = 1/T(u,\nu) + \text{higher-order terms involving } \mathbf{J}_q. \tag{46}$$

Similarly,

$$\frac{\pi}{\theta} = \frac{p(u,\nu)}{T(u,\nu)} + \text{higher-order terms involving } \mathbf{J}_q. \tag{47}$$

To relate the formalism to relaxation times of the heat flow more directly, the derivative of s with respect to $\mathbf{J}_q$ is written in the form

$$\frac{\partial s}{\partial \mathbf{J}_q} = -\frac{\nu}{T}\boldsymbol{\alpha}(u,\nu,\mathbf{J}_q), \tag{48}$$

where α is a function to be determined. To the first order in the flow $\mathbf{J}_q$, the function α may be written as

$$\boldsymbol{\alpha} = \alpha_0(u,\nu)\mathbf{J}_q, \tag{49}$$

where α_0 is a function of u and ν, as indicated. To the leading order in $\mathbf{J}_q$, the differential of the specific entropy can now be written as

$$ds = \frac{1}{T}du + \frac{p}{T}d\nu - \frac{\nu\alpha_0}{T}\mathbf{J}_q\cdot d\mathbf{J}_q. \tag{50}$$

This extension of the Gibbs equation is the basic equation of extended thermodynamics. The success and usefulness of this equation depend on the specification of α_0 and its experimental determination. As shown below,

$$\alpha_0 = \tau_q/\kappa T, \tag{51}$$

where τ_q is the relaxation time for the heat flow and κ is the heat conductivity.

The inclusion of viscous effects into the expression (50) can be similarly done. The result is the expression

$$ds = \frac{1}{T}du + \frac{p}{T}dv - \frac{v\alpha_0}{T}\mathbf{J}_q \cdot d\mathbf{J}_q - \frac{v\alpha_p}{T}p^v dp^v - \frac{v\alpha_p'}{T}\mathsf{p}^v{:}d\mathsf{p}^v, \qquad (52)$$

in which the dissipative part of the pressure tensor p, defined by (32), has been expressed as

$$\mathsf{p} = p^v\mathsf{I} + \mathsf{p}^v, \quad p^v = \tfrac{1}{3}Tr(\mathsf{p}). \qquad (53)$$

The tensor p^v is the traceless part of the dissipative pressure tensor p. As in the case of α_0, the terms α_p and α_p' can be related to the relaxation times of the viscous flows (Jou, 1993):

$$\alpha_p = \tau_\zeta/\zeta, \quad \alpha_p' = \tau_\eta/\eta, \qquad (54)$$

in which ζ and η are the bulk and shear viscosities and τ_ζ and τ_η are the corresponding relaxation times.

2.3 Entropy Production and Nonequilibrium Entropy

From expression (50) for the differential of the specific entropy, the following expression for the time derivative of s can be obtained using the energy conservation equation (34) when the only flow is the heat flow:

$$\rho\frac{ds}{dt} = \frac{1}{T}\nabla \cdot \mathbf{J}_q - \frac{\alpha_0}{T}\mathbf{J}_q \cdot \frac{d\mathbf{J}_q}{dt}, \qquad (55)$$

in which we have used the density $\rho = 1/v$, and the barycentric time derivative (19). Also, since the energy flow is entirely the heat flow, $\mathbf{J}_q$ has been used in the place of $\mathbf{J}_u$. As was done for the case of local equilibrium, if this equation can be cast in the form

$$\rho\frac{ds}{dt} + \nabla \cdot \mathbf{J}_s = \sigma, \qquad (56)$$

the entropy production σ and the entropy current or entropy flow $\mathbf{J}_s$ can be identified. In the above case, one can easily see that

$$\mathbf{J}_s = \frac{\mathbf{J}_q}{T} \quad \text{and} \quad \sigma = \mathbf{J}_q \cdot \left[\nabla\frac{1}{T} - \frac{\alpha_0}{T}\frac{d\mathbf{J}_q}{dt}\right]. \qquad (57)$$

As can be seen, the expression for σ is a product of the flow $\mathbf{J}_q$ and the force $\nabla(1/T) - (\alpha_0/T)(d\mathbf{J}_q/dt)$. Comparing it with (39), we see an additional term containing the time derivative of the heat flow. The thermodynamic flow is driven by the thermodynamic force, and it vanishes when the force vanishes. Thus, to the first order, i.e., the linear approximation, we may write

$$\mathbf{J}_q = L_{qq}\left[\nabla\frac{1}{T} - \frac{\alpha_0}{T}\frac{d\mathbf{J}_q}{dt}\right]. \qquad (58)$$

This equation is essentially the same as the following Cattaneo equation (Jou, 1993; Müller and Ruggeri, 1993) for heat conduction, which is derived using kinetic theory of gases and which takes the relaxation time of the heat current into account:

$$\mathbf{J}_q = -\tau_q\frac{d\mathbf{J}_q}{dt} - \kappa\nabla T. \qquad (59)$$

Comparing (58) and (59) we see that

$$L_{qq} = \kappa T^2, \quad \alpha_0 = \tau_q/\kappa T. \qquad (60)$$

Thus the coefficients α_0 and L_{qq} can be related to measurable quantities such as κ and τ_q. Using the relation (60) for α_0 in (50), one can now obtain a more explicit expression for ds:

$$ds = \frac{du}{T} + \frac{p}{T}dv - \frac{\tau_q v}{\kappa T}\mathbf{J}_q \cdot d\mathbf{J}_q. \qquad (61)$$

When the heat current vanishes, the specific entropy corresponds to the equilibrium entropy. Thus, if we integrate for the equilibrium state of $\mathbf{J}_q = 0$ to $\mathbf{J}_q$, we obtain

$$s(u,v,\mathbf{J}_q) = s(u,v)_{\text{eq}} - \frac{\tau_q v}{2\kappa T}\mathbf{J}_q \cdot \mathbf{J}_q. \qquad (62)$$

This expression shows that because of the flow the system has slightly smaller entropy than the equilibrium entropy. Expressions (57) and (62) can be generalized to include other thermodynamic flows and forces (Jou, 1993; Müller and Ruggeri, 1993).

As in the case of local equilibrium theory, in extended thermodynamics the second law is stated as $\sigma > 0$. The specific entropy is assumed to be an additive, convex function of all the independent variables.

3. LINEAR NONEQUILIBRIUM THERMODYNAMICS

The thermodynamic flows are a function of the thermodynamic forces. At equilibrium, the forces and the flows vanish. Close to equilibrium, the flows are linear functions of the forces. This is the regime of linear nonequilibrium thermodynamics. General results valid in this regime are summarized in this section. When a system is driven far from equilibrium, the flows become nonlinear functions of the forces. In the nonlinear regime, instability, self-organization, and complex behavior can arise. Nonlinear conditions can most easily be achieved in chemical systems.

3.1 Linear Phenomenological Laws

In the linear regime, the thermodynamic flows J_α are linear functions of forces X_α:

$$J_\alpha = \sum_\alpha L_{\alpha\beta} X_\beta. \tag{63}$$

The coefficients $L_{\alpha\beta}$ are called the *phenomenological coefficients*. Equation (63) implies that the forces and their corresponding flows do not act independently; they are coupled to each other. As is clear from Table 1, the forces X_β have various tensorial characters. In the case of a chemical reaction, the thermodynamic force is a scalar; for the case of heat flow, it is a vector; and for viscous dissipation, it is a tensor of the second rank. Symmetry considerations restrict the possible coupling between forces and flows. In isotropic systems, forces and flows of different tensorial character do not couple. This symmetry principle, sometimes referred to as the Curie principle (Prigogine, 1947, 1967; De Groot and Mazur, 1969), implies, for example, that a chemical affinity, which is a scalar, could not be coupled to heat flow, which is a vector. Thus, the corresponding phenomenological coefficients $L_{\alpha\beta}$ vanish. On the other hand, the coupling of diffusion to heat flow or the coupling of heat flow to electrical current is possible. These cross effects are the thermal-diffusion and thermoelectric effects, respectively.

In the linear regime, the entropy production σ takes the quadratic form

$$\sigma = \sum_\alpha J_\alpha X_\alpha = \sum_{\alpha,\beta} L_{\alpha\beta} X_\alpha X_\beta \geq 0. \tag{64}$$

For the above quadratic form, the positivity of entropy production leads to the following conditions on $L_{\alpha\beta}$:

$$L_{\alpha\alpha} > 0 \quad \text{and} \quad 4L_{\alpha\alpha}L_{\beta\beta} \geq (L_{\alpha\beta} + L_{\beta\alpha})^2. \tag{65}$$

Long-known empirical laws relating flows and the corresponding causes have been unified by nonequilibrium thermodynamics. Some simple examples of well-known empirical linear laws are Fourier's law of heat conduction,

$$\mathbf{J}_q = -\kappa \nabla T(x), \tag{66}$$

Fick's law of diffusion,

$$\mathbf{J}_k = -\rho D_k \nabla \omega_k(x), \tag{67}$$

and Ohm's law,

$$\mathbf{I} = \mathbf{E}/\rho_e, \tag{68}$$

in which κ is the heat conductivity, D_k is the diffusion coefficient, ω_k is the mass fraction of k [cf. Eq. (7)], $\mathbf{I}$ is the electric current density, $\mathbf{E}$ is the electric field, and ρ_e is the specific resistance. These laws remain nearly linear even for very large gradients. The relation between the empirical constants such as κ in (66) and the corresponding phenomenological coefficient L_{qq} can be obtained by equating the phenomenological heat current with the one according to (66):

$$\mathbf{J}_q = L_{qq} \nabla(1/T) = -\kappa \nabla T, \tag{69}$$

from which it follows that

$$\kappa = L_{qq}/T^2. \tag{70}$$

For diffusion in a multicomponent system, the currents are not independent because $\Sigma_k \mathbf{J}_k = 0$ [cf. (17)]. For dilute solutions in which the isothermal diffusion of a minor component is considered, we may assume that the center of mass is essentially fixed to the stationary major component. In this case, the relation between the phenomenological coefficient L_{kk} and the diffusion coefficient D_k is (see Sec. 3.5)

$$D_k = \left(\frac{\partial \mu_k}{\partial \omega_k}\right) \frac{L_{kk}}{\rho T}, \tag{71}$$

in which μ_k is the chemical potential and ω_k is the mass fraction. Similarly, for electrical conduction at constant temperature (see Sec. 3.3),

$$1/\rho_e = L_{ee}/T, \tag{72}$$

in which ρ_e is the specific resistance. For chemical systems, however, the linear laws are valid only for small perturbations in the concentrations from the equilibrium values. If R_{fj} and R_{rj} are the forward and reverse reaction rates of an elementary reaction, the reaction velocity is

$$v_j = R_{fj} - R_{rj}. \tag{73}$$

The relation between the velocity and the affinity can be shown to be (Prigogine, 1967)

$$v_j = R_{fj}[1 - \exp(-A_j/RT)], \tag{74}$$

in which R is the gas constant. Equation (74) shows that only when the affinities are much smaller than RT is there a linear relation between the velocity and the affinity. Affinities of the order of 100 $\mathrm{kJ \cdot mol^{-1}}$ are commonly encountered. At room temperature, since RT is about 2.5 $\mathrm{kJ \cdot mol^{-1}}$, chemical systems are generally not in the linear regime of thermodynamics.

3.2 The Onsager Reciprocal Relations

For the phenomenological coefficients $L_{\alpha\beta}$, based on the assumption of microscopic reversibility, Lars Onsager (Onsager, 1931a, 1931b) proposed the *reciprocal relations*

$$L_{\alpha\beta} = L_{\beta\alpha}. \tag{75}$$

The theoretical basis of these relations requires careful considerations (Casimir, 1945; Wigner, 1954; Truesdell, 1969; Kreuzer, 1981) that are beyond the scope of this article. Examples of cross effects and the reciprocal relations are discussed in Sec. 3.3–3.9. In the presence of a magnetic field **B**, the reciprocal relations take the form

$$L_{\alpha\beta}(\mathbf{B}) = L_{\beta\alpha}(-\mathbf{B}). \tag{76}$$

As we have noted above [cf. (17)], in the center-of-mass reference frame the flows are not all independent. However, the reciprocal relations are valid even when the flows are not all independent. In general, if there exists a linear relation between the n flows,

$$\sum_{\alpha=1}^{n} y_\alpha J_\alpha = 0, \tag{77}$$

then the expression for the entropy production can be expressed in terms of the $n - 1$ independent flows:

$$\sigma = \sum_{\alpha=1}^{n} J_\alpha X_\alpha = \sum_{\alpha=1}^{n-1} J_\alpha \left(X_\alpha - \frac{y_i}{y_n} X_n\right). \tag{78}$$

For these $n - 1$ flows, we have the new linear phenomenological relations

$$J_\alpha = \sum_{\alpha=1}^{n-1} \tilde{L}_{\alpha\beta} \left(X_\beta - \frac{y_i}{y_n} X_n\right). \tag{79}$$

Given that $L_{\alpha\beta} = L_{\beta\alpha}$, it can be shown that the reciprocal relations are also valid for $\tilde{L}_{\alpha\beta}$, i.e.,

$$\tilde{L}_{\alpha\beta} = \tilde{L}_{\beta\alpha}. \tag{80}$$

In addition to a linear relation between the thermodynamic flows, if there is also a linear relation between the thermodynamic forces, then the reciprocal relations are not generally valid for any set of phenomenological coefficients $L_{\alpha\beta}$. However, it is always possible to choose a set of flows and forces for which the reciprocal relations are valid. Examples of cross effects and reciprocal relation are discussed in the following sections.

3.3 Thermoelectric Phenomena

As a first illustration of the above theory, we consider thermoelectric effects that involve the flow of heat $\mathbf{J}_q$ and electric current $\mathbf{I}_e$ in conducting wires (in which the subscript e indicates that the flow corresponds to the flow of electrons). The entropy production per unit volume due to these two irreversible processes and the linear phenomenological laws associated with it are

$$\sigma = \mathbf{J}_q \cdot \nabla(1/T) + \mathbf{I}_e \cdot \mathbf{E}/T, \tag{81}$$

$$\mathbf{J}_q = L_{qq}\nabla(1/T) + L_{qe}\mathbf{E}/T, \tag{82}$$

$$\mathbf{I}_e = L_{ee}\mathbf{E}/T + L_{eq}\nabla(1/T). \tag{83}$$

In the above equations, **E** is the electric field. For a one-dimensional system, such as a conducting wire, the vectorial aspect of $\mathbf{J}_q$ and $\mathbf{I}_e$ is unimportant and they may be treated as scalars. To relate the coefficients L_{qq} and L_{ee} with the heat conductivity κ and resistance R, we can write Eqs. (82) and (83) in a one-dimensional system as

$$J_q = -\frac{1}{T^2}L_{qq}\frac{\partial T}{\partial x} + L_{qe}\frac{E}{T}, \tag{84}$$

$$I_e = L_{ee}\frac{E}{T} - \frac{1}{T^2}L_{eq}\frac{\partial T}{\partial x}. \tag{85}$$

To find the relation between L_{ee} and the resistance R, we note that the emf $V = -\Delta\phi = \int_0^l E dx$ in which l is the length of the system. The current I_e is a constant in the entire system. At uniform temperature ($\partial T/\partial x = 0$), the current is entirely due to electrical potential difference. Integrating (85) over the length of the system we obtain

$$L_{ee} = \frac{T}{(R/l)} = \frac{T}{r}, \tag{86}$$

in which R is the total resistance of the wire and r is the resistance per unit length. More generally,

$$L_{ee} = T/\rho_e, \tag{87}$$

in which ρ_e is the specific resistance. When we consider a one-dimensional system, ρ_e is replaced by r, resistance per unit length. We have already seen that $L_{qq} = T^2\kappa$ [cf. (70)].

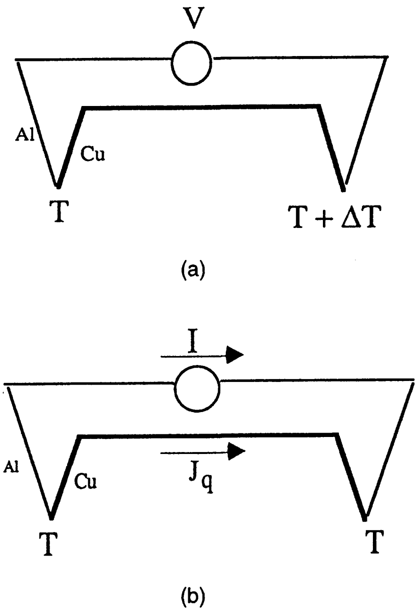

FIG. 2. The thermoelectric effects, examples of "cross effects" between thermodynamic forces and flows. (a) In the Seebeck effect, two dissimilar metal wires are joined and the junctions are maintained at different temperatures. (b) In the Peltier effect, the two junctions are maintained at the same temperature, and a current is passed through the system. The current flow drives a heat flow J_q from one junction to the other.

3.3.1 The Seebeck Effect The cross coefficients L_{qe} and L_{eq} can also be related to experimentally measured quantities. In the Seebeck effect (see Fig. 2), a temperature difference between two junctions of dissimilar metals produces an emf. This emf is measured at zero current. Setting $I_e = 0$ in Eq. (85) we obtain

$$0 = L_{ee}ET - L_{eq}\frac{\partial T}{\partial x}. \tag{88}$$

This equation may now be integrated to obtain a relation between the temperature difference ΔT and the emf generated due to this temperature difference, $\Delta\phi = -\int E dx$. In doing this integration, we shall assume that the total variation ΔT is small and make the approximation $\int TE dx \approx T\int E dx = -T\Delta\phi$. This gives us the relation

$$L_{eq} = -L_{ee}T\left(\frac{\Delta\phi}{\Delta T}\right)_{I=0}. \tag{89}$$

Experimentally, the ratio $-(\Delta\phi/\Delta T)_{I=0}$, called *thermoelectric power*, is measured. Using (87) and (89), the coefficient L_{eq} can be related to the measured quantities.

3.3.2 The Peltier Effect In the Peltier effect, the two junctions are maintained at a constant temperature while a current I is passed through the system (see Fig. 2). This causes a flow of heat from one junction to another. The two junctions are maintained at the same temperature by supplying heat to one junction and removing heat from the other junction—thus maintaining a steady heat flow J_q. Under these conditions, the ratio

$$\Pi = J_q/I, \tag{90}$$

which can be measured, is called the *Peltier heat.* The cross coefficient L_{qe} can be related to the Peltier heat as follows. Since there is no temperature difference between the two junctions, $\partial T/\partial x = 0$, and Eqs. (84) and (85) become

$$J_q = L_{qe}E/T, \tag{91}$$

$$I_e = L_{ee}E/T. \tag{92}$$

Dividing one equation by the other and using Eqs. (90) and (86) we obtain

$$L_{qe} = \Pi L_{ee} = \Pi\frac{T}{(R/l)} = \Pi\frac{T}{r}. \tag{93}$$

In this manner, all the phenomenological coefficients L_{qe} and L_{eq} can be related to the experimental parameters of the cross effects.

According to the Onsager reciprocal relations, one must find $L_{qe} = L_{eq}$. Upon using Eq. (89) for L_{eq} and Eq. (93) for L_{qe}, we find

$$-L_{ee}T\left(\frac{\Delta\phi}{\Delta T}\right) = \Pi L_{ee}, \quad \text{or} \quad -\left(\frac{\Delta\phi}{\Delta T}\right) = \frac{\Pi}{T}. \tag{94}$$

Extensive data verifying the reciprocal relations may be found in Miller (1960, 1974).

3.4 Thermogalvanomagnetic Phenomena

Thermogalvanomagnetic phenomena deal with the cross effects between the flows of heat and electric current in the presence of a magnetic field. An example is the Hall effect (see Fig. 3) in which a current flow in the x direction in the presence of a magnetic field in the z direction results in the generation of a voltage in the y direction. The entropy production due to thermal and electric currents in a system under mechanical equilibrium is [cf. Eq. (81)]

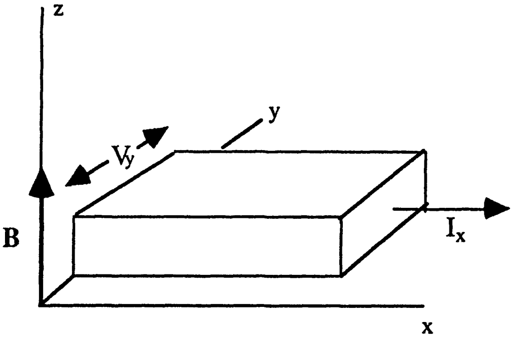

FIG. 3. The Hall effect, an example of a galvanomagnetic effect. If an electric current I_x is made to flow in the x direction in the presence of a magnetic field B in the z direction, a voltage V_y is generated in the y direction.

$$\sigma = \mathbf{J}_q\cdot\nabla(1/T) + \mathbf{I}_e\cdot\mathbf{E}/T. \tag{95}$$

In this case the vectorial character of the current is essential to the analysis. The phenomenological laws are

$$\mathbf{I}_e = \mathsf{L}_{ee}(\mathbf{B})\cdot\mathbf{E} + \mathsf{L}_{eq}(\mathbf{B})\cdot\nabla(1/T), \tag{96}$$

$$\mathbf{J}_q = \mathsf{L}_{qe}(\mathbf{B})\cdot\mathbf{E} + \mathsf{L}_{qq}(\mathbf{B})\cdot\nabla(1/T). \tag{97}$$

In the presence of a magnetic field $\mathbf{B}$, the coefficients are tensors of the second rank instead of scalars, and, as shown explicitly, the elements of L_{ee}, L_{qe}, etc., depend on the magnetic field. In this case, the Onsager reciprocal relations take the form

$$\mathsf{L}_{ee}(\mathbf{B}) = \mathsf{L}_{ee}^{T}(-\mathbf{B}), \tag{98}$$

$$\mathsf{L}_{qq}(\mathbf{B}) = \mathsf{L}_{qq}^{T}(-\mathbf{B}), \tag{99}$$

$$\mathsf{L}_{eq}(\mathbf{B}) = \mathsf{L}_{qe}^{T}(-\mathbf{B}), \tag{100}$$

where the superscript T stands for the transpose of the tensor, in which the rows and columns of the matrix representation are interchanged. In the absence of thermal gradients, the phenomenological coefficients are the Hall coefficients. In terms of the elements of the tensors L, the reciprocal relations (100), for example, take the form

$$[\mathsf{L}_{eq}(\mathbf{B})]_{ij} = [\mathsf{L}_{qe}(-\mathbf{B})]_{ji}. \tag{101}$$

3.5 Isothermal Diffusion

For isothermal diffusion, the entropy production is

$$\sigma = -\sum_k \mathbf{J}_k \cdot \nabla(\mu_k/T), \tag{102}$$

in which $\mathbf{J}_k$ is the matter current and μ_k is the chemical potential of the species k. Under isothermal conditions the associated linear laws are

$$\mathbf{J}_i = -\sum_k \frac{L_{ik}}{T} \nabla\mu_k. \tag{103}$$

For simultaneous diffusion of several species (under isothermal conditions), Fick's law takes the form

$$\mathbf{J}_i = -\sum_k \rho D_{ik} \nabla\omega_k(\mathbf{x}). \tag{104}$$

Since the diffusion flows in a two-component system are not independent, to verify Onsager's reciprocal relations we need at least three components. For three components the entropy production per unit volume is

$$\sigma = -\frac{\mathbf{J}_1}{T}\cdot\nabla\mu_1 - \frac{\mathbf{J}_2}{T}\cdot\nabla\mu_2 - \frac{\mathbf{J}_3}{T}\cdot\nabla\mu_3, \tag{105}$$

in which [cf. (17)]

$$\mathbf{J}_1 + \mathbf{J}_2 + \mathbf{J}_3 = 0. \tag{106}$$

The Gibbs–Duhem equation gives the following relation between the gradients of μ_k:

$$\omega_1(\nabla\mu_1)_{p,T} + \omega_2(\nabla\mu_2)_{p,T} + \omega_3(\nabla\mu_3)_{p,T} = 0. \tag{107}$$

If $\mathbf{J}_3$ and μ_3 are the variables for the solvent while $\mathbf{J}_1$, μ_1 and $\mathbf{J}_2$, μ_2 are the variables of two solutes whose diffusion cross effects are of interest, then, by use of (106) and (107), $\mathbf{J}_3$ and μ_3 can be eliminated from the expression for the entropy production. The entropy production can then be written in terms of only the variables $\mathbf{J}_1$, μ_1 and $\mathbf{J}_2$, μ_2 of the two solutes:

$$\sigma = \mathbf{X}_1\cdot\mathbf{J}_1 + \mathbf{X}_2\cdot\mathbf{J}_2, \tag{108}$$

in which the thermodynamic forces $\mathbf{X}_1$ and $\mathbf{X}_2$ are

$$\mathbf{X}_1 = -\frac{1}{T}\left[\nabla\mu_1 + \frac{\omega_1}{\omega_3}\nabla\mu_1 + \frac{\omega_2}{\omega_3}\nabla\mu_2\right], \tag{109}$$

and

$$\mathbf{X}_2 = -\frac{1}{T}\left[\nabla\mu_2 + \frac{\omega_2}{\omega_3}\nabla\mu_2 + \frac{\omega_1}{\omega_3}\nabla\mu_1\right]. \tag{110}$$

The associated phenomenological laws then take the form

$$\mathbf{J}_1 = L_{11}\mathbf{X}_1 + L_{12}\mathbf{X}_2, \tag{111}$$

$$\mathbf{J}_2 = L_{12}\mathbf{X}_1 + L_{22}\mathbf{X}_2. \tag{112}$$

To verify the reciprocal relations, we must now relate L_{ik} and the experimentally measured diffusion coefficients D_{ik} of Fick's law:

$$\mathbf{J}_1 = -\rho D_{11}\nabla\omega_1 - \rho D_{12}\nabla\omega_2, \tag{113}$$

$$\mathbf{J}_2 = -\rho D_{21}\nabla\omega_1 - \rho D_{22}\nabla\omega_2. \tag{114}$$

The gradient of the chemical potential μ_1 may be written as

$$\nabla\mu_1 = \sum_k \left(\frac{\partial\mu_1}{\partial\omega_k}\right)\nabla\omega_k. \tag{115}$$

A similar relation can be written for the gradient of μ_2. By use of these relations in (109) and (110) and substituting them in (111) and (112), the flows $\mathbf{J}_k$ can be written in terms of the gradients of ω_k. On comparison of these with Fick's law (113) and (114), the following relations between the diffusion coefficients and the linear Onsager coefficients can be obtained:

$$L_{11} = \frac{dD_{11} - bD_{12}}{ad - bc} \qquad L_{12} = \frac{aD_{12} - cD_{11}}{ad - bc}, \tag{116}$$

$$L_{21} = \frac{aD_{21} - bD_{22}}{ad - bc} \qquad L_{22} = \frac{aD_{22} - bD_{21}}{ad - bc}, \tag{117}$$

in which

$$a = \left(1 + \frac{\omega_1}{\omega_3}\right)\left(\frac{\partial\mu_1}{\partial\omega_1}\right) + \frac{\omega_2}{\omega_3}\left(\frac{\partial\mu_2}{\partial\omega_1}\right),$$
$$b = \left(1 + \frac{\omega_2}{\omega_3}\right)\left(\frac{\partial\mu_2}{\partial\omega_1}\right) + \frac{\omega_2}{\omega_3}\left(\frac{\partial\mu_1}{\partial\omega_1}\right), \tag{118}$$

$$c = \left(1 + \frac{\omega_1}{\omega_3}\right)\left(\frac{\partial\mu_1}{\partial\omega_2}\right) + \frac{\omega_2}{\omega_3}\left(\frac{\partial\mu_2}{\partial\omega_2}\right),$$
$$d = \left(1 + \frac{\omega_2}{\omega_3}\right)\left(\frac{\partial\mu_2}{\partial\omega_2}\right) + \frac{\omega_2}{\omega_3}\left(\frac{\partial\mu_1}{\partial\omega_2}\right). \tag{119}$$

From these relations it is easy to see that reciprocal relations $L_{12} = L_{21}$ imply that

$$aD_{12} + bD_{22} = cD_{11} + dD_{21}. \tag{120}$$

Experimental data for several three-component systems may be found in Miller (1960), Sugawara *et al.* (1977), and Spera and Trial (1993).

3.6 Heat Conduction in Anisotropic Solids

In an anisotropic solid, the flow of heat $\mathbf{J}_q$ may not be in the direction of the temperature gradient. The entropy production is

$$\sigma = \sum_{i=1}^{3} J_{qi} \frac{\partial}{\partial x_i}\left(\frac{1}{T}\right), \tag{121}$$

in which x_i are the Cartesian coordinates. The phenomenological laws for this system are

$$J_{qi} = \sum_k L_{ik} \frac{\partial}{\partial x_k}\left(\frac{1}{T}\right) = \sum_k \left(\frac{-L_{ik}}{T^2}\right)\frac{\partial T}{\partial x_k}. \tag{122}$$

For anisotropic solids the heat conductivity κ is a tensor of the second rank. The empirical Fourier law of heat conduction then is written as

$$J_{qi} = -\sum_k \kappa_{ik} \frac{\partial T}{\partial x_k}. \tag{123}$$

Comparison of (122) and (123) leads to

$$L_{ik} = T^2 \kappa_{ik}. \tag{124}$$

Reciprocal relations $L_{ik} = L_{ki}$ then imply that

$$\kappa_{ik} = \kappa_{ki}; \tag{125}$$

i.e., the heat conductivity is a symmetric tensor. However, for many solids the symmetry of the crystal structures itself implies that (125) be valid. Hence experimental verification of (125) would not be a confirmation of the reciprocal relations. On the other hand, for solids with trigonal (C_3,C_{3i}), tetragonal (C_4,S_4,C_{4h}), or hexagonal (C_6,C_{3h},C_{6h}) symmetry the crystal symmetries imply

$$\kappa_{12} = -\kappa_{21}. \tag{126}$$

If the reciprocal relations are valid, then

$$\kappa_{12} = \kappa_{21} = 0. \tag{127}$$

One method of experimental verification of this relation is due to Voigt and Curie as shown in Fig. 4. Another method may be found in Miller (1960, 1974).

3.7 Thermal Diffusion

The interaction between heat and matter flows results in two effects: the Soret effect and the Dufour effect. In the Soret effect, heat flow causes a flow of matter. In the Dufour effect, concentration gradients drive a heat flow. The effects and the reciprocal relations in this context can be obtained by writing the entropy production due to diffusion and heat flow. In this case, it is more convenient to write the entropy production using the "heat flow" defined as

$$\mathbf{J}_q \equiv \mathbf{J}_u - \sum_{k=1}^{n} h_k \mathbf{J}_k, \tag{128}$$

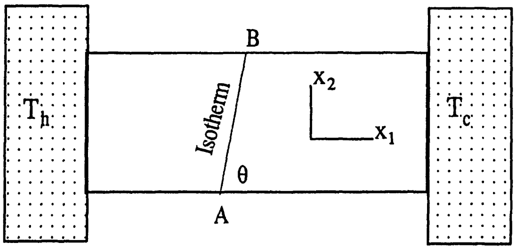

FIG. 4. The method of Curie–Voigt to verify the reciprocal relations for anisotropic heat conduction. An anisotropic solid whose crystal structure implies $\kappa_1 = -\kappa_2$ is placed in contact with two heat reservoirs of temperatures T_h and T_c. If the reciprocal relations are valid, then $\kappa_{12} = \kappa_{21} = 0$. If this is true, then the isotherms should be perpendicular to the direction x_1; i.e., θ should be 90°.

in which h_k is the partial specific enthalpy of the component k. In terms of $\mathbf{J}_q$ the entropy production may be written as

$$\sigma = \mathbf{J}_q \cdot \nabla\left(\frac{1}{T}\right) - \sum_{k=1}^{n-1} \mathbf{J}_k \cdot \frac{[\nabla(\mu_k - \mu_n)]_{T,p}}{T}, \tag{129}$$

in which Eq. (17) has been used to eliminate the flow $\mathbf{J}_n$. The corresponding chemical potential can be eliminated by use of the Gibbs–Duhem relation at constant p and T:

$$\sum_{k=1}^{n} \omega_k(\nabla\mu_k)_{p,T} = 0. \tag{130}$$

In terms of the $n - 1$ independent $\mathbf{J}_k$ and μ_k, the entropy production becomes

$$\sigma = \mathbf{J}_q \cdot \nabla\left(\frac{1}{T}\right) - \sum_{k,j=1}^{n-1} \mathbf{J}_k \cdot \frac{[\delta_{kj} + \omega_j/\omega_n](\nabla\mu_k)_{T,p}}{T}, \tag{131}$$

in which δ_{ij} is the Kronecker delta. The forces and flows can now be identified as

$$\mathbf{J}_q = L_{qq}\nabla\left(\frac{1}{T}\right) - \sum_{k,j=1}^{n-1} L_{qk} \frac{[\delta_{kj} + \omega_j/\omega_n](\nabla\mu_k)_{T,p}}{T}, \tag{132}$$

$$\mathbf{J}_k = L_{kq}\nabla\left(\frac{1}{T}\right) - \sum_{j,m=1}^{n-1} L_{kj} \frac{[\delta_{jm} + \omega_m/\omega_n](\nabla\mu_j)_{T,p}}{T}. \tag{133}$$

As was done in Sec. 3.5, to relate these equations to the empirical laws such as Fick's law, we may use

$$(\nabla\mu_k)_{p,T} = \sum_{j=1}^{n-1} \left(\frac{\partial\mu_k}{\partial\omega_j}\right)_{p,T} \nabla\omega_j, \tag{134}$$

in which ω_k are the mass fractions. The reciprocal relations in this case are

$$L_{qk} = L_{kq} \quad \text{and} \quad L_{jk} = L_{kj}. \tag{135}$$

If we consider a two-component system, the empirically measured constants such as the heat conductivity κ and the Dufour coefficient D'' are related to the phenomenological coefficients through the following (De Groot and Mazur 1969): heat conductivity,

$$\kappa = L_{qq}/T^2; \tag{136}$$

Dufour coefficient,

$$D'' = L_{q1}/\rho\omega_1\omega_2T^2; \tag{137}$$

Soret coefficient,

$$D' = L_{1q}/\rho\omega_1\omega_2T^2; \tag{138}$$

and diffusion coefficient,

$$D = L_{11}\left(\frac{\partial\mu_1}{\partial\omega_1}\right)_{p,T}(\rho\omega_2T)^{-1}. \tag{139}$$

[Note that if the mass fraction $\omega_2 \approx 1$, Eq. (139) reduces to Eq. (71).] The reciprocal relation $L_{q1} = L_{1q}$ implies that $D' = D''$.

3.8 Electrokinetic Phenomena and the Saxen Relations

Electrokinetic phenomena are due to the coupling between electrical current and matter flow. Consider two chambers, I and II, separated by a porous wall. We assume that the temperature and the concentrations are uniform throughout the system. If a voltage V is applied between the two chambers [see Fig. 5(a)], a current will flow until a pressure difference Δp is established at the steady state. This pressure difference is called the *electro-osmotic pressure.* Conversely, if a fluid flow J from one chamber to another is achieved by a piston, an electric current I, called the *streaming current,* flows through the electrodes. As before, the thermodynamic description of these effects begins with the expression for the entropy production under the conditions specified above. In this case we essentially have a discontinuous system in which there are no gradients but differences such as $\mu^{\mathrm{I}} - \mu^{\mathrm{II}}$. For discontinuous systems, the entropy production per unit volume σ is replaced by the total entropy production d_iS/dt. Furthermore, the entropy produced by the flow from chamber I to chamber II may be formally thought of as from a chemical reaction for which the difference in the electrochemical potential becomes the affinity (Prigogine, 1967). Thus we have

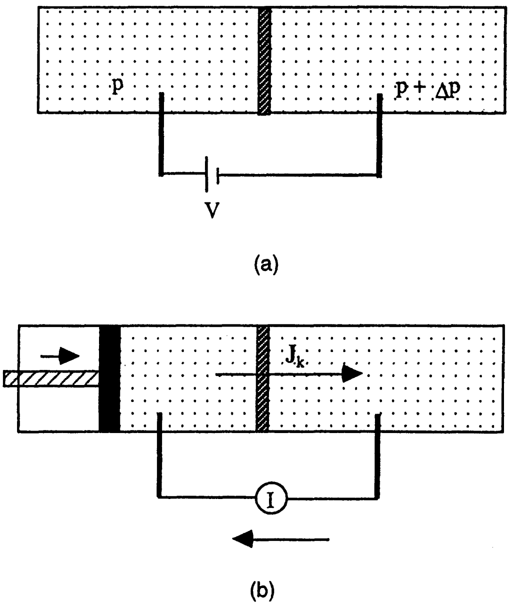

FIG. 5. Electrokinetic phenomena. Two chambers containing electrolytes are separated by a porous wall or capillary. (a) An applied potential V generates a pressure difference Δp called the *electro-osmotic pressure.* (b) If the fluid flows from one chamber to the other by action of a piston, there is generated an electrical current I called the *streaming current.*

$$\frac{d_iS}{dt} = \sum_k \frac{A_k}{T}\frac{d\xi_k}{dt}, \tag{140}$$

in which

$$A_k = (\mu_k^{\mathrm{I}} + z_kF\varphi^{\mathrm{I}}) - (\mu_k^{\mathrm{II}} + z_kF\varphi^{\mathrm{II}}), \tag{141}$$

$$d\xi_k = -dn_k^{\mathrm{I}} = dn_k^{\mathrm{II}}. \tag{142}$$

In the above equations z_k is the ion number of the component k, F is the Faraday constant, and φ is the electrical potential. For a relatively small difference in the pressure between the two chambers, since $\partial\mu_k/\partial p = \nu_k$, the partial specific volume, we may write

$$\mu_k^{\mathrm{I}} - \mu_k^{\mathrm{II}} = \nu_k\Delta p. \tag{143}$$

Equation (140) may now be written as

$$\frac{d_iS}{dt} = \frac{1}{T}\sum_k\left(-\nu_k\frac{dn_k^{\mathrm{I}}}{dt}\right)\Delta p + \frac{1}{T}\sum_k(-I_k)\Delta\varphi, \tag{144}$$

in which $\Delta\varphi = \varphi^{\mathrm{I}} - \varphi^{\mathrm{II}}$ and $I_k = z_kF dn_k^{\mathrm{I}}/dt$, the electric current due to the flow of component k. On combining of all the matter flow terms and the ion flow terms, (144) can now be written in the compact form

$$\frac{d_iS}{dt} = \frac{J\Delta p}{T} + \frac{I\Delta\varphi}{T}, \tag{145}$$

where

$$J = -\sum_k \nu_k\frac{dn_k^{\mathrm{I}}}{dt} \tag{146}$$

is the "volume flow" and

$$I = -\sum_k I_k \tag{147}$$

is the electric current. The phenomenological equations that follow from (145) are

$$I = L_{11}\Delta\varphi/T + L_{12}\Delta p/T \tag{148}$$

$$J = L_{21}\Delta\varphi/T + L_{22}\Delta p/T, \tag{149}$$

the reciprocal relations being

$$L_{12} = L_{21}. \tag{150}$$

Experimentally, the following quantities can be measured: the streaming potential,

$$\left(\frac{\Delta\varphi}{\Delta p}\right)_{I=0} = -\frac{L_{12}}{L_{11}}; \tag{151}$$

the electro-osmosis,

$$\left(\frac{J}{I}\right)_{\Delta p=0} = \frac{L_{21}}{L_{11}}; \tag{152}$$

the electro-osmotic pressure,

$$\left(\frac{\Delta p}{\Delta\varphi}\right)_{J=0} = -\frac{L_{21}}{L_{22}}; \tag{153}$$

and the streaming current,

$$\left(\frac{I}{J}\right)_{\Delta\varphi=0} = \frac{L_{12}}{L_{22}}. \tag{154}$$

As a consequence of the reciprocal relations $L_{12} = L_{21}$, we see from (151)–(154) that

$$\left(\frac{\Delta\varphi}{\Delta p}\right)_{I=0} = -\left(\frac{J}{I}\right)_{\Delta p=0}, \qquad (155)$$

$$\left(\frac{\Delta p}{\Delta\varphi}\right)_{J=0} = -\left(\frac{I}{J}\right)_{\Delta\varphi=0}. \qquad (156)$$

These two relations, called the Saxen relations, were obtained originally by kinetic considerations for particular systems, but by virtue of the formalism of nonequilibrium thermodynamics, we see their general validity.

3.9 Other Cross Effects

A number of other cross effects, such as thermomolecular pressure, thermomechanical effect, viscous flow in magnetic fields, and electrochemical phenomena, exist for which the above formalism can be applied. Description of these phenomena can be found in Miller (1960, 1974); Katchalsky (1965); Prigogine (1967); De Groot and Mazur (1969); Kreuzer (1981); Haase (1990); and Jou (1993). In the case of chemical reactions, the reciprocal relations imply the generally accepted principle of detailed balance. According to the principle of detailed balance, at equilibrium, every chemical reaction is balanced by the corresponding reverse reaction. In all cases that have been experimentally studied, Onsager's reciprocal relations were verified within experimental uncertainty.

3.10 Dielectric and Magnetic Relaxation

The formalism presented in Sec. 1 can also be used to describe dielectric and magnetic relaxation. When an electric or magnetic field is applied to the system, the electric and magnetic dipole moments relax to their equilibrium value. This irreversible process is accompanied by the production of entropy. Let us consider a simple example of a system at rest in which the only irreversible process is the relaxation of the electric dipole moment. For magnetic relaxation the magnetic dipole moment takes the place of the electric dipole moment. By using the methods similar to those used in Sec. 1, it can be shown (De Groot and Mazur, 1969) that the entropy production associated with electric relaxation is given by

$$\sigma = -\frac{1}{T}\frac{\partial \mathbf{P}}{\partial t}\cdot[\mathbf{E}_{\mathrm{eq}} - \mathbf{E}(t)] \geq 0, \qquad (157)$$

in which $\mathbf{P}$ is the dipole moment per unit volume, $\mathbf{E}_{\mathrm{eq}}$ is the electric field at equilibrium, and $\mathbf{E}(t)$ is the instantaneous electric field. For this case, the linear phenomenological relation between flow and the force is

$$\frac{\partial \mathbf{P}}{\partial t} = -\frac{L}{T}[\mathbf{E}_{\mathrm{eq}} - \mathbf{E}(t)]. \qquad (158)$$

If the electrical susceptibility is χ_e, then $\mathbf{P} = \chi_e \mathbf{E}_{\mathrm{eq}}$, and the above equation can be written as

$$\frac{\partial \mathbf{P}}{\partial t} = -\frac{L}{T\chi_e}[\mathbf{P} - \chi_e \mathbf{E}(t)]. \qquad (159)$$

For a static field $\mathbf{E}(t) = \mathbf{E}_0$, the solution of the above equation is

$$\mathbf{P}(t) = \chi_e \mathbf{E}_0(1 - e^{-t/\tau}), \qquad (160)$$

in which the relaxation time is $\tau = \chi_e T/L$. For a time-dependent $\mathbf{E}(t)$, the Fourier transform of (159) gives

$$\tilde{\mathbf{P}}(\omega) = \tilde{\chi}_e(\omega)\tilde{\mathbf{E}}(\omega), \qquad \tilde{\chi}_e(\omega) = \chi_e/(1 - i\omega\tau), \qquad (161)$$

in which the quantities with a tilde denote the Fourier transforms. The inverse Fourier transform of (161) gives $\mathbf{P}(t)$, the polarization as function of time.

3.11 Theorem of Minimum Entropy Production

A system maintained in the linear nonequilibrium regime reaches a steady state. A simple example is a system in contact with two thermal reservoirs of different temperatures (Fig. 6). For systems in the linear regime, where the linear phenomenological laws and the Onsager reciprocal relations are valid, the following general theorem due to Prigogine (Prigogine 1947, 1967) characterizes the stationary states:

> In the linear regime, the total internal entropy production, d_iS/dt reaches a minimum value at the nonequilibrium stationary state.

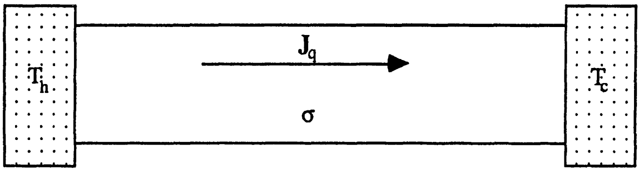

FIG. 6. A conducting solid in contact with two heat reservoirs at temperatures T_h (hot) and T_c (cold). The temperature of such a solid reaches a stationary state in which the total entropy production is minimized.

This theorem may be thought of as an extension of the situation at equilibrium at which $d_iS/dt = 0$: the entropy production, unable to reach zero because of nonequilibrium constraints, reaches the minimum possible value. The following examples illustrate this theorem.

3.11.1 Stationary States in Thermal Conduction Let us consider a system of length L in contact with a hot thermal reservoir with a temperature T_h (hot) at one end and a cold thermal reservoir with a temperature T_c (cold) at the other (see Fig. 6). We assume that the conduction of heat is the only irreversible process. The entropy production per unit volume is given by

$$\sigma = \mathbf{J}_q \cdot \nabla(1/T). \tag{162}$$

In the linear regime, we have the phenomenological law $\mathbf{J}_q = L_{qq}\nabla(1/T)$. The total entropy production P is given by

$$P \equiv \frac{d_iS}{dt} = \int_V L_{qq}\left(\nabla \frac{1}{T}\right)^2 dV. \tag{163}$$

According to the theorem of minimum entropy production, the temperature distribution at the stationary state corresponds to the one that minimizes P. Close to equilibrium, we may assume that L_{qq} is nearly constant throughout the system. Using the calculus of variation, one could obtain the following Euler–Lagrange equation whose solution minimizes P:

$$\nabla \cdot [\nabla(1/T)] = 0 \quad \text{or} \quad \nabla \cdot \mathbf{J}_q = 0. \tag{164}$$

That Eq. (164) represents the stationary state can be confirmed as follows. For the flow of heat the conservation of energy gives

$$\rho \frac{\partial u}{\partial t} = -\nabla \cdot \mathbf{J}_q. \tag{165}$$

The change in the energy due to heat flow is $du = c_V dT$, in which c_V is the specific heat. Hence (165) may be written as an equation for the temperature T:

$$\rho c_V \frac{\partial T}{\partial t} = -\nabla \cdot \mathbf{J}_q. \tag{166}$$

We can now see that (164) and (166) imply that the state that minimizes P by satisfying (164) is also a stationary state for which $\partial T/\partial t = 0$.

3.11.2 Stationary States in Chemical Systems The open near-equilibrium chemical system that we consider is shown in Fig. 7. The chemical reaction scheme is

$$A \overset{(1)}{\rightleftharpoons} X \overset{(2)}{\rightleftharpoons} B. \tag{167}$$

We assume that suitable flows of A and B keep the chemical potentials μ_A and μ_B fixed. This in turn implies that the sum of the affinities of reactions (1) and (2), $A_1 + A_2 \equiv \bar{A}$, is also fixed:

$$\begin{aligned} A_1 + A_2 &= (\mu_A - \mu_X) + (\mu_X - \mu_B) \\ &= \mu_A - \mu_B \equiv \bar{A}. \end{aligned} \tag{168}$$

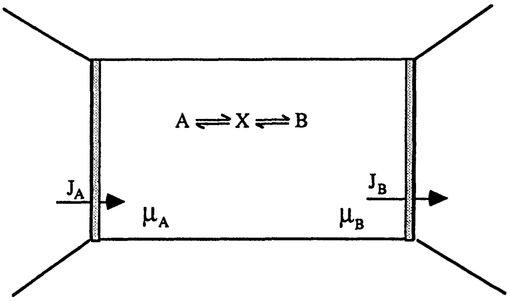

FIG. 7. An open chemical system in which the chemical potentials μ_A and μ_B are maintained at a given nonequilibrium value by an inflow of the component A and an outflow of the component B. In this system the concentration of X is maintained at a nonequilibrium value.

Let v_1 and v_2 be the velocities of the two reactions in (167). We shall now obtain the condition that v_1 and v_2 must satisfy to minimize the entropy production. The entropy production per unit volume for this system (which we assume is homogeneous), can be written as

$$\frac{1}{V}P = \frac{1}{V}\frac{d_iS}{dt} = \sigma = \frac{A_1}{T}v_1 + \frac{A_2}{T}v_2 = \frac{A_1}{T}v_1 + \frac{(\bar{A} - A_1)}{T}v_2, \tag{169}$$

in which V is the system volume and in which we have included the constraint (168) explicitly. The value of the chemical potential (or concentration) of X determines the value of A_1 and hence the value of the entropy production (169). In the linear regime, since the two reactions are independent, we have

$$\begin{aligned} v_1 &= L_{11}A_1, \\ v_2 &= L_{22}A_2 = L_{22}(\bar{A} - A_1), \end{aligned} \tag{170}$$

in which we have used (168). Substituting (170) into (169) we obtain σ as a function of A_1:

$$\sigma(A_1) = L_{11}\frac{A_1^2}{T} + L_{22}\frac{(\bar{A} - A_1)^2}{T}. \tag{171}$$

This function reaches its minimum value when

$$\frac{\partial\sigma(A_1)}{\partial A_1} = \frac{L_{11}}{T}2A_1 - \frac{L_{22}}{T}2(\bar{A} - A_1) = 0, \tag{172}$$

i.e.,

$$L_{11}A_1 - L_{22}A_2 = v_1 - v_2 = 0. \tag{173}$$

It is easy to see that the condition $v_1 = v_2$ corresponds to the stationary state. In the reaction scheme (167), since the concentrations of A and B are fixed, X is the only independent variable. Since reaction 1 produces X and reaction 2 consumes X, the kinetic equation for the concentration $[X]$ of X is

$$\frac{d[X]}{dt} = v_1 - v_2. \tag{174}$$

At the stationary state $d[X]/dt = 0$, which is the same as the state that minimizes the entropy production.

3.12 Entropy Production and the Stability of Stationary States

In the previous section we have seen that the stationary states in the linear regime are also states that minimize the entropy production. The *stability* of these stationary states can also be studied using the entropy production P. First we note that the approach to equilibrium can be described not only as a steady increase in entropy to its maximum value but also as a steady decrease in entropy production to zero. The stability of the equilibrium state is guaranteed by the fact that any perturbation from equilibrium is countered by irreversible processes that drive the system back to equilibrium. This fact may also be seen as the system being driven by irreversible processes to a state in which the entropy production vanishes. It is this later approach that naturally extends to the linear regime close to equilibrium.

The stationary states near equilibrium have a constant positive value for the entropy production P that is also a minimum. To establish the stability of this state, we must show that for all perturbations from the stationary state

$$\frac{dP}{dt} < 0. \tag{175}$$

The validity of this inequality depends on the fact that quantities such as specific heat c_v are positive. For example, in the case of the heat conduction discussed in Sec. 3.10.1, the time derivative of P given by (163) is

$$\frac{dP}{dt} = \int_V L_{qq}2\left(\nabla\frac{1}{T}\right)\cdot\left(\nabla\frac{\partial}{\partial t}\frac{1}{T}\right)dV. \tag{176}$$

By use of the phenomenological relation $\mathbf{J}_q = L_{qq}\nabla(1/T)$ and the identity $\nabla\cdot(\mathbf{A}f) = f(\nabla\cdot\mathbf{A}) + \mathbf{A}\cdot(\nabla f)$, Eq. (176) may be written as

$$\frac{dP}{dt} = 2\int_V \nabla\cdot\left(\mathbf{J}_q\frac{\partial}{\partial t}\frac{1}{T}\right)dV - \int_V\left(\frac{\partial}{\partial t}\frac{1}{T}\right)\nabla\cdot\mathbf{J}_q dV. \tag{177}$$

By Gauss's theorem the first integral can be expressed as a surface integral. Since the boundary conditions are time independent, on the boundary $\partial(1/T)/\partial t = 0$, and the first integral vanishes. By using Eq. (166) in the second integral of Eq. (177) we find

$$\frac{dP}{dt} = -2\int_V \frac{\rho c_v}{T^2}\left(\frac{\partial T}{\partial t}\right)^2 dV. \tag{178}$$

Since $c_v > 0$, it follows that $dP/dt < 0$. In fact, this is generally true for all stationary states in the linear regime in which the linear phenomenological relations are valid. The general situation is summarized in Fig. 8.

4. FAR-FROM-EQUILIBRIUM SYSTEMS

By increasing the flow of matter and energy, a system can be driven farther and farther from the state of equilibrium. In contrast to equilibrium and near-equilibrium states, there is no general principle that characterizes far-from-equilibrium states or guarantees their stability. Indeed, these states can become unstable and evolve to new states. The new states thus reached can be complex and highly organized. In fact, much of the complexity and organized behavior we see in nature occurs under far-from-equilibrium conditions. The complex behavior is a consequence of irreversible processes such as chemical reactions and diffusion. In this section we present an overview of entropy production, stability, and self-organization under far-from-equilibrium conditions.

4.1 General Properties of Entropy Production

As we have seen, in the linear regime the total entropy production $P = \int_V \sigma dV$ reaches its minimum value for the stationary states and $dP/dt < 0$. In the far-from-equilibrium nonlinear regime, there are no such general principles that characterize stationary states. There are, however, some general statements that can be made regarding the total entropy production P. Since $P = \int_V \sigma dV = \int_V \Sigma_\alpha X_\alpha J_\alpha dV$,

$$\frac{dP}{dt} = \int_V \left(\sum_\alpha \frac{\partial X_\alpha}{\partial t} J_\alpha\right) dV + \int_V \left(\sum_\alpha X_\alpha \frac{\partial J_\alpha}{\partial t}\right) dV \equiv \frac{d_X P}{dt} + \frac{d_J P}{dt}, \tag{179}$$

in which $d_X P/dt$ is the first integral, which contains the time derivative of the forces X_α, and $d_J P/dt$ is the second integral, which contains the time derivative of the flows J_α. We state without proof two general properties that have been proved by Glansdorff and Prigogine (1971):

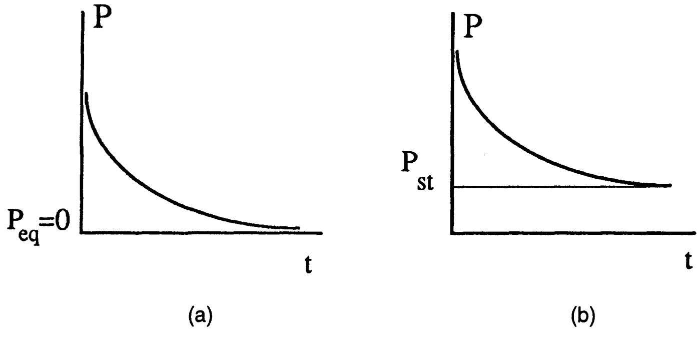
1. In the linear regime,

$$\frac{d_X P}{dt} = \frac{d_J P}{dt}. \tag{180}$$

2. Under all conditions,

$$\frac{d_X P}{dt} < 0. \tag{181}$$

Equations (179) and (180) give the earlier result that in the linear regime $dP/dt < 0$. Though Eqs. (180) and (181) are among the



(a) (b)

FIG. 8. The time variation of the entropy production $P = d_iS/dt$ for equilibrium and near-equilibrium states. (a) For a fluctuation from the equilibrium state, the initial nonzero value of P decreases to its equilibrium value of zero. (b) In the linear regime, a fluctuation from a nonequilibrium stationary state in which $P = P_{st}$ increases P; the subsequent time development of P drives the system back to the stationary state.

most general result in thermodynamics, they do not provide a means to specify nonequilibrium states or their stability.

4.2 Stability of Far-from-Equilibrium Systems

A general condition for the stability of any state is the existence of a Lyapunov functional. A functional is a rule by which a number can be associated with a state. Let y be a perturbation from a state Y_0 whose stability is of interest. A Lyapunov functional $\Lambda(y)$ associated with a state Y_0 has the following properties:

1. For all perturbations y,

$$\Lambda(y) > 0. \tag{182}$$

2. For all times t,

$$\frac{d\Lambda(y)}{dt} \le 0. \tag{183}$$

If such a Λ exists, then Y_0 is stable. In the linear regime, we see that the total entropy production P is a Lyapunov functional.

Under all conditions, a functional that always has a definite sign is the second variation of entropy $\delta^2 S$, which is defined as follows (Glansdorff and Prigogine, 1971). The change in entropy ΔS due to a perturbation δx_k from a stationary state x_{sk} can be written as

$$\begin{aligned}\Delta S &= \int \left[\sum_k \left(\frac{\partial(\rho s)}{\partial x_k}\right)_{xk=xsk} \delta x_k\right] dV \\ &\quad + \frac{1}{2}\int \left[\sum_{ij} \left(\frac{\partial^2 \rho s}{\partial x_i \partial x_j}\right)_{xk=xsk} \delta x_i \delta x_j\right] dV \\ &= \delta S + \tfrac{1}{2}\,\delta^2 S,\end{aligned} \tag{184}$$

in which δS is the first integral and $\delta^2 S$ is the second integral. Based on the validity of local equilibrium, it has been shown (Glansdorff and Prigogine, 1971) that

$$\begin{aligned}\delta^2 S = &-\int \frac{\rho}{T}\left[\frac{c_V}{T}(\delta T)^2 + \frac{\rho}{\chi}(\delta \nu)_c^2 \right. \\ &\left. + \sum_{i,j}\left(\frac{\partial \mu_k}{\partial \omega_j}\right)_{T,p} \delta\omega_i \delta\omega_j\right] dV \le 0,\end{aligned} \tag{185}$$

in which

$$(\delta\nu)_c = \left(\frac{\partial \nu}{\partial T}\right)_{p,\omega k} \delta T + \left(\frac{\partial \nu}{\partial p}\right)_{T,\omega k} \delta p \tag{186}$$

and

$$\chi = -\frac{1}{\nu}\left(\frac{\partial \nu}{\partial p}\right)_{T,ck}. \tag{187}$$

Thus $-\delta^2 S$ is a functional that satisfies one of the conditions (182) for a Lyapunov functional. In addition, if $d(-\delta^2 S)/dt \le 0$, we have a Lyapunov functional. Now it has been shown (Glansdorff and Prigogine, 1971) that the derivative of $-\delta^2 S$ has the general form

$$\frac{d(-\delta^2 S)}{dt} = -\sum_\alpha \delta X_\alpha \delta J_\alpha, \tag{188}$$

in which δX_α and δJ_α are the perturbations of the forces and flows from the stationary state whose stability is of interest. Thus the general *sufficient* condition for the stability of a nonequilibrium stationary state is

$$\sum_\alpha \delta X_\alpha \delta J_\alpha \ge 0. \tag{189}$$

The quantity $\Sigma_\alpha \delta X_\alpha \delta J_\alpha$ is called the *excess entropy production.* One must note that (189) is sufficient but not a necessary condition for stability. When (189) is not satisfied, i.e., $\Sigma_\alpha \delta J_\alpha \delta F_\alpha \le 0$, the nonequilibrium steady state *may* become unstable. As a consequence of the instability, a perturbation may grow, driving the system to a new state.

In chemical systems, violation of the condition (189) occurs in autocatalytic systems. As an example we may consider the autocatalytic reaction

$$2X + Y \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 3X, \tag{190}$$

which appears in a reaction scheme called the "Brusselator" that we consider below. For this reaction, let a nonequilibrium stationary state have the concentrations $[X]_s$ and $[Y]_s$ and consider a perturbation δX. Using the forward and reverse rates $\rho_f = k_f[X]^2[Y]$ and $\rho_r = k_r[X]^3$ in the general expressions for A and v, one can calculate the expression for the excess entropy production and obtain

$$\sum_{\alpha} \delta A_{\alpha} \delta v_{\alpha} = -R(2k_f[X]_s[Y]_s - 3k_r[X]_s^2)\frac{(\delta X)^2}{[X]_s}. \tag{191}$$

The excess entropy production (191) can become negative, particularly if $k_r \ll k_f$. Hence the stability is no longer assured and the steady state *may* become unstable.

Instability often leads to organized states as summarized in Fig. 9. In it, the value of the parameter Δ is a measure of the distance from equilibrium. For each value of Δ, the system will relax to a stationary state, denoted by X_s. The equilibrium state corresponds to $\Delta = 0$. X_s is a continuous extension of the equilibrium state, and it is called the *thermodynamic branch.* As long as the condition (189) is satisfied, the thermodynamic branch is stable. If (189) is violated, then the thermodynamic branch may become unstable.

4.3 Linear Stability Analysis and Bifurcation of New States

The above-mentioned instability of the thermodynamic branch often gives rise to organized states. These states, which are created and maintained by dissipative processes, are called *dissipative structures.* The onset of instability as the system is forced away from equilibrium is analyzed by means of linear stability theory. Consider a system whose state is represented by variables x_k. Let λ be a parameter representing the value of a constraint that keeps the system away from equilibrium. We wish to study the behavior of the system as λ changes. The conservation laws and other empirical laws for the rates of chemical reaction and heat conduction give us a set of equations for the time variation of x_k, which we represent by

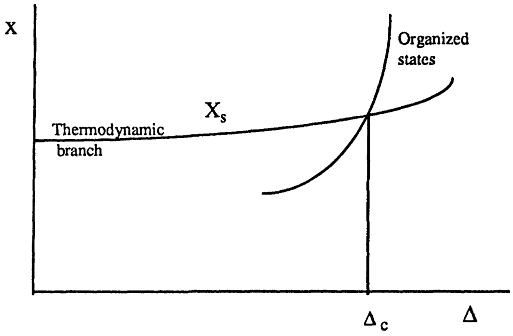


FIG. 9. Here each value of X represents a state of the system. The distance from equilibrium is represented by the parameter Δ. When Δ is small, the system is in a near-equilibrium state, which is an extrapolation of the equilibrium state; this family of states is called the *thermodynamic branch.* In some systems, such as those that have autocatalysis, when Δ reaches a critical value Δ_c, the state belonging to the thermodynamic branch becomes unstable. When this happens, the system makes a transition to a new branch of organized states.

$$\frac{dx_i}{dt} = F_i(x_1 \ldots x_n; \lambda). \tag{192}$$

We assume that there is a stationary state x_{sk} whose stability is of interest. Since x_{sk} is a stationary state, we have

$$F_k(x_{s1}, x_{s2}, \ldots, x_{sn}, \lambda) = 0. \tag{193}$$

The stability of the state x_{sk} depends on the eigenvalues of the Jacobian matrix M whose elements are

$$M_{ij} \equiv \left(\frac{\partial F_i}{\partial x_j}\right)_{x_k = x_{sk}}. \tag{194}$$

[If Eq. (192) is a partial differential equation, then a linear partial differential operator M is defined.] If the real parts of all the eigenvalues of M are negative, the stationary state x_{sk} is stable. As λ changes, a negative real eigenvalue or a pair of complex eigenvalues with negative real parts may cross the imaginary axis. One or more eigenvalues crossing the imaginary axis defines the onset of instability. At this point, new solutions to Eq. (192) become available. The new states are the dissipative structures. A detailed description of the onset of instability and the appearance "bifurcation" of new solution (which may be found in Nicolis and Prigogine, 1977) is beyond the scope of this article.

4.4 Dissipative Structures

In general, dissipative structures have lower entropy compared to that of a corresponding equilibrium system. As an illustration of a nonequilibrium transition to a dissipative structure, let us consider a few examples.

The first is a simple example related to a fundamental aspect of biochemistry. It is well known that the building blocks of life, viz., amino acids, DNA, and RNA, have a fundamental asymmetry: of the two possible mirror-image molecular structures, only one appears in nature. Molecules that are not identical to their mirror image are said to be *chiral,* and the two forms or *enantiomers* are termed L (levo) and D (dextro). Amino acids are almost all of the L form, and the ribose in DNA and RNA is of the D form. This is remarkable because chemical reactions that produce chiral molecules from achiral molecules produce equal numbers of L and D molecules. The "organized state" that contains predominantly one of the two chiral forms is an example of a dissipative structure that arises under far-from-equilibrium conditions.

Through a variation of a model reaction devised by Frank (1953) (see Fig. 10), we can see how a set of chemical reactions that produce mirror image forms X_L and X_D of a molecule X, with equal preference, can nevertheless make a transition to a state dominated by either X_L or X_D. The reaction scheme we consider, which includes two autocatalytic reactions, is shown in the upper part of Fig. 10. In a closed or an isolated system, the set of reactants S, T, X_L, X_D, and P will reach the state of equilibrium, which is a *symmetric state,* i.e., $[X_L] = [X_D]$. The symmetric state corresponds to the thermodynamic branch. However, if we consider an open system into which S and T are pumped and P is removed, then on account of the instability of the thermodynamic branch created by the autocatalysis, the system can break the chiral symmetry and make a transition to an *asymmetric state* in which $[X_L] \neq [X_D]$ (For details see Kondepudi and Nelson, 1984, 1985).

The onset of instability and transition to a state of broken symmetry may be analyzed by defining a parameter $\lambda = [S][T]$. When λ is greater than λ_c, the symmetric state (the thermodynamic branch) becomes unstable. The symmetric and asymmetric states can be associated with a variable $\alpha = [X_L] - [X_D]$. The transition from a symmetric state to an asymmetric state can now be described by

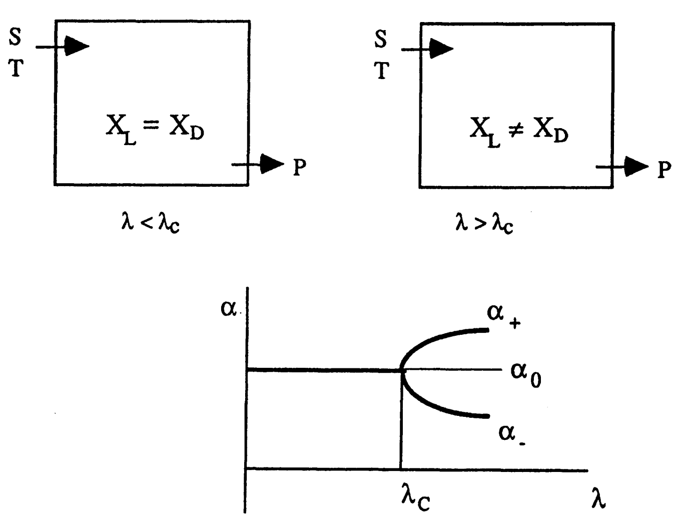

FIG. 10. A reaction scheme showing some general features of transitions to dissipative structures. The autocatalytic reaction scheme in which X_L and X_D are produced with equal preference in an open system leads to a dissipative structure in which $X_L \neq X_D$.

the variables λ and α. When the transition to an asymmetric state occurs, α can be positive or negative. Thus there are two possible asymmetric states to which the system can make a transition. The variables α and λ obey a general equation of the form

$$\frac{d\alpha}{dt} = -A\alpha^3 + B(\lambda - \lambda_c)\alpha, \tag{195}$$

in which A and B are constants. The form of this equation is independent of the details of the particular chemical scheme that breaks the chiral symmetry; only the numerical values of A and B depend on the details of the kinetics. The stationary states of α, obtained from (195) by setting $d\alpha/dt = 0$, are shown in Fig. 10. They are given by:

$$\alpha = 0 \quad \text{and} \quad \alpha = \pm[(B/A)(\lambda - \lambda_c)]^{1/2}. \tag{196}$$

When $\lambda > \lambda_c$, the state $\alpha = 0$ becomes unstable and the system evolves to one of the two states $\alpha = \pm[(B/A)(\lambda - \lambda_c)]^{1/2}$. The instability described by Eq. (195) and the associated steady-state diagram is generally valid for any nonequilibrium system that breaks a twofold symmetry. In each of these systems, parameters α and λ can be defined that, in the vicinity of the critical point λ_c, obey an equation of the form (195).

The next example we consider illustrates oscillations and spatial structures in chemical systems. For this purpose, we use a model reaction scheme, which has acquired the name "Brusselator." Proposed by Prigogine and Lefever in 1968 (Prigogine and Lefever, 1968; Nicolis and Prigogine, 1977), this model has been used extensively as a prototype to gain an understanding of the various aspects of chemical dissipative structures. Since then, several other models have been studied in great detail both experimentally and theoretically (Nicolis and Prigogine, 1977; Vidal and Pacault, 1981; Field and Burger, 1985; Baras and Walgraef, 1992). Many of the general features discovered theoretically have been experimentally realized in the most extensively studied Belusov–Zhabotinsky (B-Z) reaction (Belusov, 1958; Zhabotinsky, 1974) for which a kinetic model was proposed by Field and Noyes (1974).

The reaction scheme of the Brusselator is shown in Fig. 11. We assume that the concentrations of the reactants A and B are maintained at a desired nonequilibrium value through appropriate flows. The products D and E are removed as they are formed. All the reverse reactions are assumed to be slow enough that they could be neglected. The rates of reaction are assumed to obey mass-action kinetics. For example, the rate of the first reaction in the scheme is $k_1[A]$, that of the second reaction is $k_2[B][X]$, and so on. Since all other concentrations are fixed, the state of the system is determined by the concentrations $[X]$ and $[Y]$. Transport of X and Y occurs through diffusion. With these assumptions, it is straightforward to write the kinetic equations for the concentrations of X and Y. For mathematical convenience, one can redefine "normalized" concentrations (Nicolis and Prigogine, 1977) in such a way that all the rate constants are equal to unity. These normalized concentrations, which are denoted by X, Y, etc., obey the following equations, in which D_x and D_y are the diffusion coefficients:

$$\frac{\partial X}{\partial t} = A - (B + 1)X + X^2Y + D_x\nabla^2X, \tag{197}$$

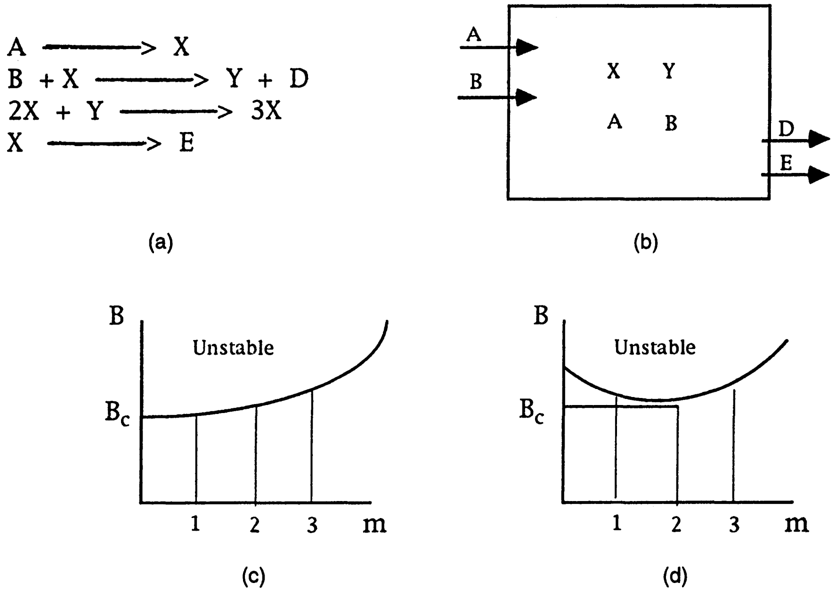
$$\frac{\partial Y}{\partial t} = BX - X^2Y + D_y\nabla^2Y. \tag{198}$$

A detailed analysis of this (and many other models) may be found in Nicolis and Prigogine (1977). Here we state some of the main features. For appropriate values of the diffusion coefficients and of concentrations A and B, the concentrations of X and Y may exhibit homogeneous oscillations, form stationary spatial patterns, or form time-dependent patterns that are propagating waves. Almost every feature observed experimentally appears in this system under appropriate conditions.

When the two diffusion coefficients are nearly equal, for a fixed value of A, as the value of B increases, the thermodynamic branch becomes unstable. The reason for this instability is the autocatalytic reaction $2X + Y \rightarrow 3X$. When D_x is nearly equal to D_y, the condition for the instability is

$$B > 1 + A^2 + (\pi^2m^2/l^2)(D_x + D_y). \tag{199}$$

This condition is derived by linear stability



(a) (b)

(c) (d)

FIG. 11. (a) Reaction scheme of the Brusselator. (b) The conditions under which dissipative structures are formed are indicated. The concentrations of reactants A and B are maintained at constant values through an inflow, and the products D and E are removed. Under these conditions, the concentrations of X and Y may oscillate in time or form spatial patterns, depending on the values of the diffusion coefficients D_X and D_Y of X and Y. (c) Stability diagram showing the value of B for which modes of wave number m become unstable when D_X and D_Y are nearly equal. The instability occurs when $B = B_c$ at $m = 0$, leading to homogeneous oscillations. (d) Stability diagram showing the value of B for which modes of wave number m become unstable when the difference between D_X and D_Y is large. In this case when $B = B_c$, the corresponding mode $m = 2$ becomes unstable, leading to the formation of a spatial pattern.

analysis. In this equation, l is the size of the system, and m is an integer that corresponds to the wave number of the spatial mode that becomes unstable. Clearly, the smallest value of B that will satisfy this inequality corresponds to $m = 0$, which is the homogeneous mode. The value of B at which the mode $m = 0$ becomes unstable is shown graphically in Fig. 11(c). Here we see that when B reaches the critical value $B_c = 1 + A^2$, the homogeneous mode becomes unstable. This instability leads to the growth of homogeneous oscillation of X and Y. The amplitude of these oscillations depends on the value of $B - B_c$.

Spatial patterns can arise when the difference between D_x and D_y is large. The precise condition for this instability of the thermodynamic branch is given by the following expression (Nicolis and Prigogine, 1977):

$$B > 1 + \frac{D_x}{D_y}A^2 + \frac{A^2}{D_y\pi^2 m^2}l^2 + \frac{D_x\pi^2 m^2}{l^2}. \tag{200}$$

In this case, the minimum value of B that will satisfy this condition does not correspond to $m = 0$, but to a nonzero value of m. The minimum value of B that satisfies (200) defines the onset of instability. It can be shown (Nicolis and Prigogine, 1977) that

$$B_{\min} = \left[1 + A\left(\frac{D_x}{D_y}\right)^{1/2}\right]^2 \quad \text{when}$$
$$m = m_{\min} = \frac{Al^2}{\pi^2(D_1D_2)^{1/2}}. \tag{201}$$

If $B > B_{\min}$, all the integer values of m that satisfy (200) represent unstable modes. This is shown graphically in Fig. 11(d). Each of the unstable modes can grow. Similarly, under appropriate conditions, the Brusselator also shows that propagating waves may arise.

Though there are no general thermodynamic results for far-from-equilibrium systems, many interesting observations have been made by several people such as John Ross, Cathy Hunt, Paul Hunt, and others. A representative list of these works has been included in the list for further reading. In addition, there has been a lot of work in the statistical theory of nonequilibrium thermodynamics. This work constitutes a subject in itself and requires a separate treatment for a full description. Books and other comprehensive works on this subject are also listed under Further Reading.

INTRODUCTION

In 1823 when Thomas Seebeck discovered the effect that now bears his name, most certainly he did not realize that, a century and a half later, an entire industry would develop from the seed of his simple experiments. But indeed, his observation of the occurrence of a potential difference in a circuit composed of two dissimilar metals with junctions at different temperatures turned out to be the basis for the thermoelectric generator that today provides on-board power for interplanetary space probes. And when barely a decade later Jean Peltier discovered the inverse effect of the cooling of a junction between two dissimilar metals upon the passage of electrical current, the foundation was formed for what is today a worldwide industry of thermoelectric cooling with applications in microelectronics, defense, and recreational industries. While the laws of thermodynamics deem that all energy ultimately evolves into heat and all systems move toward increasing entropy, the concepts of converting heat to electricity and using electricity to cool act like localized, temporal rebellions against time's arrow and continue to intrigue man today.

With increasing environmental concerns over the deleterious effects of waste heat and the harmful nature of compressed gases and chemical refrigerants, thermoelectric devices have received renewed attention in recent years. The idea of getting "free" electrical power from waste heat or obtaining cooling power from a solid-state device is at first glance very appealing from both environmental and economic points of view. However, many serious challenges remain to be met before large-scale thermoelectric refrigeration and power generation become a reality: Can new more efficient materials be developed? Can device design be improved and adapted to new applications? Are the

thermoelectric materials themselves environmentally "friendly"? And, perhaps most importantly, can a new generation of thermoelectric devices for energy conversion on a large scale be made economically?

While this review is not aimed at answering all of the above questions, we must always keep these challenges in mind when discussing both realized and potential applications of thermoelectric devices. Current developments in the field of thermoelectrics are unfolding along two main fronts:

1. incremental improvements in existing thermoelectric materials and device design, and
2. research into the development of new materials (or old materials in new geometries) with enhanced thermoelectric properties.

This review first gives a brief introduction to the physical properties of thermoelectric materials, then discusses the theory of device operation, provides several examples of thermoelectric coolers and generators using state-of-the-art materials, and finally concludes with some comments on new materials for thermoelectric refrigeration and power generation.

1. THERMOELECTRIC PROPERTIES OF MATERIALS

1.1 Macroscopic Properties

It is shown later that the ability of a material to act as a thermoelectric depends on three fundamental transport properties: the thermoelectric power S, the electrical conductivity σ, and the thermal conductivity κ. Quantitatively, we define the *thermoelectric figure of merit* Z:

$$Z = S^2\sigma/\kappa. \qquad (1)$$

The efficiency of thermoelectric devices is directly determined by Z and thus by the fundamental transport properties S, σ, and κ. The "electrical" part of this relationship, namely, the numerator $S^2\sigma$, is termed the power factor P of the material. Since the dimensions of Z are inverse temperature, it is convenient to define a dimensionless quantity ZT, the product of the figure of merit and the absolute temperature. We begin our discussion with a general overview of these three fundamental transport properties in various types of materials.

1.1.1 Seebeck and Peltier Effects The observations of Seebeck in 1823 and Peltier in 1834 were based on experiments in which two different metallic materials, A and B, were connected together in a circuit. The *Seebeck effect* (Fig. 1) is the occurrence of a potential difference V_{AB} in the circuit under conditions of zero net current flow when the ends of the two metal strips are at a temperature T_0 and the junction between them is at a different temperature $T_0 + \Delta T$. The magnitude of the voltage is proportional to the temperature difference ΔT and additionally depends on the type of materials of which the circuit is comprised. The *relative Seebeck coefficient* S_{AB} of the circuit shown in Fig. 1 is given by

$$S_{AB} = \lim_{\Delta T \to 0} \left(\frac{V_{AB}}{\Delta T}\right). \qquad (2)$$

While S_{AB} is a property of the couple A and B, it is possible to define absolute Seebeck coefficients S_A and S_B for each of the materials A and B. The relative Seebeck coefficient is then just the difference between the absolute coefficients:

$$S_{AB} = S_A - S_B. \qquad (3)$$

The Seebeck effect is the means by which

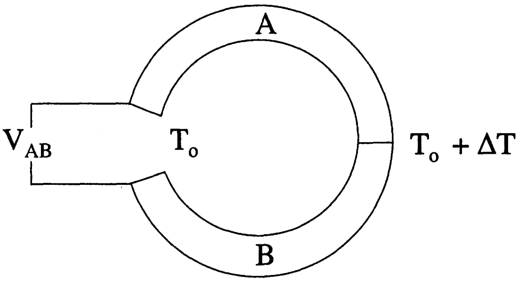

FIG. 1. Thermoelectric circuit composed by joining two dissimilar metals A and B. When the ends of the metal strips are at a temperature T_0 and the junction is at a different temperature $T_0 + \Delta T$, a thermoelectric voltage V_{AB} is developed under open-circuit conditions.

thermoelectric generators convert heat to electricity. Clearly, the larger the Seebeck coefficient, the larger the voltage that can be generated per temperature interval. The Seebeck coefficient, or thermoelectric power, can exhibit a wide range of values. In superconductors, S is rigorously zero, while in good metals it is only a few microvolts per kelvin at room temperature. Doped semiconductors, on the other hand, can have Seebeck coefficients of several hundred microvolts per kelvin.

In the *Peltier effect,* when the two dissimilar metals A and B are joined in a closed circuit and a current I is allowed to flow (Fig. 2), an amount of heat Q is absorbed per unit time at the junction between the two strips and evolved at their ends. The *relative Peltier coefficient* π_{AB} of the circuit in Fig. 2 is defined as the ratio of heat absorbed (or evolved) to the current:

$$\pi_{AB} = Q/I. \tag{4}$$

It can be shown using thermodynamic arguments that the Peltier coefficient and Seebeck coefficient are related to one another by the Kelvin relation

$$S_{AB} = \pi_{AB}/T. \tag{5}$$

As in the case of the Seebeck coefficient, it is possible to define absolute Peltier coefficients π_A and π_B for each arm of the thermoelectric circuit of Fig. 2, such that

$$\pi_{AB} = \pi_A - \pi_B. \tag{6}$$

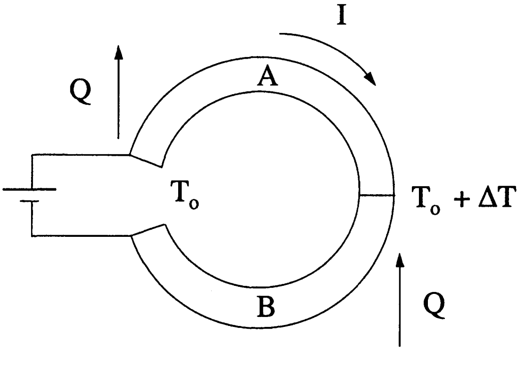

FIG. 2. Thermoelectric circuit consisting of two dissimilar metals A and B joined together. When a current is passed through the circuit, an amount of heat Q is absorbed at the junction between the metal strips and liberated at their ends.

1.1.2 Electrical Resistivity While the Seebeck coefficient of certain materials, such as wide-band-gap semiconductors and polymers, can become very large, these systems are not good thermoelectric materials since they also have low electrical conductivity. The electrical conductivity of a material is related to the number density of charge carriers in the system, designated by n, and their mobility, μ, according to

$$\sigma = ne\mu. \tag{7}$$

In good metals, the electrical conductivity is large because of large n; however, S and hence P in these systems are usually very small. In undoped wide-band-gap semiconductors, the electrical conductivity is small because of small n, and P can never be large. For thermoelectric applications, the intermediate case is of interest, namely, moderately doped semiconductors. Such systems have carrier densities smaller than in metals but can have large mobilities, so that the electrical conductivity can be reasonably large. At the same time, since the carrier density is not large, the thermoelectric power also can be fairly substantial. The precise conditions under which one obtains a large power factor are determined by the microscopic physical properties of the system such as energy band structure, carrier effective mass, and carrier mobility and are discussed in detail in the next section. However, we can already note from our discussion of the macroscopic properties of materials that large power factors will be found among the narrow- to intermediate-band-gap semiconductors.

1.1.3 Thermal Conductivity The thermal conductivity of a solid material is made up of two parts: the thermal conductivity of the charge-carrier system, κ_c, and the thermal conductivity of the lattice, or phonon system, κ_p, the total thermal conductivity being the sum of the two components. Evidently for thermoelectric materials we want to have κ as small as possible. In metallic systems, κ_c is the dominant contribution to the total thermal conductivity. The Wiedemann–Franz law (see METALS AND ALLOYS, CONDUCTIVITY IN) provides a relationship between the carrier electrical conductivity and the carrier thermal conductivity:

$$\kappa_c = LT\sigma, \tag{8}$$

where L is the Lorenz number. When the scattering of charge carriers is elastic, the Lorenz number takes on the Sommerfeld value $L_0 = 2.45 \times 10^{-8}\ \mathrm{V}^2\ \mathrm{K}^{-2}$. If the scattering is partially inelastic, the Lorenz number is depressed below L_0 and the Wiedemann–Franz law (using the value of L_0) provides an upper limit on the charge-carrier thermal conductivity. For most metals, $\kappa_c \gg \kappa_p$ and, by use of the Wiedemann–Franz law, the figure of merit reduces to

$$ZT = \frac{S^2\sigma T}{\kappa_c + \kappa_p} \approx \frac{S^2}{L_0}. \tag{9}$$

Thus to obtain $ZT = 1$ (the approximate value of state-of-the-art materials), one requires $S \approx 157\ \mu\mathrm{V}\ \mathrm{K}^{-1}$. Such a high thermopower has never been obtained on a metallic system, although some alloys made from *d*- and *f*-band metals do exhibit thermopowers of several tens of microvolts per kelvin. So once again we turn our attention to semiconducting systems for thermoelectric device applications. In this case the phonon contribution to the total thermal conductivity can be substantial and in many circumstances is the dominant mode of heat transport in these solids. The phonon thermal conductivity can span a surprisingly large range of values, from on the order of $10^{-2}\ \mathrm{W\ cm^{-1}\ K^{-1}}$ for mixed crystals to as high as $25\ \mathrm{W\ cm^{-1}\ K^{-1}}$ for diamond. The lattice thermal conductivity depends inversely on both the atom masses and the primitive-unit-cell complexity; diamond has a very high thermal conductivity because carbon is light and the unit cell contains only one atom. In order to obtain the low intrinsic thermal conductivity necessary for a thermoelectric material, one needs to work with compounds made up of heavy elements. For semiconductors this traditionally has meant working with elements in the lower right corner of the periodic table, such as Bi, Pb, Te, and Se. Thus some of the best thermoelectrics are Bi_2Te_3 and PbTe.

Of all the physical properties that determine the figure of merit, the thermal conductivity is the one most amenable to manipulation in the laboratory. A great deal of energy has been spent on reducing the thermal conductivity of thermoelectric materials by virtually every means possible—for example, using mixed crystals, substitutional point defects, radiation-induced damage, and large-scale inclusions, to name just a few techniques. When this methodology is combined with the restriction that the carrier mobility in a thermoelectric should be as large as possible, the engineering of thermoelectric materials can be summarized in a single sentence: How can I impede the phonons as much as possible while not upsetting charge-carrier transport? While at first it might seem that this is an impossible endeavor, an important difference in phonon and electron spectra does in fact make it possible to achieve such a condition: and that is that while the wavelength of a typical heat-carrying phonon is only a few lattice spacings, the deBroglie wavelength of a charge carrier is many times larger. Thus it is possible to "engineer" structures in which defects interact strongly with phonons but essentially do not perturb the Bloch waves.

This completes our discussion of the macroscopic properties of thermoelectric materials. We have seen that a good thermoelectric material will have a large Seebeck coefficient, large electrical conductivity, and small thermal conductivity, and we have identified semiconducting compounds of heavy constituent-atom masses as the most likely materials for thermoelectrics. In the next section we look in detail at the microscopic properties of such materials with the object of understanding at a fundamental level how these properties can be achieved.

1.2 Underlying Microscopic Properties

The relevant transport properties of thermoelectric materials, namely, the Seebeck coefficient and electrical and thermal conductivities, depend on a variety of microscopic parameters of the system, including the electronic structure and electron- and phonon-scattering processes. We begin our discussion by introducing the concepts of energy bands, the energy gap, and doping.

1.2.1 Energy Gap and Doping A semiconductor is a material that possesses a forbidden energy gap between the valence band

and the conduction band; see Fig. 3. In an *intrinsic* semiconductor, the topmost valence band is completely filled with electrons and the lowest-lying conduction band, lying above the top of the valence band by an energy E_g, is empty [Fig. 3(a)]. Thermal excitation across the gap produces electrons in the conduction band, leaving behind an equal number of empty states, or holes, in the valence band. The holes act as current carriers of positive charge $+e$. In an extrinsic semiconductor, impurity atoms (called *donors*) produce electrons in an energy level close to the bottom of the conduction band [Fig. 3(b)]. Because in this situation the energy difference ΔE between the donor level and the conduction band is relatively small, these electrons can be excited into the conduction band at fairly low temperatures, and an *n-type* semiconductor is obtained. Analogously, impurity atoms of another class, called *acceptors*, produce energy levels in the forbidden zone of the semiconductor but near the top of the valence band [Fig. 3(c)]. Here electrons can be promoted into states in the impurity level, thereby leaving mobile holes in the valence band that are then capable of carrying current; in this situation a *p-type* semiconductor is obtained.

In an intrinsic material, conduction proceeds via both electrons and holes (see INSULATORS AND SEMICONDUCTORS, CONDUCTIVITY IN). The total electrical conductivity in such a circumstance is the sum of the partial conductivities of electrons and holes:

$$\sigma = \sigma_e + \sigma_h = ne\mu + pe\nu. \tag{10}$$

Here n and μ are the electron concentration and mobility and p and ν are the hole concentration and mobility, respectively. The total Seebeck coefficient of an intrinsic material is given by

$$S = \frac{S_e\sigma_e + S_h\sigma_h}{\sigma_e + \sigma_h}. \tag{11}$$

Because S_e is negative and S_h is positive, the total Seebeck coefficient is smaller in magnitude than either of the partial Seebeck coefficients. For this reason, it is not desirable to use intrinsic semiconductors for thermoelectric applications. Instead it is preferable to dope the material n or p type in order to take full advantage of the thermoelectric properties of a single carrier type. Even in such an extrinsic semiconductor, intrinsic conduction will take place at a high enough temperature, and the thermoelectric properties will be degraded. As a rule of thumb,

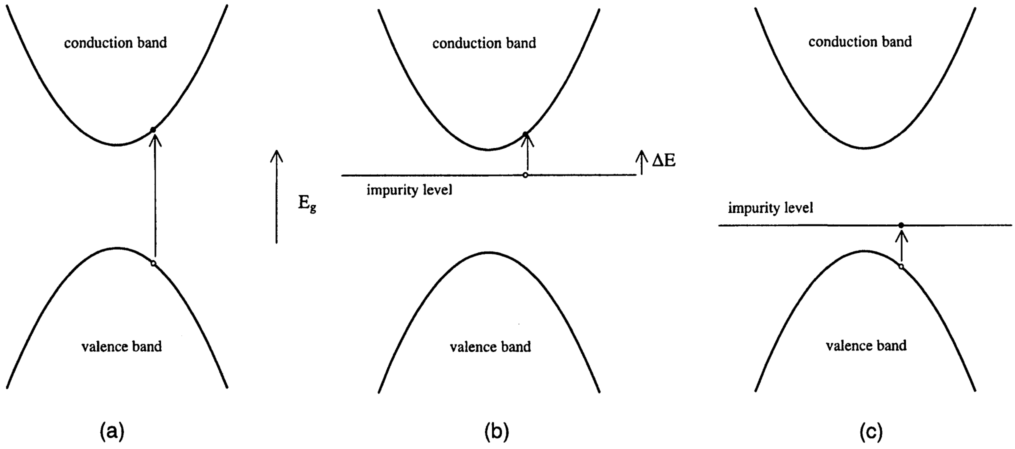

FIG. 3. (a) Energy-band structure of an intrinsic semiconductor. The empty conduction band is at an energy E_g above the full valence band. Thermal excitation of an electron across the gap can occur, leaving an empty state, or hole, in the valence band. (b) Band structure of a semiconductor doped *n* type. An impurity level is situated at an energy $\Delta E < E_g$ below the bottom of the conduction band. Electrons from this level can be easily promoted into the conduction band. (c) Band structure of a semiconductor doped *p* type. An impurity level is situated at an energy $\Delta E < E_g$ above the top of the valence band. Electrons from the valence band can be promoted easily to this level, creating a mobile hole.

one usually chooses a material such that the intrinsic energy gap is greater than a few times $k_B T$ in order to avoid intrinsic conduction at the operating temperature T.

The extent to which energy levels within the conduction band (or valence band in a p-type semiconductor) are occupied is determined by the Fermi level E_F. The probability that a state is occupied is determined by the difference between that state's energy and E_F. When E_F lies deep within the gap, the material is termed nondegenerate, and Boltzmann statistics apply. When E_F lies high up in the conduction band, the material is called degenerate, and the properties are similar to those of a metal. For thermoelectric applications, enough carriers are required to maintain good electrical conductivity, and we are interested in the intermediate case of partial degeneracy, in which case E_F is just below, at, or slightly above the band edge. In this case it is necessary to use Fermi–Dirac statistics in order to determine the probability of occupation of a state.

The Fermi level of an extrinsic semiconductor is adjusted by the degree of doping. In the partial or complete degeneracy cases, the carrier concentration is given by

$$n = \frac{\sqrt{2}}{\pi^2 \hbar^3}(m^* k_B T)^{3/2} F_{1/2} \tag{12}$$

where $\hbar = h/2\pi$ (with h = Planck's constant), m^* is the carrier *effective mass,* and

$$F_i = \int_0^\infty \frac{x^i dx}{1 + \exp(x - \mu^*)}, \tag{13}$$

where $\mu^* = E_F/k_B T$ is the reduced Fermi potential. The Seebeck coefficient, on the other hand, is given by

$$S = \frac{\pm k}{e}\left[\frac{(\frac{5}{2} + \lambda)F_{3/2+\lambda}}{(\frac{3}{2} + \lambda)F_{1/2+\lambda}} - \mu^*\right], \tag{14}$$

where λ is determined by the energy dependence of the electron-scattering time τ:

$$\tau \propto E^\lambda. \tag{15}$$

For scattering of electrons by acoustic phonons, $\lambda = -\frac{1}{2}$, whereas for scattering of electrons by ionized impurities, $\lambda = \frac{3}{2}$. In many cases, it is not possible to assign a unique value to λ.

1.2.2 Effective Mass and Effective Mobility As can be seen from Eq. (14), the Seebeck coefficient for a given type of electron scattering is determined only by the Fermi level and increases in magnitude with decreasing μ^*. On the other hand, n (and thus the conductivity) decreases with decreasing μ^* but also depends on the electron effective mass m^*. In order to maintain high electrical conductivity a relatively high carrier mobility is required. Clearly a large power factor $S^2\sigma$ is obtained by optimization of the carrier concentration by adjusting E_F by doping. It has been shown (Slack, 1995) that the power factor is largest for materials having a large *effective mobility* U*:*

$$U = \mu(m^*/m_0)^{3/2}. \tag{16}$$

Thus we seek semiconductors with both large mobility and large effective mass. These two criteria are to some extent mutually exclusive, since a large electron mass normally implies low mobility, and vice versa. However, U does in fact reach a maximum for certain types of materials, and these indeed have been found to be good thermoelectrics.

1.2.3 Phonon Conduction and Phonon Scattering As we have seen in Sec. 1.1.3, for most thermoelectric materials the main component of heat conduction is via lattice vibrations, or phonons, and we seek to reduce the lattice thermal conductivity as much as possible in order to obtain a large figure of merit and corresponding large device efficiency. It is desirable to begin with compounds whose intrinsic thermal conductivity (that is, the thermal conductivity determined by phonon–phonon scattering) is already quite low. Slack (1979) has shown that the intrinsic thermal conductivity of pure crystals depends on the average atomic mass M, Debye temperature θ, Grüneisen parameter γ, and number of atoms in the primitive unit cell N. Thus PbTe ($M = 167.4$, $\theta = 127$ K, $N = 2$) has a thermal conductivity at the Debye temperature of $\kappa_\theta = 0.068$ W cm^{-1} K^{-1}, while diamond ($M = 12$, $\theta = 1800$ K, $N = 1$) has $\kappa_\theta \approx 2$ W cm^{-1} K^{-1}. This simple criterion can thus be used to judge which materials might possess a low thermal conductivity.

Even though materials such as PbTe and Bi_2Te_3 have low intrinsic thermal conductivity, it is necessary to reduce their thermal conductivity still further in order to enhance Z to the point that these compounds and others can be technologically useful thermoelectrics. This is done by introducing defects or some type of disorder into the crystals. The subject of phonon–defect scattering and the resultant reduction in thermal conductivity is a very rich one of its own accord (see PHONONS IN CRYSTAL LATTICES), and several excellent reviews and monographs on the subject are available; see, for instance, Klemens (1958) and Berman (1976). We simply note here that the thermoelectrician has at his or her disposal several experimental methods of reducing the lattice thermal conductivity without substantially altering the power factor of a given thermoelectric material. We will illustrate this important technique with a couple of examples.

Probably the most popular and effective method of reducing the thermal conductivity of a compound is to make a mixed crystal. In this technique one of the constituent atoms of the compound is replaced by an element from the same column of the periodic table; as an example, one can start with PbTe and partially substitute Se for Te to make the mixed crystal $PbTe_{1-x}Se_x$. Simple valence-electron arguments indicate that in many cases the resulting electronic structure of the mixed crystal will not differ greatly from that of the pure compound, and thus the electrical properties will be quite similar. On the other hand, the resulting mass difference is capable of producing strong phonon scattering, and the thermal conductivity can be reduced over a fairly large temperature range.

A second example of an effective means of reducing the thermal conductivity is given in the Si/20% Ge mixed crystal system. This thermoelectric material was developed for a high-temperature generator application. In this system scattering of high-frequency phonons is achieved by the mass fluctuation scattering of the Ge impurity atoms, and low-frequency phonons are scattered by grain boundaries and electrons. However, a large range of intermediate-frequency phonons that carry a substantial amount of heat at high temperature are relatively unaffected by these scattering mechanisms. In order to decrease the mean free path of this part of the phonon spectrum, inert particulates of approximate size of 50 Å can be placed inside of the SiGe grains. Experiments on hot pressed samples containing BN, B_4C, and Y_2O_3 scattering centers indeed showed a remarkable reduction in thermal conductivity by as much as 50% relative to standard SiGe alloys. The theoretical predictions and subsequent experiments on this system showed the strong predictive power of lattice thermal conductivity models based on frequency-dependent scattering rates.

This ends our discussion of the macroscopic and microscopic properties of thermoelectric materials. We have seen how the desired properties of high Seebeck coefficient, large electrical conductivity, and small thermal conductivity are related to underlying physical properties such as Fermi level, effective mass, effective mobility, atomic masses, unit-cell complexity, and phonon-scattering mechanisms. On this basis we have identified the most likely high-Z thermoelectric materials to be high-mobility, large-effective-mass semiconductors with heavy constituent atom masses and large unit cells. Now that an understanding of thermoelectric materials is in hand, we look briefly at the theory of thermoelectric device operation.

2. DEVICE OPERATION AND DESIGN

2.1 Efficiency of a Thermoelectric Generator

Consider the thermocouple consisting of one n-type element and one p-type element, both of length L and cross-sectional area A, as shown in Fig. 4. The two elements are connected together at one end by a metal strip, and across the other end is placed a load of resistance R_L. The hot end of this couple is at temperature T_H and the cold end at temperature T_C. For simplicity we assume that the thermoelectric properties of the thermoelements are identical so that $S_n = S_p = S$, $\kappa_n = \kappa_p = \kappa$, and $\rho_n = \rho_p = \rho$, where S, κ, and ρ are the Seebeck coefficient, thermal conductivity, and electrical resistivity of the elements. The general case of differing

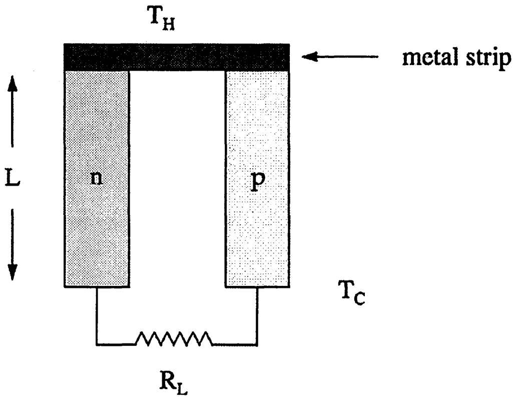

FIG. 4. Thermoelectric generator consisting of one *n*-type element and one *p*-type element, each of length *L* and cross-sectional area *A* (not shown), joined by a metal strip. With a temperature difference $T_H - T_C$ across the couple, a current will flow in the load resistance R_L.

thermoelectric properties for the two legs is more detailed than we wish to include here but may be found in Kerr (1960). Let R and K equal the combined electrical resistance and thermal conductance of the couple, respectively:

$$R = 2\rho L/A \quad \text{and} \quad K = 2\kappa A/L. \tag{17}$$

The relative Seebeck coefficient of the couple is $2S$.

The arrangement shown in Fig. 4 is a thermoelectric generator because the temperature difference $T_H - T_C = \Delta T$ across the thermoelements causes a current I to flow in the load resistance R_L. The efficiency of this generator is defined as the ratio of electrical power P delivered to the load to the energy consumed from the heat source, Q_s. Consider now the conservation of energy at the hot junction. The heat delivered by the source Q_s is balanced by the heat conducted down the arms of the thermocouple Q_c, and the Peltier heat developed at the hot junction Q_p due to the flow of current. In addition, of the Joule heat I^2R developed in the arms of the thermocouple, one-half is returned to the hot junction. Thus

$$Q_s = Q_p + Q_c - \tfrac{1}{2} I^2 R. \tag{18}$$

Now $Q_p = 2SIT_H$ and $Q_c = K(T_H - T_C)$. In addition, the current in the circuit is the thermoelectric voltage divided by the total circuit resistance:

$$I = \frac{2S(T_H - T_C)}{R_L + R}. \tag{19}$$

The generator efficiency ϵ can thus be written

$$\epsilon = \frac{I^2 R_L}{Q_p + Q_c - I^2 R}, \tag{20}$$

$$\epsilon = \frac{T_H - T_C}{T_H} \times \frac{m/(m+1)}{1 + KR(m+1)/4S^2 T_H - (T_H - T_C)/2T_H(m+1)}, \tag{21}$$

where $m = R_L/R$.

The maximum power delivered to the load occurs when the load resistance is equal to the generator internal resistance, i.e., when $m = 1$. Under this condition the efficiency is

$$\epsilon = \frac{\Delta T}{T_H} \frac{1}{2 + 4/ZT_H - \Delta T/2T_H}, \tag{22}$$

where $Z = 4S^2/KR = S^2/\kappa\rho$ is the figure of merit of one of the arms of the thermocouple. Figure 5 shows the efficiency under maximum power output conditions as a function of the figure of merit and temperature difference ΔT.

It is interesting to note that the efficiency under maximum power transfer to the load is not the maximum efficiency $\epsilon_{\max}$. This latter quantity can be determined by differentiating ϵ with respect to R_L (i.e., m) and setting the result equal to zero. This condition yields the value for the load resistance at maximum efficiency:

$$(R_L)_{\max} = R\sqrt{1 + ZT_{\text{ave}}}, \tag{23}$$

where $T_{\text{ave}} = (T_H + T_C)/2$. Thus the load resistance required for maximum generator efficiency is always greater than that required for maximum power output. Substituting the value of R_L/R from Eq. (23) into Eq. (21) yields an expression for the maximum generator efficiency:

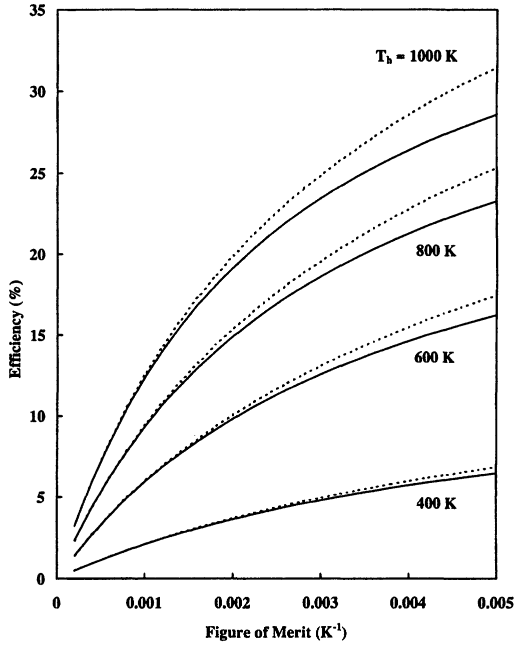

FIG. 5. Efficiency of a thermoelectric generator as a function of the figure of merit for several hot-side temperatures, assuming a cold-side temperature of 300 K. Solid lines: under conditions of maximum power transfer; dashed lines: under conditions of maximum efficiency.

$$\epsilon = \frac{\Delta T}{T_H} \frac{\sqrt{1 + ZT_{\text{ave}}} - 1}{\sqrt{1 + ZT_{\text{ave}}} + T_C/T_H}. \tag{24}$$

Thus we see that the efficiency of a thermoelectric generator cannot exceed the Carnot efficiency given by $\Delta T/T_H$. The generator efficiency increases with increasing values of Z and for larger Carnot efficiency. Figure 5 shows the maximum efficiency as a function of both Z and the temperature difference ΔT. For state-of-the-art thermoelectrics today ϵ does not exceed 10%. Recent theoretical models (Slack, 1995) have suggested that actual Z values may be augmented by at most a factor of 2–4. With such materials the thermoelectric efficiency could be increased to more than 20%.

2.2 Coefficient of Performance of a Thermoelectric Cooler

For the case of thermoelectric cooling we consider the circuit shown in Fig. 6. Here a dc power supply is connected in the circuit at T_H while the thermocouple legs are joined at the source (at temperature T_C) from which heat is to be removed. Considering conservation of energy at the source, an amount of heat Q_p is removed from the source by Peltier cooling at the junction, but an amount of heat Q_c flows into the source due to conduction down the arms of the thermocouple. In addition, of the Joule heat I^2R developed in the arms of the thermocouple, one-half is returned to the cold junction. Thus the total rate of heat removal Q_r from the cold junction is given by

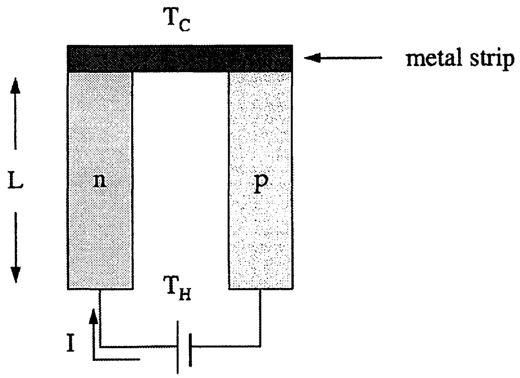

FIG. 6. Thermoelectric cooler consisting of one n-type element and one p-type element, each of length L and cross-sectional area A (not shown), joined by a metal strip. With current flowing in the circuit, heat is liberated at the hot junction and absorbed at the cold junction, producing cooling.

$$Q_r = Q_p - Q_c - \tfrac{1}{2} I^2 R. \tag{25}$$

Under the same notation and assumptions as in the case of the thermoelectric generator, the rate of heat conduction down through the thermocouple legs to the source is $Q_c = K(T_H - T_C)$, and the rate of Peltier cooling at the cold junction is $Q_p = 2SIT_C$. Thus

$$Q_r = 2SIT_C - K(T_H - T_C) - \tfrac{1}{2} I^2 R, \tag{26}$$

and the temperature difference achieved is

$$T_H - T_C = \Delta T = 2SI - \tfrac{1}{2} I^2 R - Q_r. \tag{27}$$

The ability of a refrigerator to cool is given by the coefficient of performance (COP), which is the ratio of the rate of heat removal Q_r to the amount of power consumed, P:

$$\mathrm{COP} = Q_r/P. \tag{28}$$

The power consumed is the sum of the Joule heat generated in the arms of the thermocouple and the power required to overcome the thermal EMF:

$$P = I^2R + 2IS\Delta T. \tag{29}$$

Substitution of (25) and (28) into (27) yields

$$\mathrm{COP} = \frac{2SIT_c - K(T_H - T_C) - \frac{1}{2}I^2R}{I^2R + 2IS\Delta T}. \tag{30}$$

Thus both the temperature difference attainable (27) and the COP (30) depend on the current in the circuit. The maximum temperature difference occurs when $Q_r = 0$ and for a current given by the condition $d(\Delta T)/dI = 0$, which yields

$$I(\max \Delta T) = 2ST_c/R. \tag{31}$$

The corresponding maximum temperature difference is

$$\Delta T_{\max} = \tfrac{1}{2}ZT_C^2. \tag{32}$$

The maximum COP, on the other hand, occurs for a current given by the condition $d(\mathrm{COP})/DI = 0$, which gives

$$I(\max \mathrm{COP}) = \frac{2S\Delta T}{[\sqrt{1 + \frac{1}{2}Z(T_H + T_C)} - 1]R}. \tag{33}$$

The corresponding maximum COP is

$$(\mathrm{COP})_{\max} = \frac{T_C}{\Delta T}\,\frac{\sqrt{1 + ZT_{\mathrm{ave}}} - T_H/T_C}{\sqrt{1 + ZT_{\mathrm{ave}}} + 1}. \tag{34}$$

2.3 Some General Design Considerations

There are many different designs of thermoelectric devices for specific applications of this technology. However, all of these designs share several common features that are required for operation, including *n*- and *p*-type thermoelectric elements; contact metallization; electrical connections to supply current in the case of a cooling device or to draw off current in the case of a generator; and heat exchangers on both the hot and cold sides to maintain the maximum possible temperature difference. The overall efficiency can depend strongly on these factors, and several key points should be kept in mind when preparing to implement them in a device.

2.3.1 Thermoelectric Material Typically the figure of merit of a particular thermoelectric material is a rather strong function of temperature, and one wishes to choose a material the figure of merit of which is optimized for the temperature range of the particular application and which is chemically stable at the operating temperature. For thermoelectric coolers operating near room temperature and for thermoelectric generators operating below 300 °C, the material of choice is Bi_2Te_3. Above about 200 °C the figure of merit of Bi_2Te_3-based materials begins to decline as intrinsic conduction becomes important, and for temperatures between about 400 and 700 °C PbTe-based compounds have the highest figure of merit. For temperatures above 700 °C the best materials today are SiGe compounds.

2.3.2 Contact Metallization and Electrical Connections A critical issue in the successful implementation of thermoelectric technology is the ability to make low-resistance electrical contact to the thermoelectric elements. Because of the relatively low resistivity of thermoelectric materials (a necessity for their operation in order that Joule heating effects be negligible), it is essential that the electrical contacts to the elements have low resistance as well. Sizable contact resistances can act against the Peltier cooling in a thermoelectric refrigerator and can limit the power delivered to the load in a thermoelectric generator, and every effort should be made to minimize these effects. What must be kept in mind is that the thermoelectric elements are semiconductors, and making good low-resistance contacts is a nontrivial problem involving a large amount of both solid-state physics and engineering and has been the subject of a good deal of literature in its own right (e.g., Williams, 1984). For our purposes we simply point out that a contact between a semiconductor and a metal may be rectifying rather than Ohmic. Rectifying contacts can become highly resistive depending on conditions such as current magnitude and direction, and temperature, and thus must be avoided. In addition to the nature of the contact itself, two additional contact problems can arise, particularly in the case of thermoelectric devices operating at high temperature; these are *diffusion* and *thermal expansion mismatch*. Certain metals can have very high rates of diffusion into the bulk of the semiconductor elements, resulting in not only degradation of the contact but also an undesirable alteration of the properties of the thermoelectric material itself. A classic example is the influence of copper on bismuth telluride; plating copper onto *p*-type bismuth telluride even at room temperature can transform the material into an *n*-type semiconductor (Goldsmid, 1960). The problem of thermal expansion mismatch is also a delicate one, as a metallic contact with an expansion coefficient greatly different from that of the thermoelement may crack, peel, or delaminate under temperature excursions. Taken together, the problems of nature of the contact, diffusion, and thermal expansion can present a difficult challenge depending on the thermoelectric material and the temperature range of interest. Frequently one finds that, for instance, a material that makes a good Ohmic contact also has a high diffusion coefficient, or a metal that has a good thermal expansion match makes a rectifying contact. These situations can be dealt with by using multiple layers of metals to provide a diffusion barrier, thermal match, and Ohmic contact at the same time.

2.3.3 Heat Exchangers The purpose of heat exchangers is to bring the temperature of the hot side of the thermoelectric device as close as possible to that of the heat sink (or source) and the temperature of the cold side of the thermoelectric device as close as possible to the cold sink. This means that the heat exchanger should have a large surface area and be made of a material with high thermal conductivity. Because of its low density and high thermal conductivity, aluminum is usually chosen as the exchanger material, and in order to maximize surface area for a given volume, some type of fin arrangement is employed. A related issue is the requirement that the heat exchanger obviously must be in good thermal contact with, but electrically insulated from, the thermoelectric elements. A popular method of achieving this is to use strips of mica or alumina in between the exchangers and the elements, but the added thermal resistance of such a layer will produce a non-negligible temperature difference between the element and the heat exchanger. With the wide variety of technologies available today (such as sputtering, vapor deposition, and thermal spray, to name a few) for producing thin layers of insulating films, it should be possible to provide high-quality electrically insulating, thermally conducting layers that minimize the temperature differences between the elements and exchangers.

3. EXAMPLES OF THERMOELECTRIC GENERATORS AND COOLERS

3.1 Radioisotope Thermoelectric Generator for Interplanetary Spacecraft Propulsion

Probably the most well-known application of thermoelectric power generation is the use of a radioisotope thermoelectric generator (RTG) to provide electrical power for interplanetary spacecraft such as Voyager, Galileo, and Ulysses. These generators were developed by the Jet Propulsion Laboratory over the last quarter-century. Of primary concern was the spacecraft missions' requirements of long life and high reliability, rather than generator efficiency or overall system cost, thus making thermoelectrics the technology of choice for this application.

The source of thermal energy for the RTG is the heat generated during the radioactive decay of a plutonium-238 heat source. In order to produce enough electrical power for the spacecraft (about 250 W per RTG), 4300 W of thermal power is required. The active thermoelectric elements are Si/20% Ge alloys doped *p* type and *n* type with boron and phosphorus, respectively. Degradation of the electrical power output as a function of time for the RTG is due principally to the decay of the radioactive source and increase in thermoelement resistivity due to dopant diffusion. The output electrical power for these generators is typically 90, 80, and 75% of the original output power after 4, 10, and 16 years, respectively. Because of the high operating temperature of the RTG (hot-side temperatures in excess of 1000 °C), several materials issues related to diffusion, sublimation, oxidation, and metallization had to be solved. The successful implementation of these power sources in long-term interplanetary space missions represents the greatest testament to the reliability and long life of thermoelectric devices.

3.2 Bi-Te–Based Coolers for Electronic and Optical Applications

Compared to the extreme conditions to which an RTG is exposed in outer space, the operational conditions of thermoelectric coolers are considerably less stringent. To begin with, the temperature range of operation (typically −50 to 100 °C) minimizes and eliminates several difficulties. Problems associated with thermal-expansion mismatch, contact resistance, and dopant diffusion are far less severe. That is not to say that these issues can be neglected. In the operation of a cooler, the heat rejected from the device must be removed using a heat sink. If this is not done, the hot side of the cooler can overheat, and some or all of the problems listed above can become an issue. Single-stage coolers are commercially available with cooling powers of up to almost 70 W and maximum temperature differences of nearly 70 °C. A typical thermoelectric cooler is depicted in Fig. 7. Several hundred p- and n-type elements are arranged in an electrical series connection and placed between two ceramic plates. The thermoelements are thus connected in parallel thermally; one of the plates is the hot side, and the other, the cold side. The electrical connection between neighboring elements is a small copper strip soldered to each element. The ceramic plates serve the purpose of providing a structurally strong member for mounting the device to a heat sink on the hot side and the part to be cooled on the cold side, while at the same time providing electrical insulation between the elements and these entities. It is desirable for the ceramic to have a low thermal resistance in order to minimize any temperature difference across it. Thin sheets of adamantine compounds such as Al_2O_3 and BeO are the materials of choice. If the surface area of the cooler is not too large, the outer surface of the ceramics can be metallized so that they can be soldered to the heat and cold sinks. For large surface areas, thermal-expansion mismatch can be a problem, and it is usually desirable to make thermal contact by means of a thermally conducting grease or compression. A very nice feature of thermoelectric coolers is that the temperature difference obtained and the cooling power are functions of the device current, thus allowing precise temperature control using a feedback loop.

Thermoelectric devices have been used to great advantage for cooling solid-state lasers and infrared detectors, to name just two applications. In addition, they have been employed in small-scale volume-cooling applications such as small refrigerators, picnic baskets, and electronic-equipment enclosures. They are not currently used in applications requiring cooling powers in excess of a couple of hundred watts, because the coefficient of performance of present-day thermoelectric coolers is smaller than that of standard vapor-compression air conditioning units in this cooling-power range. However, with the development of new materials of enhanced figure of merit, the COP of thermoelectrics will become comparable to that of standard units even for higher–cooling-

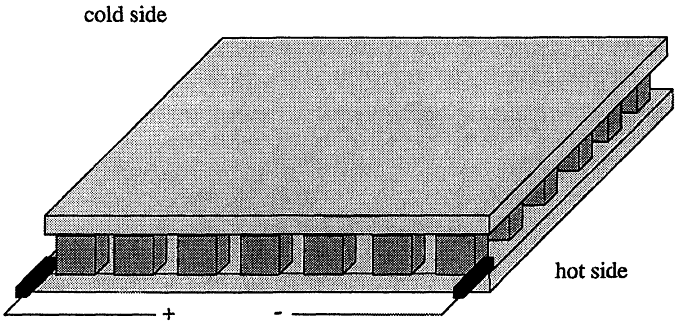

FIG. 7. Typical thermoelectric cooler. Several hundred p- and n-type elements are joined together in an electrical series, thermal parallel arrangement and sandwiched between high–thermal-conductivity electrical insulators.

power applications such as room or vehicle air conditioning. Assuming that such materials are found and the COP of TE coolers becomes competitive, whether such large-scale application occurs will depend on many highly variable factors. Certainly the all-solid-state operation, high reliability, long life, low noise, and low vibration levels of TE coolers are strong advantages. But several questions remain: Can device design be improved and adapted to new applications? Is there enough raw material available to satisfy the needs of the industry? Are the thermoelectric materials themselves environmentally friendly, easy to manufacture, and recyclable? Can thermoelectric cooling on a large scale really be done economically? These are serious issues that will have to be addressed somewhere down the road. But the first step and the real key to opening up large markets for thermoelectric devices is the *development of new materials with enhanced properties.* An area of intense research in the early 1960s, thermoelectric materials research has been done on a very small scale over the last 30 years. However, our knowledge today of the minimum thermal conductivity achievable in materials together with the development of new materials with unusual and exotic transport properties has renewed hope that thermoelectric materials with figures of merit substantially larger than that of Bi_2Te_3 can exist. Within the last two years, activity on both the theoretical and experimental fronts has increased dramatically. This review concludes with a short description of some potentially interesting materials systems that are just beginning to give us the hint that better and more efficient thermoelectric materials may be just around the corner.

4. POTENTIAL NEW MATERIALS FOR THERMOELECTRIC CONVERSION DEVICES

In the past 50 years, hundreds of compounds have been investigated with the hopes of finding a material with thermoelectric properties significantly better than Bi_2Te_3, with decidedly negative results. Thus one may rightly ask the question, If we have failed at this endeavor in the past, why should we hope to succeed now? There are several reasons why there is hope today that better thermoelectrics might someday be developed. In the last 20 years we have witnessed explosive growth in the field of materials research. New material systems, such as the two-dimensional electron gas and heavy-fermion, intermediate-valence, hybridization-gap, and correlated-electron systems, have been discovered. Innovative ways of making materials, including molecular-beam epitaxy and sputtering, have been developed. And, not least of all, a deeper understanding of the physical processes underlying the observed properties of materials has been developed. One potential route to high Z is to take advantage of unusual structures, geometries, or effects in order to produce outstanding thermoelectric properties. Some examples would include using quantum confinement to alter in a positive way the density of states of traditional thermoelectric materials such as PbTe and BiSb; fabricating unusual "rattling atom" structures such as filled skutterudites or clathrate compounds to produce solids with good electrical properties but very low thermal conductivity; taking advantage of strong phonon-scattering processes such as $4f$-electron scattering in rare earth-compounds or charge-transfer type scattering in mixed-valence systems. These are some of the several areas of research that have become very active in the last two years. Since the purpose of this article is to review the physics and technology of thermoelectric *devices*, it is not our desire to give an exhaustive review of thermoelectric *materials*. On the other hand, we would be remiss to not include a brief discussion of some potential new thermoelectric materials, since the development of such materials can potentially revolutionize the thermoelectric device industry.

In order to give the reader a flavor for the type of research currently being carried out on advanced thermoelectric materials, we will highlight a couple of specific examples. The first is the so-called skutterudite compounds that have emerged as a fertile area to search for high-Z thermoelectrics. These little-known compounds, apparently semiconductors, are of the form AB_3 where $A = Ir$, Rh, or Co and $B = Sb$, As, or P. One reason it was suggested that these materials may be interesting is that the unit cell is large and contains many (16) heavy atoms, one of the criteria for low lattice thermal conductivity. In addition, p-type samples can exhibit mobilities of nearly 10 000 $\mathrm{cm^2\ V^{-1}\ s^{-1}}$, with effective masses of approximately $0.1m_0$, leading to quite large effective mobility. It turns out that the thermal conductivity, while small, is still too large (by about a factor of 5–10) to make these materials effective thermoelectrics. Mixed crystals can be made that decrease the thermal conductivity and increase Z, but no systems have been found to date with ZT in excess of about 0.6. What makes the skutterudite system so fascinating, however, is an unusually large void in the unit cell. This void can be filled with a rare-earth (RE) atom, creating structures of the form $\mathrm{REFe_4B_{12}}$. Such "filled skutterudite" structures have been known for several years. An important feature of the filled systems is that the radius of the rare-earth atom is significantly smaller than the radius of the void in which it resides. The rare earth "rattles" in a cage of Sb atoms, or in other words, exhibits a soft-phonon mode. It has been predicted and experimentally verified that similar rattling atom systems, such as clathrates, exhibit extremely low, almost glasslike thermal conductivity. Thus it might be possible to create filled skutterudite compounds that exhibit the desirable electrical properties of the binary but with strongly depressed thermal conductivity, thus leading to high Z. Slack (1995) has appropriately termed such structures "phonon-glass electron-crystal," or PGEC, systems. The first demonstration of a strong decrease in the thermal conductivity of a skutterudite upon filling the void was given by Morelli and Meisner (1995). They studied the transport properties of the compound $\mathrm{CeFe_4Sb_{12}}$ and showed that the thermal conductivity was about a factor of 10 lower than that of $\mathrm{CoSb_3}$ and $\mathrm{IrSb_3}$. Unfortunately, the filling of the void with a trivalent rare-earth atom changes the band structure significantly: the filled compounds become metallic, and the power factor decreases substantially. An active area of research today is creating filled skutterudite compounds in which the three electrons donated by the rare-earth atom are compensated by the presence of three electron-deficient atoms on the Sb site, e.g., $\mathrm{NdIr_4Sn_3Sb_9}$. These or similar structures may maintain the high power factor of binary skutterudites while also exhibiting the glassy thermal conductivity of the filled compounds.

Another potential area of interest is in semiconductors in which one of the constituent elements is a rare earth. The $4f$ electrons of the rare-earth atom are subject to the crystalline electric field due to its neighbors. Because of the interaction of the electron spin with the field, the ground-state energy levels of these electrons become split. The splittings of the $4f$-electron levels in the rare-earth atoms are much smaller (typically less than 100 meV) than those in the d-shell electrons in transition metals because the latter, being the outermost electrons, are much more strongly influenced by the crystal field. However, it will be noted that the splitting in the rare-earth case is on the order of the energy of a typical phonon. This means that a phonon of the proper energy can be absorbed by an electron in the lowest lying sublevel in order to promote the electron to the next highest level. When this electron falls back down to the lowest level, a phonon will be re-emitted incoherently; thus this process is a phonon-scattering process. Here we have a means by which phonons can be strongly scattered but which in principle should not strongly affect the conduction electrons in the material. In other words, one can use the magnetic scattering of phonons by crystal-field-split $4f$ electron levels to decrease the phonon mean free path while leaving the electrons alone, a potential route to high Z. One possible area of research would be to search for ternary semiconducting rare-earth–containing compounds that have energy-level splittings corresponding to the energy of the dominant heat-carrying phonons for a particular temperature range.

As a final example we make mention of heavy-fermion, intermediate-valence, and Kondo systems. These structures possess a wide variety of interesting and exotic properties including superconductivity, magnetism, and very heavy electron masses, to name just a few. These features all arise from the proximity of the $4f$-electron energy levels of the rare-earth or actinide atom to the Fermi energy. This same feature leads to anomalously large peaks in the thermoelectric power. In fact, such systems are known to have thermoelectric power factors much larger than even the best thermoelectric materials, but they unfortunately are almost always metals with high thermal conductivity. The question arises as to whether such "heavy-electron" behavior can occur in systems of lower carrier density. This is an emerging area that provides great potential for finding very high-Z materials. If the large power factors of intermediate-valence and heavy-fermion type systems can be combined with the low thermal conductivity of a complex semiconducting structure, there is a good chance of finding substantially larger values of Z.

GLOSSARY

Acceptor: An impurity atom in a semiconductor that produces an energy level close to the top of the valence band. Electrons from the valence band can be easily promoted into this level, producing empty states, or holes in the valence band.

Coefficient of Performance: The ratio of the heat removed by a thermoelectric cooler to the amount of electrical power consumed.

Contact Resistance: The electrical resistance at the junction between a metal and a semiconductor.

Diffusion: The migration of one species or element into another.

Electrical Conductivity: A measure of the ability of a material to conduct electrical charge.

Energy Gap: The energy difference between the completely filled topmost valence band and the totally empty lowest lying conduction band in a semiconductor.

Figure of Merit (Z): The quantity that determines the efficiency of a thermoelectric generator and the coefficient of performance of a thermoelectric cooler; it is related to the Seebeck coefficient S, electrical conductivity σ, and thermal conductivity κ of a material according to $Z = S^2\sigma/\kappa$.

Heat Exchanger: A large-surface-area metallic member of a generator (cooler), the purpose of which is to maintain the temperature of the hot side of the device as close as possible to that of the heat source (sink) and the cold side of the device as close as possible to the cold sink (source).

Mobility: A measure of the ability of a charge carrier to move through a crystal lattice.

Peltier Effect: The liberation of heat at one junction and the absorption of heat at the second junction when current is allowed to flow in a circuit composed of two dissimilar metals.

Phonon: A quantum of vibrational energy in a crystalline material.

Power Factor: The product of the square of the Seebeck coefficient and the electrical conductivity.

Seebeck Coefficient, or Thermoelectric Power: The ratio of the open-circuit electric field to the temperature gradient in a material.

Seebeck Effect: The occurrence of a potential difference in a circuit consisting of two dissimilar metals under conditions of zero net current flow when the two junctions are held at different temperatures.

Thermal Conductivity: A measure of the ability of a material to conduct heat.

Thermal Expansion Mismatch: The difference in the thermal expansion coefficient of two materials joined together.

Thermoelectric Efficiency: The ratio of electrical power produced by a thermoelectric generator to the amount of thermal power absorbed from the heat source.

INTRODUCTION

> Ninthly, I found that holding it a while near the Flame of a Candle, (from which yet I was careful to avert my Eyes) and being immediately remov'd into the Dark, it disclosed some faint Glimmering, but inferiour to that, it was wont to acquire by Rubbing. And afterward holding it near a Fire that had but little Flame, I found the Stone to be rather less than more excited, than it had been by the Candle.
>
> Tenthly, I likewise indeavour'd to make it Shine, by holding it a pretty while in a very Dark place, over a thick piece of Iron, that was well Heated, but not to that Degree as to be Visibly so. And though at length I found that by this way also, the stone acquired some Glimmering, yet it was less than by either of the other ways above mention'd.
>
> Sir Robert Boyle, 1664

Thus is written the first scientific description of a phenomenon that would later become popularly known as *thermoluminescence,* although the modern word would not appear in print for over two centuries (Wiedemann and Schmidt, 1895). The above quotation comes from Boyle's discourse to the Royal Society, *Experiments and Considerations Touching Colours* (Boyle, 1664), and is included alongside a discussion of a related phenomenon, now known as *triboluminescence,* which is the stimulation of luminescence from an object by fracture of the material. The advance of more than 300 years has resulted in a quantification and understanding of thermoluminescence that, although still far from complete, has enabled

it to be used to great effect in the fields of radiation dosimetry, archaeological dating, and many more.

Stated in language less archaic than Boyle's, thermoluminescence (TL) is the emission of light from an insulator (or semiconductor) when the object is heated, following an initial irradiation of the sample. This latter component (i.e., radiation absorption) is an essential feature of the TL phenomenon. Thermoluminescence is one of a family of processes collectively known as thermally stimulated phenomena. Also included in the family are thermally stimulated conductivity (TSC), thermally stimulated capacitance (TSCap), thermally stimulated polarization (TSPC) and depolarization currents [TSDC, including ionic thermocurrents (ITC)], deep-level transient spectroscopy (DLTS), thermogravimetry (TG), and several more (Chen and Kirsh, 1981). Each of these phenomena may be described by two fundamental stages: *stage I*, the perturbation of the system from equilibrium into a metastable state; and *stage II*, the thermally stimulated relaxation of the system back to equilibrium. In each of the above techniques one monitors the nonisothermal change of a particular property of the material (e.g., luminescence, conductivity, capacitance, etc.) as the system returns to equilibrium during stage II.

In the case of TL, stage I necessitates the absorption of energy, normally from ionizing radiation, in order to perturb the material into a nonequilibrium state. Energy storage occurs through the processes of electron–hole pair production, exciton creation, and/or direct displacement damage, followed by charge localization (trapping) at defects within the host lattice of the irradiated material.

During stage II, the stored energy is released as the temperature of the sample is increased, and a fraction of the released energy is in the form of luminescence. The luminescence originates from electron–hole recombination or vacancy–interstitial recombination. In either case, electrons undergo de-excitation from metastable excited states to the ground state, thereby restoring equilibrium. The simplest manner in which this can be achieved is via electron–hole recombination. For example, we may assume that electrons are the thermally freed charges (although the discussion could just as well proceed on the basis that it is holes that are thermally liberated). The process is initiated when phonon coupling between the trapped electron and the lattice results in the absorption of an amount of thermal energy by the electron. The probability per second that this amount of energy is enough to release the trapped electron from its localized state (i.e., to overcome the energy barrier E and undergo a transition into the conduction band) is given by

$$p(T) = s(T)\exp\{-E/kT\}, \qquad (1)$$

where $s(T)$ is a weakly temperature-dependent term known as "the frequency factor" and is related to the local lattice vibrational frequency and the entropy change associated with the charge release. Thus, once the temperature is high enough, the electron will be released into the conduction band and will then be free either to retrap (at either the same or different localized states) or to recombine with trapped holes. The recombination process results in the emission of phonons (nonradiative recombination) or photons (radiative recombination). It is the latter that are monitored when recording TL emission. Thus, we have the thermally stimulated return of the system from its metastable state to equilibrium, with a portion of the excess energy being liberated as light. It should be noted that, for the mechanism described, TSC should also be observed during TL emission since the freed electrons spend time in the conduction band before recombination takes place. However, it is often observed that TL is not accompanied by TSC, suggesting recombination processes that do not involve the delocalized bands. Nevertheless, the concept of thermally stimulated excitation of trapped charge into an excited state from which recombination with charges of the opposite sign can occur is the main concept involved in TL, whether or not the recombination process proceeds via the delocalized bands.

The general principles and mechanisms of TL production are described in the following sections, along with the basic equations that allow a mathematical description of the phenomenon. This is followed by an outline of the principles of instrumentation and descriptions of some of the major applications of the process.

1. BASIC PHYSICAL PRINCIPLES

1.1 Phosphorescence and Thermoluminescence

Luminescence is the emission of light from a material following the initial absorption of energy from an external source—e.g., ultraviolet or high-energy radiation. The emission can be categorized as either fluorescence or phosphorescence, depending upon the characteristic lifetime τ_L between absorption of the excitation energy and emission of the luminescence. The distinction between the two processes is not always clear and is perhaps most easily made using the temperature dependence of τ_L. Consider a ground-state energy level g and an excited-state energy level e, illustrated in Fig. 1(a). Fluorescence is the emission of light that follows the excitation of an electron from g to e and its subsequent return to level g. On the other hand, if the return to the ground state is delayed by a transition into and out of a metastable level m, then delays between excitation and emission can result [Fig. 1(b)], and in this case the process is known as phosphorescence. If the transition into level m occurs at a temperature T, where the energy E of separation between m and e is such that $E \geq$ several kT (k is Boltzmann's constant), then the electron is likely to reside in m for a considerable period. In this case, assuming a Boltzmann distribution of energies, the probability p per unit time for thermal excitation from the trap is exponentially dependent upon temperature according to Eq. (1), and the time between excitation and final relaxation back to the ground state can be considerably delayed by the residence of the electron in the metastable state. The temperature dependence described by Eq. (1) provides a means for distinguishing between the weakly temperature-dependent process of fluorescence and the strongly temperature-dependent process of phosphorescence.

If the metastable level is an electron trap, at an energy E_t below the conduction band, the activation energy for phosphorescence $E = E_t$. For typical numerical values of $E_t = 1.5$ eV and $s = 10^{12}\ \mathrm{s}^{-1}$, the calculation of p at 298 K using Eq. (1) indicates that, for all practical situations, the trap would never thermally release its trapped electron, and, as a result, phosphorescence would never be observed at this temperature. However, if the temperature were to be raised, a temperature may be reached at which p is high enough to ensure that electron release occurs and luminescence is observed. For example, at $T = 300$ K and using the above values for E and s, one can calculate a lifetime $\tau = 1/p$ of 5.06×10^5 years; in contrast, at 500 K, $\tau = 0.36$ s. Thus, consider raising the temperature of the system at some arbitrary rate $\beta = dT/dt$. As T rises, so p increases, producing enhanced luminescence emission. Unlike phosphorescence, which is normally assumed to occur at a fixed temperature, this emission is stimulated in a nonisothermal situation and is thus termed *thermally stimulated luminescence* (TSL), or, more popularly, *thermoluminescence* (TL). As the temperature continues to rise, so the TL intensity increases until such time as the population of trapped electrons in the metastable state is sufficiently depleted, at which point the TL intensity decreases with further increase in temperature. The result is the

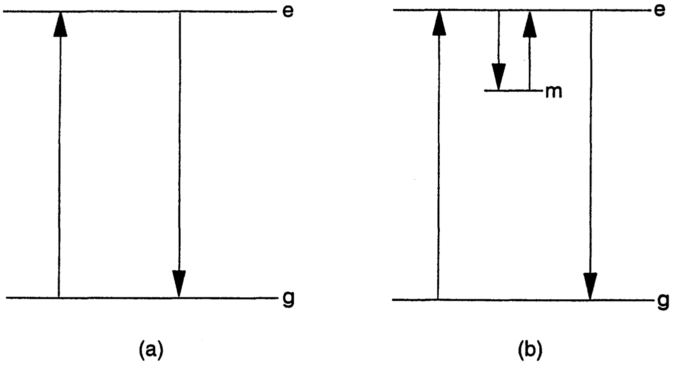

FIG. 1. (a) The ground-state (g) and excited-state (e) energy levels associated with fluorescence emission. (b) The transitions involved in phosphorescence showing the metastable level (m) that causes a temperature-dependent delay between excitation and emission.

characteristic TL peak (the "glow peak"), for which the temperature at the peak maximum is related to the trap depth E_t, the frequency factor s, and the rate of warming β.

1.2 Phenomenology: Simple Models

Using the simple concepts outlined above, Randall and Wilkins (1945) were the first to attempt a mathematical description of the TL glow-peak shape. The phenomenological model used by these authors is based on the band model of an insulator or semiconductor and is illustrated schematically in Fig. 2. Here we see a metastable localized level (level 1) at an energy E_t below the conduction band and a deep level (level 2) assumed to reside below the system's Fermi level (E_F). Prior to irradiation (at equilibrium), level 1 is assumed to be empty, and level 2 is assumed to be full. During irradiation [Fig. 2(a)], electrons are excited across the material's band gap and become trapped at level 1. Likewise, holes become localized at level 2. The result is a nonequilibrium excess of electrons above E_F, and a deficiency of electrons below E_F. During heating of the sample [Fig. 2(b)], thermal excitation of electrons out of level 1 into level 2 occurs, with transport occurring via the conduction band. Recombination of electrons and holes results in the emission of light (TL).

An important feature of the Randall–Wilkins view of TL emission is that the probability of recombination of the released electron with the trapped hole is greater than the probability of retrapping of the released electron. This leads to the concept that the rate of release is proportional to the trapped charge concentration, and is thus termed a "first-order" reaction. The release rate of the trapped electron is thus described by

$$\frac{dn}{dt} = -ns\exp\left\{-\frac{E_t}{kT}\right\}, \tag{2}$$

where n is the trapped electron concentration. [Here the explicit temperature dependence of s from Eq. (1) is dropped.] From this Randall and Wilkins developed their famous equation:

$$I(T) = \phi n_0 s\exp\left\{-\frac{E_t}{kT}\right\} \times \exp\left[-\frac{s}{\beta}\int_{T_0}^{T}\exp\left(-\frac{E_t}{k\theta}\right)d\theta\right]. \tag{3}$$

Here, ϕ is the efficiency of luminescence production from electron–hole recombination and takes into account the fact that not all recombination events lead to a detected photon, n_0 is the initial concentration of trapped charge at the starting temperature T_0, and θ is a dummy variable representing temperature.

A modification of this view was presented by Garlick and Gibson (1948), who used the same one-trap, one-center model of Fig. 2, but who included the concept of significant retrapping of the released charges. This leads to the rate of the reaction being proportional to the square of the trapped charge concentration, and, thus, we have a "second-order" reaction. Here we have

$$\frac{dn}{dt} = -n^2 s'\exp\left\{-\frac{E_t}{kT}\right\}, \tag{4}$$

where $s' = s/N$, and N is the total concentra-

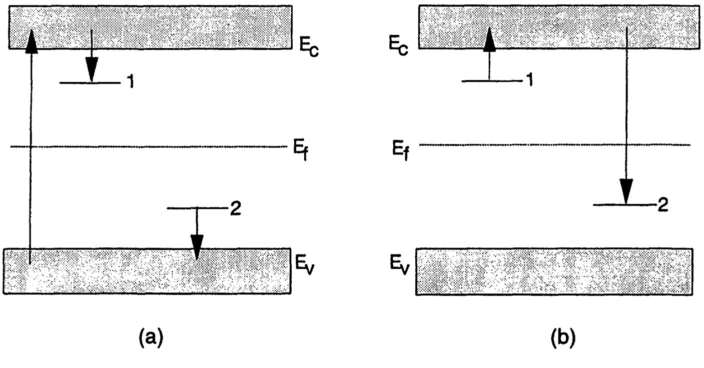

FIG. 2. Simple Randall–Wilkins model for TL. (a) Transitions during irradiation; (b) transitions during heating. E_c and E_v are the conduction- and valence-band edges; E_F is the Fermi level; 1 and 2 are the deep localized states involved in the TL process. The arrows indicate electron transitions.

tion of available electron traps (i.e., $n = N$ corresponds to all available traps full). This leads to the Garlick–Gibson equation for TL under second-order kinetics, namely

$$I(T) = \frac{\phi n_0^2 s' \exp\{-E_t kT\}}{\left[1 + \frac{n_0 s'}{\beta}\int_{T_0}^{T} \exp\left\{-\frac{E_t}{k\theta}\right\} d\theta\right]^2}. \qquad (5)$$

Examples of first- and second-order TL glow peaks are illustrated in Fig. 3. Most theories and descriptions of TL use either one or other of these simple, two-level models, although several empiricists have introduced the idea of "general order," for which the equivalent expression for TL is

$$I(T) = \frac{\phi n_0 s'' \exp(-E_t/kT\}}{\left[1 + \frac{(b-1)s''}{\beta}\int_{T_0}^{T} \exp\left\{-\frac{E_t}{k\theta}\right\} d\theta\right]^{b/(b-1)}}, \qquad (6)$$

where b is neither 1 nor 2 and $s'' = s' n_0^{b-1}$.

1.3 More Advanced Models

The choice of a model for the TL process is not trivial, since it places restrictions upon the number of TL phenomena that one can describe. Since at any given temperature one might expect traps that are "shallow" enough (i.e., E_t small compared with kT so that they are empty of trapped charge) as well as traps that are "deep" enough for the charge to be stable at that temperature, several authors have preferred a more realistic model to that illustrated in Fig. 2, consisting of an active electron level (AT), a set of shallow electron traps (ST), a set of deep, thermally disconnected electron traps (DET), and a set of thermally disconnected hole traps (DHT), as shown in Fig. 4. The term "thermally disconnected" refers to the thermal stability of the traps. If, during TL production, the charge trapped in deeper centers is stable, the deeper traps are said to be "thermally disconnected." The shallow traps (ST) play no role in governing the shape of the TL peak due to AT.

Over the temperature region of interest (the "active" temperature range), electrons from AT are released, and the freed electrons recombine with holes trapped at DHT, with the subsequent emission of thermoluminescence, of intensity $I(T)$. Defining n_c to be the concentration of free electrons, we may write a set of rate equations describing the traffic of charge between the various energy levels, thus:

$$\frac{dn}{dt} = -ns \exp\left\{-\frac{E_t}{kT}\right\} + n_c(N - n)A \qquad (7)$$

and

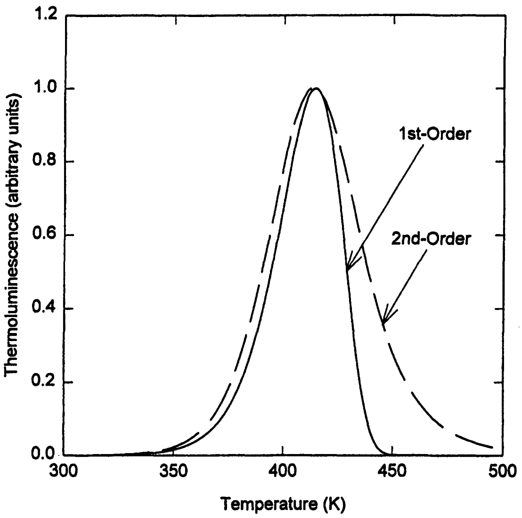

FIG. 3. Normalized first- and second-order TL glow peaks calculated with $E_t = 1.0$ eV, $s = 10^{11}$ s^{-1}, and $\beta = 1.0$ °C s^{-1}. For the second-order peak $n_0/N = 1$.

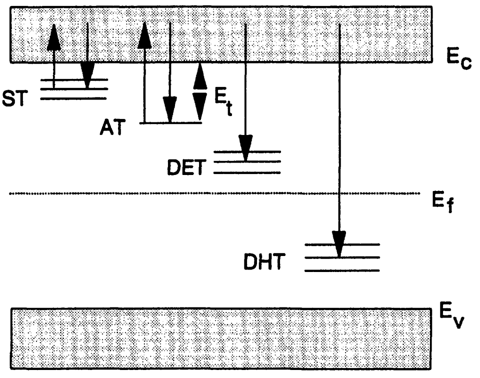

FIG. 4. More advanced model for TL (from Lewandowski *et al.*, 1994). E_c, conduction-band edge; E_F, Fermi level; E_v, valence-band edge.

$$\frac{dn_c}{dt} = -\frac{dn}{dt} - \frac{n_c}{\tau_r}, \tag{8}$$

where N is the total concentration of traps, of which n are occupied; A is the trapping transition constant ($m^3\ s^{-1}$); and τ_r is the recombination lifetime [equal to $(n_h A_r)^{-1}$, where n_h is the concentration of holes trapped at the recombination sites and A_r is the recombination transition constant]. The first term on the right-hand side of Eq. (7) represents the rate of thermal excitation of the trapped electrons from the trap, whereas the second term represents the rate of retrapping. Similarly, the second term in Eq. (8) is the rate of recombination of free electrons with trapped holes. Approximate solutions to these equations normally proceed via the introduction of the "quasiequilibrium" (QE) approximation, which states that $dn_c/dt \ll n_c/\tau_r$, or $dn/dt = -n_c/\tau_r$. Since the intensity of the thermoluminescence emission is given by $I(T) = \phi n_c/\tau_r$, then

$$I(T) = \frac{\phi n s \exp(-E_t/kT)}{\tau_r[1/\tau_r + (N - n)A]}. \tag{9}$$

With the inclusion of the "slow-retrapping" or "first-order" assumption that $\tau_r^{-1} \gg (N - n)A$, we have, after integration, the Randall–Wilkins equation given in Eq. (3). Similarly, with the assumptions $A = A_r$ and $n = n_h$, one gets the Garlick–Gibson expression, given in Eq. (5).

The importance of understanding the shape of a TL glow peak and the parameters that govern it lies in the interpretation of changes to the glow curve that often result from, say, an increase in absorbed dose, or from various thermal treatments (including preirradiation or postirradiation storage at room temperature). One sometimes finds complex alterations in the glow-curve shape that are difficult to understand without an appreciation of the shape of the individual glow peaks that make up the complete glow curve. However, before one can proceed to analyze an experimental TL glow curve, it is necessary to verify whether or not the varied assumptions used in the derivation of the simple equations are in fact justified. The most important of these is the QE approximation ($dn_c/dt \ll n_c/\tau_r$). To examine the validity of this assumption, it is useful to define a function $Q(T)$ thus:

$$Q(T)\frac{n_c}{\tau_r} = -\frac{dn}{dt}, \tag{10}$$

where $Q(T) = 1$ signifies QE. If QE is not sustained during TL emission, then, for first-order kinetics, the actual glow peak shape is the same as that described in Eq. (3), but divided by the function $Q(T)$. Modified equations that exactly describe the TL peak, even when the QE assumption is not valid, have been developed (Lewandowski *et al.*, 1994). In a wide variety of cases, however, $Q(T) \approx 1$ over the active temperature range, and thus the need for this more exact equation is weak in these circumstances. In particular, only (negligibly) small errors in E_t and s result from the use of Eq. (3) in most cases of first-order kinetics. However, similar conclusions *cannot* be reached for non-first-order kinetics, and indeed the dual assumptions of second-order kinetics *and* QE are questionable.

The second assumption of importance is that of kinetic order. A feature of first-order TL peaks is that they are characterized by an invariance of the position of the peak as a function of initial trap population—viz. Eq. (3). Thus, this property can be tested by following the variation in the peak position as a function of irradiation time (i.e., absorbed dose). Any shifts in the peak with absorbed dose should lead one to suspect non-first-order kinetics. An empirical estimate of the kinetic order was devised by Chen (1969) who used a geometrical factor $\mu_g = \delta/\omega$, where ω is the full width of the peak at its half height (in °C) and δ is the half-width on the high-temperature side of the peak (in °C). Theoretical first-order peaks were shown to have $\mu_g = 0.42$; second-order peaks gave $\mu_g = 0.52$. Intermediate values of μ_g correspond to intermediate kinetics for which, unfortunately, physical meaning is lost.

The simple models for charge trapping and detrapping can also be examined experimentally. In the model described in Fig. 4 it was explicitly assumed that only the electrons are thermally unstable over the "active" temperature range; no allowance was made for the thermal release of holes from the recombination centers. If this in fact were not the case, then the TL intensity would exhibit thermal quenching (i.e., the efficiency ϕ would be temperature dependent, decreasing with increasing temperature). One can search for this in a number of ways—for example, by monitoring the luminescence emission during irradiation (known as radioluminescence) as a function of irradiation temperature, or by performing the TL measurement at a wide variety of heating rates, such that the temperature of the TL peak is shifted to higher temperature for higher heating rates, where loss of TL would be observed if thermal quenching was occurring. Although not a unique cause of thermal quenching, one should not rule out simultaneous hole release as a potential difficulty if this phenomenon is observed. In these cases, analysis of the TL peak will reveal a value for E_t that cannot accurately be interpreted as the trap depth depicted in Fig. 4.

Other possibilities for a temperature-dependent luminescence efficiency exist. The model of Fig. 4 allows for the recombination of electrons at only one recombination center. In real materials several such centers may exist, each with a temperature-dependent recombination probability. If all photons were detected with equal efficiency, independent of their wavelength, the existence of multiple recombination sites would not be a problem. However, modern detectors exhibit a varying detection efficiency as a function of wavelength such that changes to the glow-curve shape will occur as the temperature increases, and monochromatic detection at fixed wavelengths will yield TL peaks in different positions, depending upon the wavelength chosen. Such effects are most easily accounted for by measuring simultaneously the TL intensity as a function of temperature and as a function of wavelength. An example of such a glow curve—known as a "3D" plot—is shown in Fig. 5. Such data reveal much information regarding the luminescence sites in the TL material. In this case, emission due to transitions of the 4*f* electrons in Dy^{3+} impurity ions charge compensated by fluorine interstitial ions in C_{4v} symmetry are observed at 480 nm ($^4F_{9/2}$–$^6H_{15/2}$), 575 nm ($^4F_{9/2}$–$^6H_{13/2}$), 660 nm ($^4F_{9/2}$–$^6H_{11/2}$), and 750 nm ($^4F_{9/2}$–$^6H_{9/2}$). The emission near 550 nm is probably due to Er^{3+}. The emission at 375 nm for the TL signal at 300 °C is due to Ce^{3+} charge compensated by O^{2-} ions in C_{3v} symmetry, while the doublet at 324 nm and 340 nm near 100 °C is due to the split ground states of Ce^{3+} ions (i.e., $^2D_{3/2}$–$^2F_{5/2}$ and $^2D_{3/2}$–$^2F_{7/2}$) charge compensated by fluorine interstitial ions in C_{4v} symmetry.

1.4 Analytical Methods

1.4.1 General Before analysis of a TL glow curve can be attempted, one practical difficulty that has to be overcome is that real glow curves rarely consist of isolated glow peaks. In addition there may be many decay routes that are nonradiative, yet influence the overall TL performance. These in turn give rise to problems of two kinds. First, the presence of more than one glow peak and/or more than one recombination pathway points immediately to the possibility that the traps will interact with each other. That is, charge detrapped from one level will either

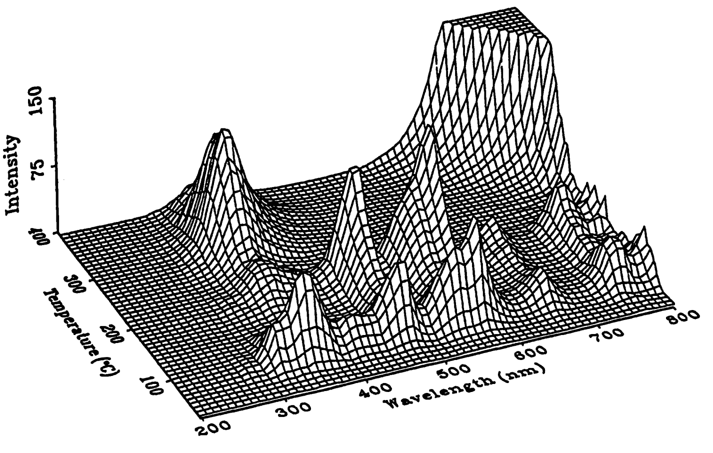

FIG. 5. A "3D" glow curve of TL versus wavelength versus temperature for a sample of Brazilian fluorite, mixed with sodium chloride as a binder. Reproduced from McKeever *et al.* (1995) with kind permission of Nuclear Technology Publishing, Bristol, U.K.

recombine at the radiative recombination site, recombine at the nonradiative recombination site, or be retrapped in deeper traps. The models applied to analyze these cases, however, rarely take into account interactions of this type and treat the glow peaks as isolated entities. However, for first-order kinetics, in which there is little retrapping, problems due to interactive kinetics are minimal, and the glow curve can be considered to be the simple superposition of individual first-order peaks. Peaks that exhibit non-first-order kinetics, however, cannot be treated in isolation.

The second difficulty is a more practical one. The observed glow peaks are often overlapping to the extent that clean peaks, necessary for analysis, are seldom obtained. The usual course is to adopt a "thermal cleaning" program in which the sample is heated to an intermediate temperature that removes the low-temperature, interfering signals. Ideally, subsequent reheating of the sample will then reveal a clean, higher-temperature peak. Several variants of these cleaning processes exist (see McKeever, 1985). Each is reasonably useful in arriving at clean, rising portions of the TL signals, but rarely can a complete, clean peak be isolated, making application of some analytical methods difficult.

There have been many methods of analysis devised in order to extract parameter values (E and s in particular) from real glow curves, and there are certainly too many to review in this article. For more detailed discussions of these methods, we refer the reader to the books by McKeever (1985) and, especially, Chen and Kirsh (1981). Here we mention just three of the most popular methods.

1.4.2 Peak-Shape Methods Chen's analysis of the kinetic order of a TL peak using the geometrical factor $\mu_g = \delta/\omega$ (Chen, 1969) led to several expressions for the trap depth E_t based on the shape of the peak. With the definition of δ and ω as above, and with the additional definition of τ as the half-width on the low-temperature side of the peak, Chen arrived at the following general expression for E_t:

$$E_t = c_\gamma\left(\frac{kT_m^2}{\gamma}\right) - b_\gamma(2kT_m), \qquad (11)$$

where γ is either δ, ω, or τ. The values of the constants c_γ and b_γ depend upon whether the kinetics of the peak are first or second order and are tabulated in Table 1.

Modifications to the above values for c_γ and b_γ are necessary if the kinetics are neither first nor second order, or if the frequency factor (assumed to be constant in the above treatment) is temperature dependent.

1.4.3 Peak-Position Methods A second family of techniques utilizes the change in the peak position as a function of the heating rate β used during glow-curve readout. Differentiation of Eq. (2) and equating the result to zero at $T = T_m$ leads to

$$\frac{\beta E_t}{kT_m^2} = s\exp\left\{-\frac{E_t}{kT_m}\right\}, \qquad (12)$$

from which we see that a plot of $\ln(T_m^2/\beta)$ against $1/T_m$ will yield a straight line of slope E_t/k and intercept $\ln(E_t/sk)$. This method is useful because it relies only upon an accurate assessment of the shift in the peak as a function of heating rate β and does not require clean peaks. Too much overlap with neighboring peaks, however, can give rise to false peak positions.

Although calculated for QE and first-order kinetics, the analysis can be applied to nonequilibrium, non-first-order cases with little additional error. A linear heating function (β = constant) is not necessary; in this case the value of β at $T = T_m$ is all that is required.

1.4.4 Curve-Fitting Methods Perhaps the first of the methods that can be designated as "curve fitting" is that of Garlick and Gibson (1948), who developed the so-called "initial rise" technique. Here one relies on the fact that at low temperature, just as the trap starts to empty (i.e., when n is approximately constant), all TL equations can be described by

Table 1. Coefficients for the calculation of E_t using Chen's method.

	First order			Second order		
	ω	τ	δ	ω	τ	δ
c_γ	2.52	1.51	0.976	3.54	1.81	1.71
b_γ	1.0	1.58	0	1.0	2.0	0

$$I(T) = \text{constant} \times \exp\{-E_t/kT\}. \tag{13}$$

Thus a plot of $\ln(I)$ versus $1/kT$ for this initial-rise part of the curve will reveal a straight line of slope $-E_t/k$, from which E_t can be calculated. The frequency factor s can then be calculated from the position of the peak maximum, T_m, by use of Eq. (12).

Equation (13) applies for *all* kinetic orders and is insensitive to the QE approximation, making it a valuable analytical method. Its accurate use, however, relies on a clean rising part of the TL peak being available—fortunately, something that can be achieved with thermal cleaning techniques.

In the initial-rise analysis one fits the rising portion of the TL curve by Eq. (13). In doing so, however, one "throws away" significant amounts of data from the rest of the glow peak. This is even more true for the peak-shape and peak-position methods in which only one or two datum points are used in the analysis. Better still would be a method that utilized all of the available data—i.e., one in which the whole peak was fitted by a predetermined peak shape. The overlap of peaks is handled in this treatment by making initial guesses at the number of peaks present, and fitting the complete data set by the superposition of several peaks using nonlinear least-squares fitting. The normal procedure is to minimize the error between the experimental glow curve and the sum of the theoretical peaks, using E_t, s, and peak size as fitting parameters. An example of a LiF:Mg,Ti glow curve analyzed in this way is shown in Fig. 6.

1.5 Dose Dependence

A characteristic of thermoluminescence is that it requires the initial absorption of energy from ionizing radiation. One might expect, therefore, that a straightforward relationship between the initial absorbed dose of irradiation and the subsequent TL signal will be observed. This relationship is now examined, for both highly penetrating radiation and weakly penetrating radiation.

1.5.1 Gamma Dose The *dose response* $F(D)$ is defined as the functional dependence of the intensity of the measured TL signal upon the absorbed dose. The ideal material would have a linear dose response over a wide dose range; however, most materials used in practical dosimetry display a variety of nonlinear effects, as shown in Fig. 7. In particular, one often finds that the response of a TL material is linear, then supralinear, then sublinear as the dose is increased. The normalized dose-response function (or supralinearity index) $f(D)$ is defined as follows:

$$f(D) = \frac{F(D)/D}{F(D_1)/D_1}, \tag{14}$$

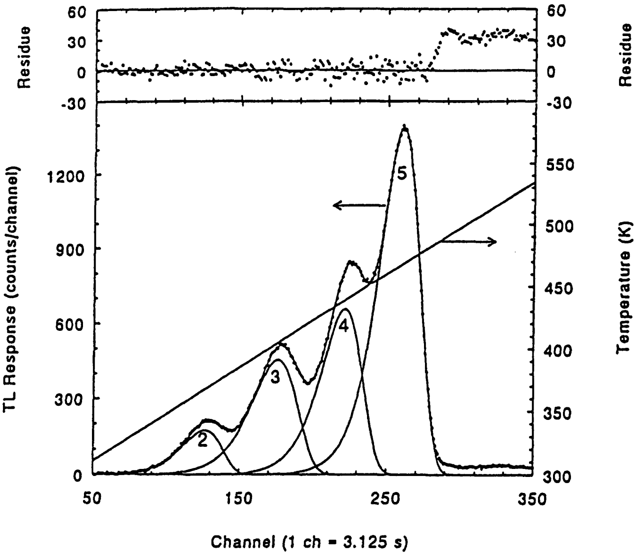

FIG. 6. Example fit of an experimental glow curve for LiF:Mg,Ti. Reproduced from Bos *et al.* (1992) with kind permission of the authors and the Institute of Physics Publishing Ltd., Bristol, U.K.

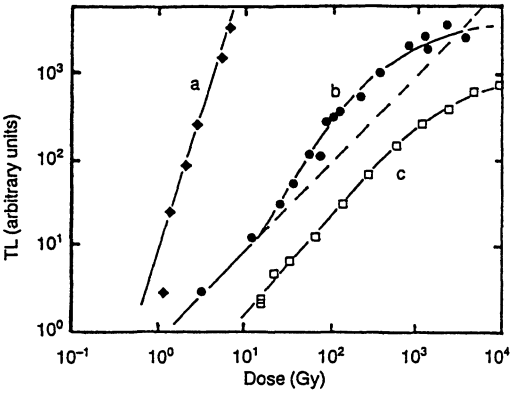

FIG. 7. The dose response of three TLD materials: (a) SiO_2, (b) LiF:Mg,Ti, and (c) CaF_2:Mn. Reproduced from McKeever *et al.* (1995) with kind permission from Nuclear Technology Publishing, Ashford, U.K.

where $F(D)$ is the dose response at a dose D and D_1 is a low dose at which the dose response is linear. Thus, our ideal material would satisfy $f(D) = 1$ over a wide dose range. In many thermoluminescence dosimeter (TLD) materials, however, $f(D) = 1$ is found only over a narrow dose range, up to a few grays. Supralinearity, defined as $f(D) > 1$, is commonly observed, while sublinearity $[f(D) < 1]$ is most often observed during the approach to saturation. These features are illustrated in Fig. 7.

The actual value of $f(D)$ at any given dose is governed by a wide range of material and external factors, the latter including the type and energy of the radiation used and the detailed procedure used to heat the sample during glow-curve measurement. Of particular importance is the observation that $f(D)$ depends upon the LET [linear energy transfer, dE/dx (eV/m)] or ionization density of the radiation field. The LET dictates the rate at which the energy E of the incident particle is lost as a function of distance x into the material. High-LET radiation loses its energy quickly, leaving regions of high ionization density within the material. Heavy charged particles (e.g., alpha particles) deposit their energy in densely ionized particle tracks. Thus, $f(D)$ values, obtained at about 200 Gy, for LiF:Mg, Ti have been observed as high as ~3.5 for ^{60}Co irradiation, but only ~1.5 for 20-kV$_p$ x-ray irradiation, and ~1.0 for alpha-particle irradiation (McKeever *et al.*, 1995). Not only is the extent of the supralinearity dependent upon LET, but the dose at which the onset of supralinearity becomes evident is also LET dependent.

Important material factors include the nature of the host material itself. For example, in Fig. 7 we see that the growth of TL with dose in quartz is highly supralinear $[f(D) > 2]$ while for CaF_2:Mn it is almost linear $[f(D) = 1]$. LiF:Mg,Ti, however, displays a linear-supralinear-sublinear growth. In LiF:Mg,Ti, decreasing the Mg content enhances supralinearity, while increasing the OH impurity content decreases supralinearity. All these factors indicate a dependence of $f(D)$ on the nature of the host material and its defect structure.

Many theories have been forwarded to explain the cause of supralinearity in TL materials—particularly LiF:Mg-type materials. Conveniently, they can be classified as models in which the critical processes occur during the absorption of radiation and models in which the critical processes occur during heating (i.e., during TL readout). However, most evidence clearly indicates that the critical mechanism is that of competition during the heating stage of TL readout. During heating, electrons released from traps may either recombine with trapped holes to produce TL or be retrapped in deeper traps, which act as competing centers. At low doses, where the distance between traps and recombination sites is large, the probability that a freed charge can find a recombination site without falling into a competing trap is low. Thus the response of the dosimeter is reduced in this low-dose region. At higher doses, however, not only is the mean distance between traps and recombination sites decreased, but the number of competing centers is also reduced. (Note that a competing trap is an *empty* trap; once filled, it no longer acts as a competitor.) Thus, at higher doses the response of the material is enhanced and more TL/unit dose is the result. Eventually, at very high doses, the material saturates. Such a material has $f(D) > 1$ over the entire dose range, up to saturation; an example is SiO_2, shown in Fig. 7. [Note that the data are plotted on a log–log plot, such that $f(D) = 1$ produces a slope = 1. Supralinearity shows as a slope > 1.]

If the material did not have any competing traps (no competition), the sensitivity (i.e., TL/unit dose) would be higher at low doses and linearity would be observed up to saturation (an example is CaF_2:Mn, shown in Fig. 7). Thus we see that supralinearity should correctly be considered to be an under-response at low doses, rather than an over-response at high doses.

With some materials one often finds a linear region *before* the supralinear region (see LiF:Mg,Ti in Fig. 7). To explain this it is necessary to invoke spatial localization between the traps and the recombination centers. Spatial association of this type produces a linear term at low doses, before one observes the nonlinear effect at higher doses.

1.5.2 LET Dependence With high-energy gamma irradiation (low LET) one may safely view the distribution of the filled traps and recombination sites as an "isotropic sea." However, for heavy–charged-particle (HCP) irradiation (high LET), we have a nonisotropic distribution of densely ionized regions along linear tracks. Calculations indicate that the dose is deposited within a few tens of nanometers of the track center for high-LET particles. Thus, there are regions *within* the tracks of high concentrations of trapped charges and very few competitors, and regions *between* the tracks of very few trapped charges and high numbers of competitors. For high enough ionization densities the mean free path of a freed electron inside the track is less than the track radius, and recombination within the track, leading to TL, is highly probable. Thus, the dose-response curve is linear, although it saturates early since all the available sites within the track volume quickly become saturated. For lower-LET particles, there is a probability that some electrons will escape from the track core without recombining and thus enter the intertrack region. Here the probability of finding a competitor is high, and the electron is likely to be lost from the TL process. However, as the dose is increased the probability of reaching an adjacent track also increases since the intertrack distance decreases. The escaped electron may now recombine with a hole in an adjacent track and so produce a TL photon. Under these circumstances, the TL output (per unit dose) will also increase, and thus supralinearity will occur. Thus, the lower the LET, the greater the degree of supralinearity. It is clear that as the LET of the HCP increases, the tracks become more localized, and consequently the dose levels at which charge exchange between tracks can take place also increase (track interaction). In this way the observed LET dependence of the value of $f(D)$, and the dose at which the onset of supralinearity occurs, are explained.

2. INSTRUMENTATION

2.1 Basic Principles

Although the instrumentation required to monitor TL has come a long way since Sir Robert Boyle's day, the simplicity of the necessary equipment is such that an accurate and reliable system can be set up for little expenditure. The basic requirements are an oven, a reliable temperature controller, a photodetector, and a data-storage medium. Additional design criteria are required if TL below room temperature is monitored, or if the spectrum of the TL emission is measured.

2.2 Heating System

The heart of any TL instrument is the heating system. Three different types of heating method can be found in widespread use. The objectives are reproducible and controllable heating profiles. Ovens and sample chambers are most often filled with inert gas during heating to enhance thermal contact between the heater and sample, and to reduce spurious emissions of light from chemical effects.

2.2.1 Resistance Heating Here one passes high current through a thin, low-impedance load, such as a tantalum, nickel-chrome, or platinum alloy strip (the planchet). The sample (powder or solid chip) is placed in direct contact with the planchet, the temperature of which is monitored via thermocouples. Alternative designs involve the use of wire coils in contact with more massive metal blocks, or in direct contact with the sample itself. (An example of the latter is the U.S. Navy's "bulb dosimeter" in which the sample is directly deposited onto the coil using adhesive and the whole encased in a glass bulb. Electrical leads protruding through the glass envelope enable electrical contact to be made.) The low thermal inertia of thin planchets or coils enables fine temperature control and rapid heating and cooling. The range of heating rates achievable with resistance-heating techniques is from fractions of a degree per minute to several tens of degrees per second.

2.2.2 Hot-Gas Heating Rapid heating of solid samples, with precision temperature control, can be achieved via the use of hot gas (usually nitrogen) as a heat-exchange medium. A jet of the hot gas is directed via nozzles, at a typical flow rate of a few liters per minute, onto the sample and extracted from the sample chamber at the same rate, thus preventing heating of the sample surroundings. Uniform heating of the sample can be achieved.

2.2.3 Optical Heating Some early, commercial TL systems utilized the absorption of infrared radiation from a tungsten lamp, filtered to remove unwanted visible and ultraviolet wavelengths. The absorption of the infrared energy by the sample resulted in a controllable rise in temperature. Only small, thin samples of low thermal mass can be used effectively with such systems. A modern development of this concept is the use of infrared (CO_2) cw lasers to heat either the sample or a substrate to which the sample has been intimately bonded. The active samples are thin (<100 μm; 10–20 μg), and extremely high heating rates ($\beta \geq 10^4$ C°/s) can be achieved with short (10–1000 ms) laser pulses (at powers of a few watts). Such high heating rates result in a correspondingly high signal-to-noise ratio because of the combined effect of an enhancement of the TL output, according to Eq. (3), (5), or (6), and the discrimination against the noise counts from the detector. Potential limitations against the use of such high rates of heating stem from "thermal quenching" of the luminescence efficiency. As the heating rate increases, the temperature at which the TL is emitted also increases. Some phosphors lose luminescence efficiency with temperature increase, and potential gains in output intensity are offset by the quenching phenomenon. Furthermore, for all materials the incandescence background also increases with temperature, sometimes to the point of intolerance.

2.3 Light-Detection System

The low-intensity light emitted during a TL experiment is normally detected with photomultiplier tubes (PMTs). Either dc current or photon-counting modes may be used, the former at high signal levels, and the latter at low signal levels. The key to high detectability is to match the energy response of the PMT photocathode to the wavelength of the emitted light. Most wide–band-gap materials emit in the visible, particularly blue, part of the spectrum, and thus bialkali photocathodes are well matched to such signals. Longer-wavelength emitters, however, require the use of extended bialkali or GaAs photocathodes. High-gain (10^6–10^7), low–dark-current (nanoamperes) PMTs are essential. Dark currents may be reduced by the use of Peltier-cooled PMT housings to limit thermionic emission from the photocathode.

2.4 Emission Spectra

An examination of the schematic energy-band diagram of Fig. 2 suggests that only one emission wavelength will be observed during TL readout since only one type of radiative recombination center is present. However, real materials often contain several types of recombination site, each of which may be represented by its own characteristic emission wavelength. Conventional measurements of TL glow curves use detectors that are sensitive over a broad range of wavelengths and make no effort to discriminate between the possible different emission colors. Detection through broadband filters, centered in the visible, is the norm. Unfortunately, in doing this, much potential information is lost regarding the emission processes. In addition, one can easily arrive at false conclusions regarding the kinetics of the TL process, and, furthermore, one may misinterpret observed changes in, for example, glow-curve shape and intrinsic sample sensitivity following thermal annealing.

Nevertheless, TL recorded through broadband filters is still the most popular recording method, and an additional dimension of information regarding the TL process is often lost. Some early attempts at measurement of spectral data were made using narrow-band interference filters, but more recently greater detail has been obtained by measuring the TL intensity as a function of temperature and wavelength simultaneously. Such isometric measurements lead to plots of intensity versus temperature versus wavelength ("3D" plots). Various spectrometers have been described in the literature to achieve this, including simple rotating filter packs and rapid-scanning monochromators. However, most information is obtained by multiplexing the data and dispersing the signal over a defined wavelength range, and measuring the intensity over each wavelength interval separately but simultaneously. Modern techniques include Fourier-transform spectroscopy or, more popularly, use of position-sensitive photodetectors. In the latter, the light is dispersed over the wavelength range of interest (using a grating or prism spectrograph) and the dispersed light is detected over the active area of a device such as a CCD camera, diode array, or position-sensitive PMT. Such measurements are now quite common. The utility of this detection mode has been reviewed by Townsend and Kirsh (1989). An example of a "3D" glow curve is shown in Fig. 5.

3. APPLICATIONS

3.1 Dosimetry

One of the earliest suggested applications of TL was in the detection and measurement of absorbed radiation—*radiation dosimetry.* Dosimetry applications fall into several general categories, including the detection of the absorbed dose to people and the environment.

3.1.1 General Principles The basic premise in the use of TL in dosimetry is that the intensity of the TL can be related, in a straightforward way, to the absorbed radiation dose. In an ideal system, the TL signal would be directly proportional to the absorbed dose over a wide dose range. The dose response could be calibrated and unknown doses determined by simply measuring the TL intensity resulting from the exposure; thereby, a useful dosimetric method is presented. In fact, although complications are abundant, this simple concept can be considered a reality. The sensitivity and wide dynamic range of TL in this application are unrivaled. The method is routinely used to measure doses as small as those delivered by the natural environment over a period of days, or doses as high as those delivered inside nuclear reactors—a dose difference of a factor of approximately 10^{11}. In what follows we describe briefly the range of uses of TL in radiation dosimetry, and in doing so we introduce the term thermoluminescence dosimeter, or TLD.

3.1.2 Personnel Dosimetry The primary objective of personnel dosimetry is the monitoring of the radiation dose delivered to personnel during routine occupational exposure. Examples include reactor workers, hospital radiotherapy technicians, or naval personnel on nuclear-powered vessels. In addition to routine monitoring, the field of personnel dosimetry also includes the determination of absorbed doses caused by accidental exposure to radiation. The overall desired aim is to limit an individual's total exposure to the maximum permissible dose values recommended by the regulatory agencies.

Broadly, personnel dosimetry covers the following:

1. Extremity dosimetry—determination of the maximum dose equivalent to any part of the hands, arms or feet.
2. Whole-body dosimetry—determination of the dose equivalent absorbed at a depth of 400–1000 mg cm^{-2} in human tissue below the surface of the body and/or the dose equivalent in critical organs. Primary interest is in penetrating radiation [gamma rays, x rays (>15 keV), and neutrons].
3. Tissue dosimetry (i.e., skin dose)—determination of the dose equivalent absorbed at a depth of 5–10 mg cm^{-2}. Here one is interested in nonpenetrating radiation (beta particles, and <15-keV x rays).

In all such applications the primary requirement of a TLD material is that of tissue equivalency. Energy independence and high sensitivity are also desirable.

3.1.3 Environmental Dosimetry The continuous monitoring of radiation released to the environment has become a major concern for industrialized nations, and TLD usage is an important factor in this type of activity. Since exposure levels are low (with equivalent doses of, typically, 10^{-2} mGy), long exposure times are required, and, thus, long-term stability of the TLD becomes vitally important, along with extreme sensitivity. Gamma and neutron emitters are the main radiation sources of interest from such potential sources as escape of gaseous radionuclides from nuclear power stations during day-to-day operations, low-level waste disposal, nuclear fuels reprocessing, nuclear power-station accidents, and others. Throughout the United States and Europe, TLD systems are in place near nuclear installations for the purpose of monitoring radiation levels, above the natural background, that can be linked with the operation of these facilities. In addition, since the advent of manned space flight, there has been a growing interest in space dosimetry. One obvious cause for this interest is the increased exposure to harmful radiations that people (astronauts) can expect in this environment. Additional concern lies in the prolonged exposure of electronic components, where the decreasing scale of the active regions in these devices (a few square microns in cross section) and the shift from analog to digital circuitry means that device failure due to discrete radiation events (interactions with single particles, known as single-event upsets) is becoming a serious concern. The radiation sources are galactic cosmic rays, of which the main component is protons (1–1000 MeV), and HCPs from the solar wind. TLDs have been used on several recent manned space flights for the purpose of determining the dose from such penetrating radiation.

3.1.4 Medical Dosimetry The small size and high sensitivity of TLD materials has long been exploited in clinical studies since small TLD samples can be inserted into appropriate openings on the human body before exposing the patient to ionizing radiations during diagnosis and/or therapy. The exposed TLDs are then retrieved and analyzed. In this way physicians are able to determine actual doses delivered to critical internal organs during these procedures and from such information are able to prescribe necessary additional treatments. Such utility is hardly possible with any other form of radiation dosimeter.

The two areas of use for clinical radiation exposure of humans are diagnostic radiology (e.g., x-ray exposure in mammography, dentistry, and general health screening) and radiotherapy (primarily cancer therapy of various types). Radiation types include x rays (as low as 10 keV), gamma rays (from ^{137}Cs or ^{60}Co), beta particles (up to 40 MeV), heavy charged particles, and neutrons. Doses range from 10^{-5} to 1 Gy in radiology and up to 10 Gy in radiotherapy. Dose estimation accuracy of better than ±3% is aimed for since errors greater than this can adversely affect the outcome of the treatment.

Clearly, the foremost requirement of a TLD material to be used in this fashion is tissue equivalency. High sensitivity is desirable so that TLD sizes can be kept as small as possible for *in vivo* measurements. Nontoxicity is also a required property. Furthermore, since the doses used can be quite high, a linear dose response over a wide dose range is an advantageous property.

3.1.5 Retrospective Dosimetry Worldwide, interest is growing in the development of new and improved methods for retrospectively assessing the radiation dose in accidentally contaminated areas. For a number of years TL techniques have been used with some success in this application. Examples include Chernobyl (Byelorussia and Ukraine) and the Techa River (Russia), along with similar efforts at Hiroshima and Nagasaki (Japan) and the Nevada bomb test site (United States). The thrust has been to use commonly available materials, located at the actual sites, that may be used as local dosimeters. Example TL materials that are proving to be useful in this context are pottery, tile, porcelain, and other ceramic objects. From these materials quartz and feldspar can be extracted, and the absorbed dose to these components is determined by TL dosimetry techniques.

3.1.6 Materials Obvious desirable properties of TLD materials include a linear response to absorbed dose and an adequate sensitivity. As discussed in Sec. 1.5, the dose response of most TL materials is far from linear, displaying a variety of nonlinear effects depending upon the dose range and the irradiation type. However, at sufficiently low doses most popular TLD materials display an approximately linear response, along with a sufficient sensitivity, to enable their use in several of the fields discussed above.

Tissue equivalency is an important consideration for those materials to be used in personnel or medical dosimetry. For photon radiation the important material factor is the so-called effective atomic number, Z_{eff}, which dictates the amount of energy absorbed by the material in a given radiation field. For human tissue $Z_{\mathrm{eff}} = 7.4$, and thus any material with an effective atomic number around this value will mimic human tissue and is known as "tissue equivalent." The higher the value of Z_{eff} and the lower the energy of incident radiation photons, the larger the TL response to a given dose. Thus, non-tissue-equivalent materials tend to exhibit an "over response" at lower photon energies. Normally, one defines the energy response of a TLD material with reference to the response at a gamma photon energy of 1.25 MeV. Thus, CaF_2 ($Z_{\mathrm{eff}} = 16.3$) has an over response of 3 at an energy of 10^{-1} MeV, while LiF ($Z_{\mathrm{eff}} = 8.14$) has almost no over response at the same energy and is approximately tissue equivalent.

TLD materials should exhibit high stability of the signal over exposure and analysis time scales, and preferably should be insensitive to light exposure, chemical reaction, and humidity.

The most popular material for dosimetry applications is LiF doped with Mg and Ti. This tissue-equivalent material has found application in all personnel and medical applications. CaF_2 (doped with Mn, Dy, or Tm impurities) is a popular environmental dosimeter, and some dosimetry services still use natural fluorite, even for personnel dosimetry. Other popular materials include $CaSO_4$ (Mn, Dy, or Tm doped) and $Li_2B_4O_7$ doped with Mn or Cu. Recent developments include new, ultrasensitive forms of LiF (LiF:Mg,Cu,P) and sapphire (Al_2O_3:C).

3.2 Dating

3.2.1 General Principles The accumulated dose absorbed by ceramic artifacts over their archaeological or geological lifetime can be appreciable, and this dose lends itself to determination using TL. The materials of interest are ceramics containing luminescent minerals—particularly quartz and feldspar—that, when heated after irradiation exposure, emit TL proportional to the time of their exposure. The radiation originates from cosmic rays and from gamma, beta, and alpha irradiation from the local surroundings (due to traces of uranium, thorium, and potassium). The "natural" TL signal is thus related to the age of the specimen by

$$\text{Age} = \text{Natural TL}/[(\text{TL per unit dose}) \times (\text{natural dose rate})]. \qquad (15)$$

Thus, age assessment consists of measurement of the natural TL, calibrating the TL signal from the material to determine the TL/unit dose, and measurement of the natural dose rate in the location of the find. Strictly, the "age" being determined is the time since the TL signal was last reset to zero. Thus a "zeroing" event—such as high-temperature heating (e.g., in the manufacture of pottery) or optical bleaching (e.g., during the deposition of sediments)—must have occurred in order for the method to be applicable. Otherwise, a TL signal related to the geological age of the component mineral will be determined instead.

In principle, a typical experiment would proceed by determining the natural dose (or "equivalent dose") by either

1. removing the natural TL signal (i.e., by the act of TL measurement itself) and subsequently calibrating the sample by exposing it to known doses of radiation in the laboratory from which the natural dose can be estimated (the "regeneration method"), or
2. adding a laboratory dose on top of the natural dose and using an addition method, analogous to many chemical analysis techniques; here, by using several equivalent samples, a plot of TL versus added dose can be constructed from which the natural dose may be estimated by extrapolation to zero TL (the "additive dose method").

Figure 8 illustrates both procedures. Since the act of reading the TL signal often alters the sensitivity of the material to subsequent radiation doses, the additive dose method is often preferred. Note that the calibration doses administered in the laboratory are usually from gamma or beta sources. Thus, since natural irradiation consists of gamma,

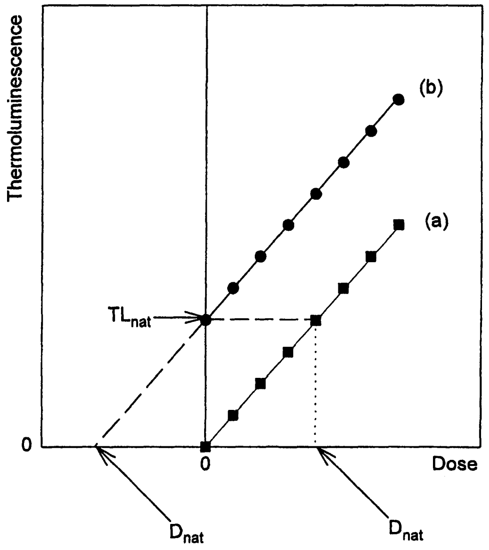

FIG. 8. Schematic illustration of the (a) "regeneration" and (b) "additive dose" methods of TL dating. T_{nat}, natural TL intensity; D_{nat}, estimated natural dose.

beta, and alpha irradiation, one has to account for the different TL production efficiencies of gamma and beta radiation, compared with alpha radiation, and determine the gamma, beta, and alpha equivalent doses separately. Alternatively, one can select large grains for which the alpha TL component is only found in the surface regions. Removal of these regions by acid etching leaves a sample from which the TL signal is due to cosmic, gamma, and beta doses exclusively.

Once the equivalent dose has been determined, one has to estimate the rate at which the sample has been irradiated in antiquity. Perhaps the most straightforward way to do this is to emplace conventional synthetic TL dosimeters in the location of the find. By leaving the dosimeter *in situ* for a number of weeks or months, one can then determine the natural absorbed dose integrated over this period, and from this, establish the dose rate.

3.2.2 Pottery Dating Pottery consists of a baked clay matrix containing small (up to a millimeter diameter) inclusions of quartz, feldspar, and minor amounts of other minerals. The discovery of TL from ancient pottery (Grögler *et al.*, 1960) led the way to the dating of pottery using the relationship in Eq. (15). Since these early observations, several methodologies have been suggested to arrive at a date for the pottery manufacture, and these can be found described in detail in several texts (e.g., Aitken, 1974, 1985).

One such method is the "inclusion method," wherein large quartz grains (~100 μm) are selected and, by etching away the alpha-irradiated surface, the age of the grains since the firing of the pottery (the "zeroing" event) can be determined from an assessment of the absorbed dose due to beta, gamma, and cosmic ray irradiation. Alternatively, in the "fine-grain method" examination of the fine grains (<10 μm) leads to an age estimation by accounting for the accumulated alpha dose, and the sensitivity of TL production of alphas compared to the other radiation types.

Each of the above methods relies on the accumulation of trapped charge as a function of irradiation time leading to the growth of the TL signal with age. A procedure that utilizes an entirely different principle is the so-called "predose method" in which the sensitivity of the sample (i.e., the propensity of the material to yield a TL signal for a fixed absorbed dose) is related to the irradiation age of the specimen. Here one monitors the TL for a small "test" dose, before subjecting the material to elevated temperatures, whereupon administration of a second test dose is found to yield a larger TL signal. The increase in the TL signal for the same test dose (i.e., the increase in the sensitivity) is related to the prior dose absorbed in nature and is activated by the heating of the sample between test doses. Calibration of the sensitivity increase provides a method for age determination.

Although many procedural difficulties are encountered, TL dating has proven to be a useful and versatile dating procedure for non-carbon-bearing artifacts and provides age estimates that overlap the more well-known ^{14}C-dating method.

3.2.3 Sediment Dating The principle of sediment dating—*vis-à-vis* determination of the dose absorbed by grains of quartz or feldspar—is the same as that described above for pottery dating. The difference lies in the mechanism presumed to be responsible for the initial zeroing of the TL signal. Whereas with pottery dating this event is the heating of the specimen during firing of the pot, with sediment dating the event is presumed to be the optical emptying of the traps by exposure to sunlight during deposition of the sediment. During deposition, be it in air or under water, the sediments are exposed to varying intensities of sunlight. Experimental tests have verified that exposure to light in this fashion empties a subset of the charge traps responsible for part of the TL signal and therefore resets these TL levels to zero. Subsequent burial of the sediment by additional layers shields the material from further light exposure and allows the buildup of the TL signal to occur as a result of the absorption of radiation from natural sources. Thus, when the material is excavated some time later, the TL signal is proportional to the burial time—i.e., the age of the sediment.

The technique was first demonstrated for deep-sea sedimentary cores wherein the TL level was found to increase with depth, corresponding to older deposits (Wintle and Huntley, 1979). More recent developments of sedimentary dating include the use of light to stimulate the luminescence signal, rather than heat. Thus, instead of TL, one monitors optically stimulated luminescence (OSL). This development has come to be called "optical dating" (Huntley *et al.*, 1985).

3.3 Other Applications

Age determination and radiation dosimetry are the two most extensive practical applications of TL. However, one must not overlook the use of TL in solid-state physics, where it is used as a tool for detecting the presence of defects and for establishing such parameters as the trap depths and capture cross sections, along with information regarding the dynamics of the various charge recombination kinetics.

Outside of these applications TL has found use in both terrestrial and extraterrestrial geology for mineral identification and for determining the classification and the irradiation and thermal histories of meteorites (Sears, 1993), source identification for various minerals, radioactive ore, and oil and gas well prospecting, and other, more esoteric uses. Descriptions of these and other applications can be found in several texts (e.g., McDougall, 1968; McKeever, 1985).

ACRONYMS

CCD: Charge-coupled device.

cw: Continuous wave (for lasers).

dc: Direct current.

DLTS: Deep-level transient spectroscopy.

DSC: Differential scanning calorimetry.

HCP: Heavy charged particle.

ITC: Ionic thermocurrents.

LET: Linear energy transfer.

OSL: Optically stimulated luminescence.

PMT: Photomultiplier tube.

QE: Quasiequilibrium.

TG: Thermogravimetry.

TL: Thermoluminescence.

TLD: Thermoluminescence dosimeter.

TSC: Thermally stimulated conductivity.

TSCap: Thermally stimulated capacitance.

TSDC: Thermally stimulated depolarization currents.

TSPC: Thermally stimulated polarization currents.

GLOSSARY

Dose (unit – Gray, Gy): The amount of energy absorbed by the target per unit mass of target. 1 Gy = 1 J/kg.

Effective Atomic Number, Z_{eff}: The effective atomic number of a compound is calculated from the atomic number of the constituent elements and the law of mixtures for the compound.

Fluorescence: *Luminescence* characterized by a decay over short-time intervals after removal of the excitation. Prompt luminescence due to electron de-excitation from an excited state to a ground state.

Luminescence: A light emission process that involves transitions between electronic energy states.

Optically Stimulated Luminescence: *Luminescence* emission stimulated by illuminating a previously irradiated sample. Optical energy excites charge from traps, initiates recombination, and causes *luminescence.* Unlike *photoluminescence,* the light only stimulates the recombination processes. The initial energy source is the radiation.

Phosphorescence: *Luminescence* characterized by a decay over long times after removal of the excitation. The distinction between *fluorescence* and *phosphorescence* based only on the characteristic time response is ill-defined, however, and somewhat arbitrary. If the process involves the trapping of charge in metastable states before thermal stimulation to the ground state, the process is clearly phosphorescence.

Photoluminescence: *Luminescence* excited by the absorption of energy from light.

Radiation Dosimetry: The measurement of absorbed radiation *dose.*

Thermoluminescence: *Luminescence* emission stimulated by heating a previously irradiated sample. Thermal energy excites charge from traps, initiates recombination, and causes luminescence. The heat only stimulates the recombination processes. The initial energy source is the radiation.

INTRODUCTION

A thin film is defined as a solid-state material, deposited on a substrate by a controllable method with uniform thickness of less than 10 μm or so. Numerous materials including almost all the elements can be prepared in the form of a thin film. The crystallographic status of the thin films ranges from amorphous through polycrystalline to crystalline depending on the thin-film materials, substrates, and deposition conditions. The electrical conductivity of thin films ranges from insulating through semiconducting to conducting and superconducting depending on the materials as well as the structure of the thin film.

This article reviews the electrical properties of thin films, focusing on the basic principles of conductor, semiconductor, and insulator thin films. Superconductors are discussed in SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY, HIGH-TEMPERATURE; and SUPERCONDUCTIVITY, LOW-TEMPERATURE. We discuss amorphous and polycrystalline thin films in the article. Crystalline thin films are reviewed in CRYSTAL GROWTH.

Thin films are modeled as a medium confined between a pair of parallel surfaces. The electrical properties of conductor and semiconductor thin films are greatly affected by the existence of the surfaces and the defects. We discuss the effects of surfaces and defects in conductor thin films, amorphous semiconductor thin films, and polycrystalline semiconductor thin films. In insulator thin films, carrier transport in the direction perpendicular to the surface occurs under sufficiently high electric field. Current mechanisms in insulator thin films are also discussed.

Thin films are the essential components in many industrial applications. Typical examples are microdevices including very large-scale integration (VLSI). Driven by the strong demands, research and development have been conducted actively in industry and academia. In this article, we discuss the applications of thin films taking VLSI and thin-film transistors (TFT) as examples.

1. PREPARATION OF THIN FILMS

Various technologies have been developed to deposit high-quality thin films. There are three basic types of deposition methods: evaporation, sputtering, and chemical vapor

deposition (CVD). Each method is reviewed in detail in the articles CVD (CHEMICAL VAPOR DEPOSITION); SPUTTERING; and THIN-FILM DEPOSITION. There are two kinds of CVD methods; one is thermal CVD, which uses thermal decomposition of material gases, and the other is plasma CVD, which uses plasma to enhance the deposition rate. Plasma CVD allows thin-film deposition at lower temperatures than thermal CVD. This category includes the glow discharge method in which material gas is decomposed by discharging.

Another way to form thin films is thermal oxidation or nitridation of silicon. Silicon substrate can be oxidized or nitrided at high temperatures, typically 900 °C or higher. Chemical reactions of silicon with the ambient gases O_2 or N_2 occur at the surface to form thin films of SiO_2 or Si_3N_4. Thermally grown SiO_2 thin films are used as gate oxides of metal-oxide-semiconductor (MOS) transistors. They are also used as local-oxidation-of-silicon (LOCOS) thin films to isolate transistors in MOS devices. Thermally grown Si_3N_4 thin films are used in nonvolatile memory devices. In general, thermal oxidation and nitridation provide not only low-resistivity insulator thin films but also much lower trap-state density at the interface with the underlying silicon. This is the reason that this method is used for gate-insulator formation in MOS devices, in which insulator quality is crucial to achieve high device performance.

The sputtering method covers the widest range of thin-film materials among the three deposition methods mentioned above, from metals through semiconductors to insulators. Use of the evaporation method is mostly limited to metals with relatively low melting points. The CVD method requires appropriate material gases, and this limits the thin-film materials that can be deposited by this method. The electrical properties of thin films depend on deposition methods as well as the materials and deposition conditions. Thus it is not easy to generalize the relations between electronic properties and deposition methods. The most appropriate deposition method is chosen after examining experimental results in many cases. Throughput in the deposition method is also a factor to be considered in manufacturing.

Thin films are often processed after the deposition to improve or change their properties. A typical process is annealing, including furnace annealing and laser annealing. Defects in thin films can be reduced by an annealing process. By an annealing process with proper conditions, amorphous thin films can be transformed to polycrystalline thin films. In polycrystalline thin films, defects can be drastically reduced by an annealing process, which results in a lower resistivity in conductor and semiconductor thin films.

2. MEASUREMENT TECHNIQUES OF THIN-FILM ELECTRICAL PROPERTIES

Carrier concentration and carrier mobility are two basic properties of conductor and semiconductor thin films. In this section we discuss the measurement methods for resistivity and carrier mobility. Carrier concentration is derived from mobility and resistivity.

2.1 Resistivity Measurement

Here we define a thin-film pattern delineated on an insulating substrate with a length L, a width W, and a thickness d as shown in Fig. 1. When a voltage V is applied between a and b in Fig. 1, the current I that flows along the direction of L is

$$I = V/R \tag{1}$$

according to Ohm's law. R in Eq. (1) is the resistance we define.

The resistance R of the pattern in Fig. 1 along L is proportional to L and inversely proportional to the cross section of the pat-

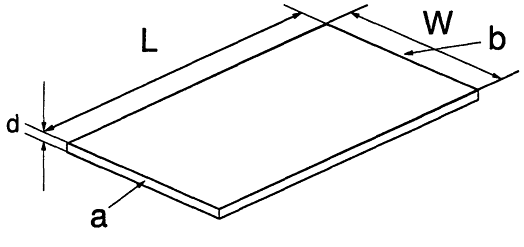

FIG. 1. Schematic view of a thin-film pattern with length *L*, width *W*, and thickness *d*.

tern, i.e., Wd. Therefore, R is expressed using the formula.

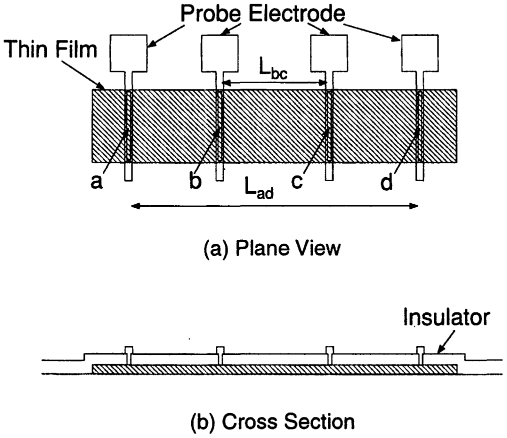
$$R = \rho L/Wd. \tag{2}$$

The proportionality constant ρ is defined as the resistivity. As we discuss later, ρ is dependent on d when the thickness is relatively thin, typically thinner than 200 nm. We also define the conductivity σ as

$$\sigma = 1/\rho. \tag{3}$$

The four-probe method is effective in order to measure the resistance accurately. A measurement structure for this method is schematically shown in Fig. 2. When a voltage V_{ad} is applied between point a and point d through the probe electrodes, the current I between point a and point d can be measured by using an ampere meter. The voltage difference between point b and point c, V_{bc}, on the other hand, is measured using a voltmeter. In the structure shown in Fig. 2, there exists resistance called contact resistance at the interface between the thin-film material and the electrode material due to the work-function difference and impurities. Here we denote such a resistance as $R_{contact}$.

The relations between R_{ad}, R_{bc}, $R_{contact}$, V_{ad}, V_{bc}, and I are expressed by $V_{ad} = (R_{ad} + 2R_{contact})I$, $V_{bc} = (R_{bc} + 2R_{contact})I$, and $R_{ad}/R_{bc} = L_{ad}/L_{bc}$. From these relations, R_{ad} and $R_{contact}$ are obtained independently as follows:



(a) Plane View

(b) Cross Section

FIG. 2. A structure for four-probe resistance measurement.

$$R_{ad} = (V_{ad} - V_{bc})L_{ad}/(L_{ad} - L_{bc})I, \tag{4}$$

$$R_{contact} = (V_{bc}L_{ad} - V_{ad}L_{bc})/2(L_{ad} - L_{bc})I. \tag{5}$$

The resistivity of the thin film is obtained by normalizing R_{ad} with the length, the width, and the thickness using Eq. (2).

Another convenient method to measure the resistance of thin films is to form a Wheatstone bridge circuit as shown in Fig. 3 (see ELECTRICAL INSTRUMENTATION). The bridge circuit has four resistors. Two of them are fixed resistors with known resistance (R_1 and R_2 in Fig. 3). The other two resistors are a variable resistor R_3 and the thin-film specimen (R_x) of which the length, the width, and the thickness are known. A voltage is applied between a and b in Fig. 3 and the current between c and d is measured. In the measurement, R_3 is varied to make the current between c and d zero. When the current is zero, the resistance of the thin-film specimen is determined as

$$R_x = R_3(R_2/R_1). \tag{6}$$

The resistivity of the thin film is derived from R_x, the length, the width, and the thickness using Eq. (2).

2.2 Hall-Mobility Measurement

By making use of the Hall effect, carrier concentrations of the conductor and semiconductor thin films can be measured (see MICROSENSORS). Figure 4 shows a schematic configuration of the Hall effect. When a

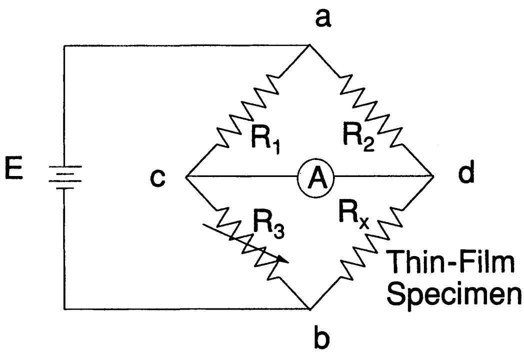


FIG. 3. Wheatstone bridge circuit for resistance measurement.

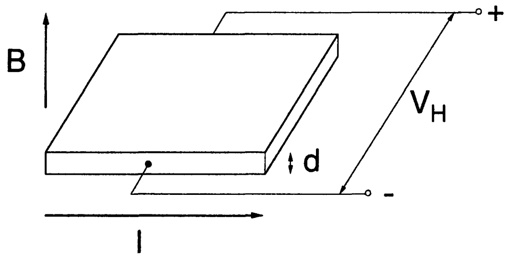

FIG. 4. Schematic representation of the Hall effect.

magnetic field B is applied perpendicularly to a thin film in which the current I is flowing, a voltage V_H is produced perpendicular to the directions of both the current I and the field B. The voltage V_H is proportional to the current I and the magnetic field B and inversely proportional to the thickness d as follows:

$$V_H = R_H IB/d, \tag{7}$$

where R_H is called Hall coefficient. R_H is negative when the carriers in the thin film are electrons and positive when the carriers are holes.

For an n-type semiconductor, the Hall coefficient is written as

$$R_H = -1/n_e q, \tag{8}$$

where n_e is the electron concentration and q is the electron charge. For a p-type semiconductor, R_H is written as

$$R_H = 1/n_h q, \tag{9}$$

where n_h is the hole concentration. The carrier concentration n (either n_e or n_h) is derived from Eqs. (8) and (9) as

$$n = 1/q|R_H|. \tag{10}$$

The conductivity of the thin film σ is related to the Hall mobility μ_H as

$$\mu_H = \sigma|R_H| = |R_H|/\rho. \tag{11}$$

From this relation, the Hall mobility is derived from the Hall coefficient and resistivity.

The Hall mobility reflects the conductive properties of the bulk of the thin films. This is in contrast to the field-effect mobility, which reflects the surface or interface properties of thin films.

3. ELECTRICAL PROPERTIES OF THIN FILMS

In this section, we discuss electrical properties of conductor, semiconductor, and insulator thin films. Conductivity in metals and alloys is discussed in detail in METALS AND ALLOYS, CONDUCTIVITY IN. Here, we focus on electrical properties that are unique in thin films.

Thin films are modeled as a medium with numerous defects confined between a pair of parallel surfaces. The unique properties of thin films that are different from those of bulk materials originate from the effects of surfaces and defects in conductor and semiconductor thin films.

3.1 Conductor Thin Films

3.1.1 Islandlike Thin Films At an early stage of conductor thin-film deposition, typically when the thickness is less than a few nanometers or so, thin films consist of islandlike structures separated from one another. In such thin films, it has been experimentally known that the resistivity is much higher than in bulk, of the order of 10^{10} to 10^{13} Ω cm. It has also been known that the thermal coefficient is negative and the thermal-activation type conductivity is observed, as given by

$$\sigma = \sigma_0 \exp(-E_a/kT), \tag{12}$$

where E_a is the activation energy, k is the Boltzmann constant, and T is the temperature. The activation energy E_a is of the order of −0.1 eV or less. It decreases as the thickness increases. Figure 5 shows experimental results on the temperature dependence of gold conductivity (Kazmerski and Rachine, 1975).

Although several theoretical models have been proposed to analyze the electrical conductivity of the islandlike conductor thin films, it has not been possible yet to explain every aspect of the observed phenomena. Possible electron transport mechanisms are thermal emission and tunneling. The path of

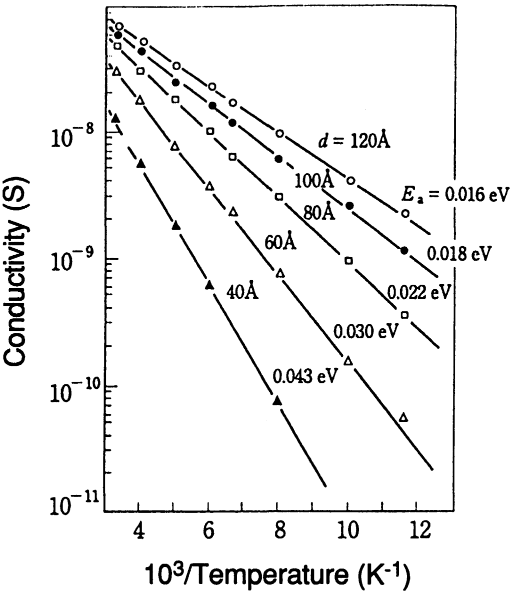

FIG. 5. Temperature dependence of conductivities in gold thin films.

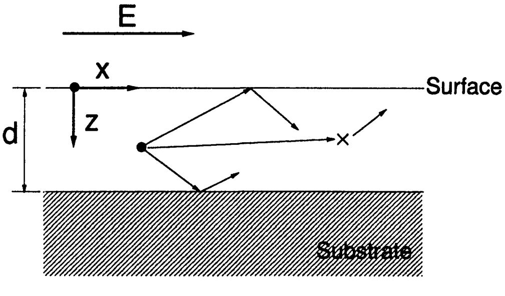

FIG. 6. Schematic electron scattering in thin film.

the electron transport can be free space (vacuum) and/or the surface of the substrate.

3.1.2 Continuous Thin Films When the thin-film thickness is thicker than a few nanometers or so, the film becomes continuous. Even in continuous thin films, the properties are different from those of the bulk materials. It has been known that conductivity, Hall coefficient, and thermal coefficient depend on the film thickness. This has been attributed to the effects of surfaces. It has also been known that the above characteristics still differ from those of bulk materials even when their change with the film thickness saturates as the thickness is increased. This is obviously due to the structural defects incorporated in the film during deposition.

The surface effects are prominent when the film thickness is comparable with or smaller than the mean free path of electrons. Figure 6 shows a schematic of the electron transport mechanism in a conductor thin film. Fuchs (1938) and Sondheimer (1950) formulated the effects of scattering at surfaces on the resistivity of conductor thin films. Electron transport characteristics can be derived by solving the Boltzmann equation for the conduction-electron distribution function $f(r,v)$,

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\frac{\partial f}{\partial \mathbf{r}} + \mathbf{F}\cdot\frac{\partial f}{\partial \mathbf{v}} = \left(\frac{\partial f}{\partial t}\right)_{\text{collision}}, \tag{13}$$

with appropriate boundary conditions. In Eq. (13), F represents the external field, and the right-hand term represents the change due to relaxation. When we assume that the distribution f_0 changes to $f_0 + f_1$ and the relaxation time is t, Eq. (13) becomes

$$v_z\frac{\partial f_1}{\partial z} + \frac{f_1}{2} = \frac{eE}{m_0}\frac{\partial f_0}{\partial v_x}, \tag{14}$$

and the boundary condition is

$$f_1(z = 0) = f_1(z = d) = 0. \tag{15}$$

We define here the probability of an electron being elastically scattered at the surface as p $(0 < p < 1)$. By solving Eq. (15), the ratio of a thin-film resistivity ρ to the resistivity of a virtual thin film with infinite thickness ρ_{inf} can be expressed as follows (Kimbara, 1987):

$$\rho/\rho_{\text{inf}} = 1 + \tfrac{3}{8}(1 - p)l_{\text{inf}}/d, \tag{16}$$

where l_{inf} is the mean free path of electrons in a thin film with infinite thickness and d is the thin-film thickness. If $p = 1$, the ratio ρ/ρ_{inf} is 1, and there is no surface effect.

Figure 7 shows the relation between ρ/ρ_{inf} and d/l_{inf} obtained in Fuchs–Sondheimer theory (Kamiyama, 1983). It shows that the normalized resistivity increases drastically as the normalized thickness d/l_{inf} becomes smaller than 1, except in the case in which $p = 1$.

It has been experimentally shown that p ranges from 0.5 to 1 in epitaxial and single-

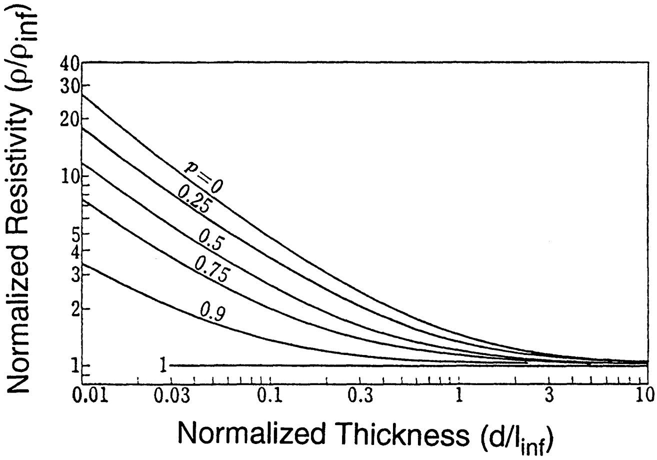

FIG. 7. Plots of normalized resistivity as a function of normalized thin-film thickness as the results of Fuchs–Sondheimer theory.

crystalline thin films. In polycrystalline thin films, in general, p is close to zero.

3.1.3 Effects of Defects and Contamination If a material consists of an infinite and perfect lattice, there is no obstacle to electron passage. The deviation from that perfect situation causes the scattering of electrons (see METALS AND ALLOYS, CONDUCTIVITY IN). The existence of islandlike structures in thin films of less than a few nanometers thickness and the surfaces in continuous thin films are examples of the deviations that cause electron scattering.

Defects in thin films are also major factors that cause electron scattering. Thin films contain various kinds of defects such as point defects, dislocations, stacking faults, and grain boundaries. They are incorporated in the films at deposition. Among these defects, the point defects are known to have the greatest effects on resistivity in conductor thin films. Typical point-defect concentration is 0.1 to a few at.% in metal thin films. The increase in resistivity in metals is typically in the range of (1 to 4) $\times 10^{-6}$ $\Omega \cdot$cm per 1% increase of the defects (see METALS AND ALLOYS, CONDUCTIVITY IN).

In case of polycrystalline thin films, grain boundaries work as a kind of defect, as we discuss later.

In addition to defects, impurities in thin films cause an increase in resistivity. Some of the impurities are incorporated in thin films during deposition. Other impurities enter thin films after deposition, by adsorption. Oxygen adsorbs on metal thin films easily. In most metals, with the exception of gold, oxygen adsorption and subsequent oxidation of the surface increase the resistivity of thin films.

The increase in resistivity due to oxidation is quite harmful in insuring reliability of the thin-film electrical properties. To prevent this, a passivation technique can be used. In this technique, a stable insulator thin film such as SiO_2 and Si_3N_4 is deposited on top of thin films that are vulnerable to exposure to the air.

3.2 Semiconductor Thin Films

3.2.1 Amorphous Semiconductor Thin Films Amorphous materials lack translational symmetry in atomic configuration. This means that there is no long-range (ten atomic spacings or so) order in amorphous materials (see AMORPHOUS MATERIALS, STRUCTURE OF). It should be noted, however, that amorphous materials do maintain relatively good short-range order. Ioffe and Regel (1960) predicted that this short-range order results in a band gap in amorphous materials even when there is no long-range order. The prediction was later proved by experiments.

Amorphous semiconductors can be categorized roughly into chalcogenide semiconductors and tetrahedrally bonded semiconductors.

Chalcogenide semiconductors are materials with chemical formulas containing one or more atoms of S, Se, and/or Te. The atoms in chalcogenide semiconductors form one-dimensional or two-dimensional networks. These networks are attracted to each other by weak Van der Waals force. There are many kinds of chalcogenide semiconductors, including *a*-Se, *a*-As_2S_3, and *a*-As-S-Te-Ge. (Here, *a*- denotes amorphous.)

The electrical properties of amorphous chalcogenide thin films show some similarities to crystalline semiconductors in that the conduction is by electrons and is activation type. The conductivity of chalcogenide thin films can be expressed as

$$\sigma = \sigma_0 \exp(-E_a/kT). \tag{17}$$

In most chalcogenide amorphous semiconductors, the conduction type is weak *p*-type. They are not sensitive to the type of dopants. Thus it is not usually possible to control conduction type, *p*-type or *n*-type, by doping impurities (Kamiyama, 1983).

Another type of amorphous semiconductor thin films is tetrahedrally bonded thin film. Typical materials of this type are *a*-Si and *a*-Ge. (See SILICON, AMORPHOUS.)

a-Si thin films can be deposited by evaporation and sputtering. In such *a*-Si thin films, electronic conduction occurs through long-range hopping near the Fermi level. The conductivity is expressed as follows (Mott and Davis, 1979):

$$\sigma = \sigma_0 \exp\left\{-B\left(\frac{a^3}{kTN(E_F)}\right)^{1/4}\right\}, \tag{18}$$

where k is the Boltzmann constant, $N(E_F)$ is the electron state density at the Fermi energy E_F, and a and B are constants.

It is possible to incorporate hydrogen atoms into *a*-Si thin films by using the glow-discharge or plasma-CVD method of deposition. Here we denote hydrogenated amorphous silicon thin films as *a*-Si:H.

In *a*-Si:H, the energy state density in the band gap is significantly decreased because hydrogen atoms fill most of the dangling bonds. Thus the conductivity shows an activation type as follows:

$$\sigma = \sigma_0 \exp(-E_a/kT), \tag{19}$$

where E_a is the energy difference between E_F and the conduction-band edge energy E_c or valence-band edge energy E_v.

In *a*-Si:H thin films, *p*-type or *n*-type dopants can be incorporated during deposition. Spear and Le Comber (1975) demonstrated that phosphorus and boron can be doped into *a*-Si:H thin films using phosphine (PH_3) and diborane (B_2H_6) in glow-discharge deposition. It is well known that this discovery triggered the rush in basic and applied research in *a*-Si:H thin films.

Figure 8 shows the effect of phosphorus and boron doping on the conductivity and Fermi-level position. The conductivity changes by up to ten orders of magnitude depending on the impurity concentration. The change in Fermi level position ranges up to 1.4 eV.

With the control of *n*-type and *p*-type conduction as well as the wide range of change in conductivity, *a*-Si:H thin films have been pursued for many applications. Solar cells (see SOLAR ENERGY) and thin-film transistors are examples of very successful applications (Kanicki, 1993).

3.2.2 Polycrystalline Semiconductor Thin Films

A polycrystalline thin film consists of crystalline grains that vary in size and crystallographic orientation. In a crystalline grain, atoms configure a lattice like crystalline materials. Between adjacent grains, there exist grain boundaries where defects due to misorientation between different grains concentrate. These grain boundaries cause unique characteristics in polycrystalline semiconductor thin films. Figure 9 shows a schematic structure, charge distribution, and potential barrier height in polycrystalline semiconductor thin films (Seto, 1975).

Here, we take *p*-type polycrystalline silicon thin films as an example and analyze their electrical properties after Seto's theory (Seto, 1975). We discuss two cases, when $LN < N_t$ and when $LN > N_t$, where L is the grain size, N is the impurity concentration, and N_t is the trap state density at the grain boundary.

When LN is less than N_t, the *p*-type impurities in the grain are all ionized. A number of trap states equal to the number of ionized impurities are filled with positive charge at the grain boundary. The potential barrier V_B at the grain boundary in this case is expressed as

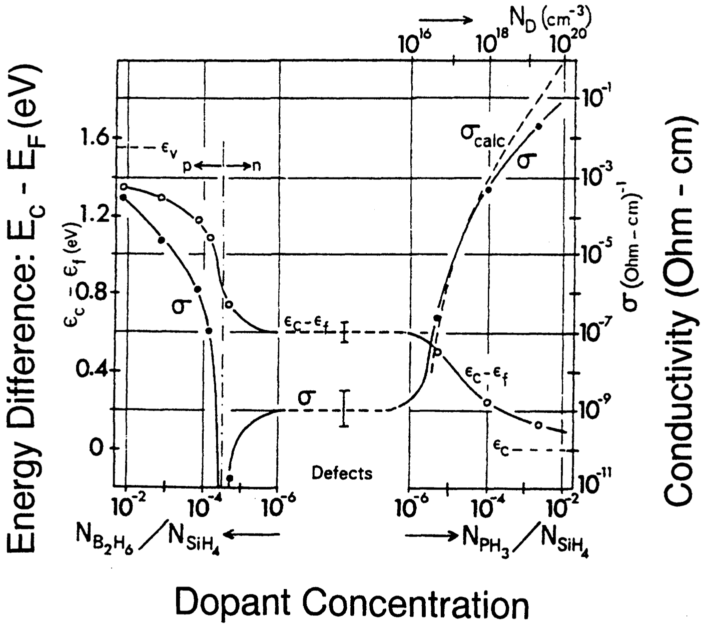

FIG. 8. Conductivity and energy difference ($E_c - E_F$) in *a*-Si:H thin films as functions of doping concentration.

$$V_B = qL^2N/8\epsilon, \tag{20}$$

where q is the electron charge and ϵ is the dielectric constant of silicon.

When LN is greater than N_t, the number of trapped carriers per unit area of grain boundaries remains constant at the value N_t. The potential-barrier height V_B is

$$V_B = qN_t^2/8\epsilon N. \tag{21}$$

From the analysis of thermionic emission at the grain boundaries (Kamins, 1988), the conductivity in polycrystalline silicon thin films is obtained as

$$\sigma = (q^2nv_cL/kT)\exp(-qV_B/kt), \tag{22}$$

where n is the free-carrier density and v_c is the collection velocity defined as $v_c = 2kT/\pi m$.

3.3 Insulator Thin Films

In insulator thin films, carrier transport in the direction perpendicular to the surface occurs when the electric field is sufficiently high. When the electric field is increased further, the thin film breaks down eventually.

In the discussion of carrier transport in insulators, we must first identify the origin of the carrier and the transport mechanism. The origin of the carrier is either from outside the insulator or from inside the insulator. We denote here the number of electrons originating in the insulator thin film as n and the number of electrons injected from outside the insulator thin film as n_e. When the electric field is relatively low, n_e is much lower than n. Therefore, the number of electrons in the thin film is approximated as n and the current is expressed as

$$J = qn\mu E. \tag{23}$$

In this case, the current is proportional to the electric field and the relation is Ohmic.

When the electric field is increased and n_e is not negligible, several carrier transport mechanisms may occur (Sze, 1981).

Schottky emission is a thermionic emission across the metal–insulator interface. The current J is expressed as a function of temperature T and the electric field E as

$$J \sim A^*T^2\exp\left[\frac{-q(\phi_B - \sqrt{qE/4\pi\epsilon i})}{kT}\right], \tag{24}$$

where A^* is the effective Richardson constant, ϕ_B is the barrier height between the insulator thin film and the metal electrode, E

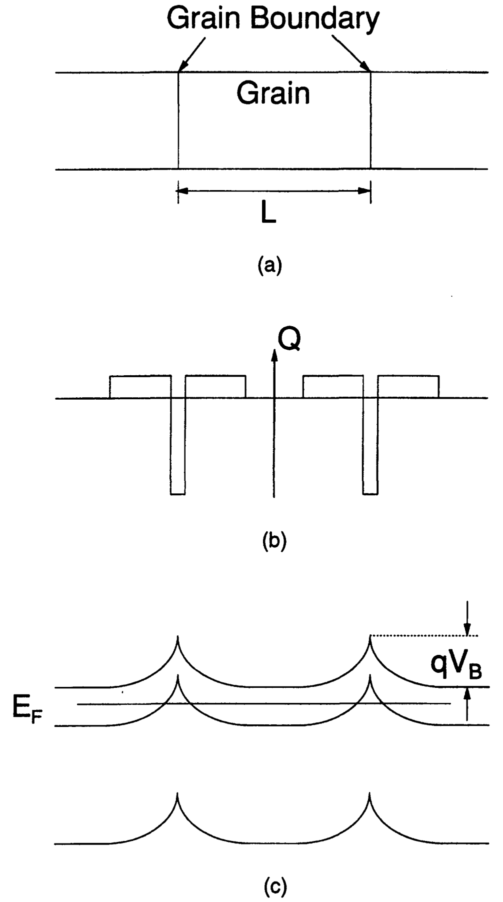

FIG. 9. (a) Schematic structure, (b) charge distribution, and (c) potential height in a polycrystalline semiconductor thin film.

is the electric field, and ϵ_i is the insulator permitivity.

Frenkel–Poole emission is due to electric-field–enhanced thermal excitation of trapped electrons into the conduction band. The current is expressed as

$$J \sim E \exp\left[\frac{-q(\phi_B - \sqrt{qE/\pi\epsilon_i})}{kT}\right]. \tag{25}$$

For trap states with Coulomb potentials, the expression is virtually identical to that of the Schottky emission.

Tunnel emission is caused by field ionization of trapped electrons into the conduction band or by electron tunneling from the metal's Fermi energy into the metal conduction band. The current is expressed in the form

$$J \sim E^2 \exp\left[-\frac{4\sqrt{2m^*}(q\phi_B)^{3/2}}{3q\hbar E}\right], \tag{26}$$

where m^* is the effective mass of the electron and $\hbar$ is the Dirac–Plank constant.

Space-charge-limited current results from carrier injection into the insulator thin film where no compensating charge is present. The current for the unipolar trap-free case is proportional to the square of the applied voltage.

For a given insulator, each conduction mechanism may dominate in a certain temperature and voltage range. However, two or more mechanisms may coexist, making the observed phenomena apparently complex.

Figure 10 shows a plot of current as a function of electric field in a Au-Si_3N_4-Si capacitor structure (Sze, 1981). The +(Au) and −(Au) show the curves with positive and negative voltages to the gold electrode, respectively. There are two distinct regions. Under high electric field, the current in-

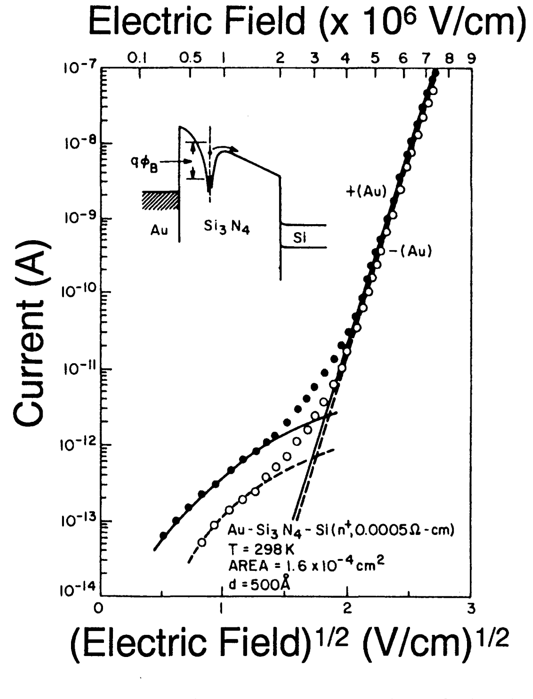

FIG. 10. A plot of current as a function of electric field in a Au-Si_3N_4-Si structure.

creases exponentially with the square root of the electric field, showing Frenkel–Poole type emission. At lower electric field, the characteristics are Ohmic. When the electric field is relatively low, the number of electrons in the insulator is much less than the number of electrons originating in the insulator. In this case, space charge does not affect the current, and the current is proportional to the electric field. This explains the Ohmic relation in Figure 10. At higher electric field, electrons are injected into the insulator, creating space charge.

The maximum dielectric strength, which is also called breakdown field, is an important property of insulator thin films. The essential breakdown processes in insulators are thermal breakdown and electronic breakdown. At relatively low temperatures, the breakdown is due to an electronic process in which the breakdown is directly caused by the electric field. The breakdown field is nearly independent of temperature in this case. At higher temperatures, thermal breakdown occurs. In this case, the breakdown is caused by the local heat in the thin film.

Figures 11(a) and 11(b) show the relation between the breakdown field and the insulator thickness in SiO_2 thin films in two different thickness ranges (Sze, 1981). When the thickness is above 100 nm the breakdown field is constant at 9×10^6 V/cm. It should be noted that the thinner the film, the higher the breakdown field. For very thin SiO_2 films, thinner than 10 nm, the breakdown field approaches 3×10^7 V/cm.

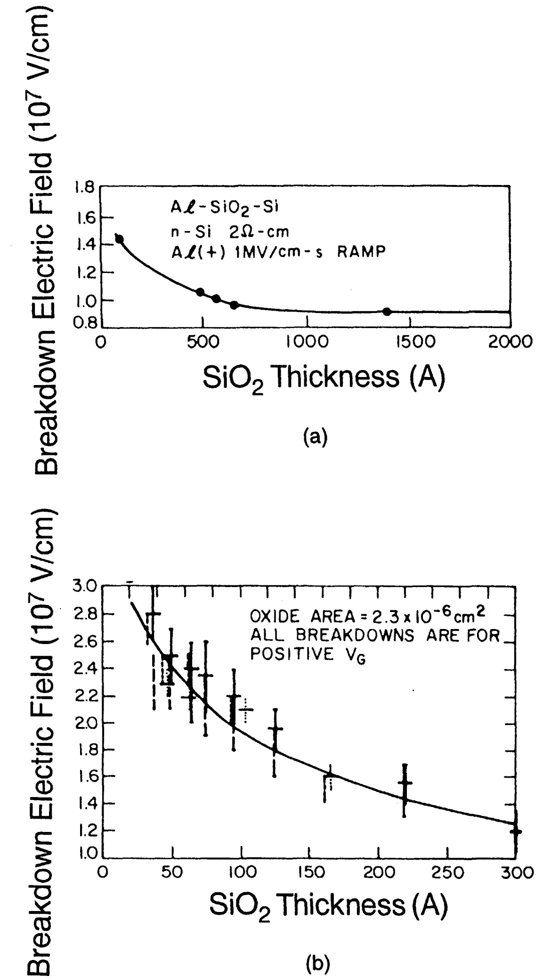

FIG. 11. Relation between breakdown electric field and insulator (SiO_2) thickness in an Al-SiO_2-Si structure.

4. APPLICATIONS OF THIN-FILM ELECTRICAL PROPERTIES

Thin films are used in various industrial products including microdevices such as very large-scale integrated circuits, thin-film transistors, and micromechanical devices to name a few. The major advantages of thin films for use in industrial products are as follows. First, they can be deposited on solid-state substrates of virtually all kinds with adequate control and throughput. Stacking one thin film on top of another is also easily achieved. Second, the control of thin films in terms of thickness and uniformity is excellent in general. This results in high reliability of products using thin films. Third, they can be patterned using microlithography technology (see MICROLITHOGRAPHY) with feature sizes down to 1 μm or less. Such fine patterning makes extremely high-density integration of active and passive devices possible.

In this section, we review the applications of thin films taking very large-scale integrated circuits and thin-film transistors as appropriate examples. In these applications, high-quality thin films of conductor, semiconductor, and insulator are fully utilized to achieve required performance with reliability (see VLSI—INTEGRATED CIRCUITS; MICROELECTRONICS).

4.1 VERY LARGE-SCALE INTEGRATION (VLSI)

The integration of active devices (transistors and diodes) and passive devices (capacitors and resistors) on semiconductor substrates, typically silicon and gallium arsenide, has achieved the revolution in electronics providing high-performance microprocessors (see MICROPROCESSORS) and high-capacity memory chips. In VLSIs, thin films are used as conductors to interconnect each device electrically and as insulators to isolate different levels of conductor patterns.

Figure 12 shows a schematic cross section of a typical CMOS dynamic random-access memory. Note that all the components, except the silicon substrate, are thin films.

Now we discuss the roles of the thin films following the fabrication process. A relatively thick ($\sim 0.5\ \mu$m) SiO_2 thin film is thermally grown first to isolate each MOS transistor. After n-type well formation using the ion implantation technique, a gate insulator SiO_2 thin film is grown by thermal oxidation. Very high dielectric strength ($>10^7$ V/cm) and high-quality interface between the SiO_2 and silicon substrate surface are achieved. A phosphorus-doped polycrystalline-silicon thin film is deposited by the CVD method and pattern delineated to form gate electrodes. This polycrystalline silicon thin film is highly doped with phosphorus ($\sim 10^{19}/cm^3$) so that it works as a conductor. Subsequently, p^+ (highly doped p-type) and n^+ (highly doped n-type) regions are formed using boron and phosphorus ion implantation. These regions will become the source and drain of each MOS transistor. To complete the integration, each device must be interconnected. For this purpose, a SiO_2 thin film is deposited by CVD or sputtering as an interlayer insulator. Phosphorus is usually doped into this SiO_2 thin film. The phosphorus captures alkaline ions in the device structure that may cause instability in MOS transistor characteristics. Next, via holes are opened to expose the source and drain regions as well as the doped polycrystalline silicon thin films. An Al thin film is then deposited by sputtering followed by pattern delineation to complete the device structure.

Since steps are formed as the fabrication process goes, step coverage of thin films is required. With optimized deposition, this requirement has been met in VLSI manufacturing.

4.2 Thin-Film Transistors

Thin film transistors (TFTs) are defined as field-effect transistors built using a semiconductor thin film that is originally deposited on an insulating substrate (Weimer, 1962). Various semiconductor materials have been studied for use in TFTs including CdS, CdSe, Te, InSb, PbTe, Se, Ge, SiGe, and Si (Yamauchi and Reif, 1994). Among these materials, only two types of TFTs that use silicon thin films, either amorphous or polycrystalline, have found practical applications.

Figure 13 shows cross sections of the three most common TFT structures: the coplanar type in Fig. 13(a), the staggered type in Fig. 13(b), and the inverted staggered

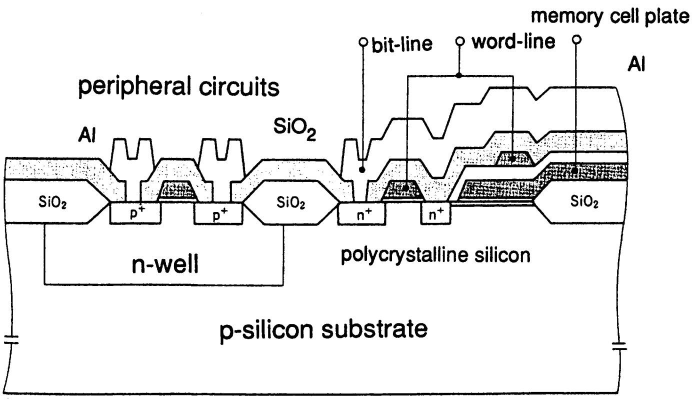

FIG. 12. Cross section of a typical CMOS dynamic random-access memory integrated circuit.

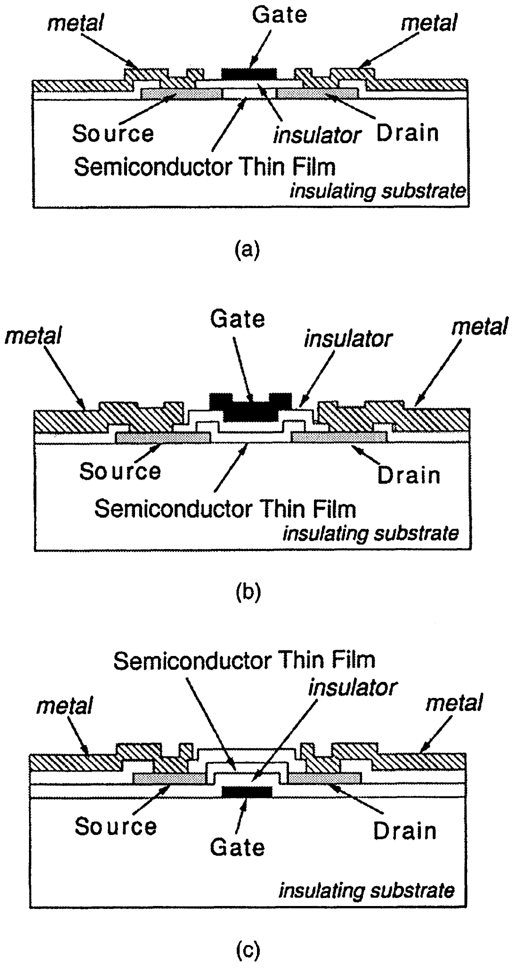

FIG. 13. Schematic cross section of thin-film transistors.

structure in Fig. 13(c). As shown in Fig. 13, all types of thin films, conductor, semiconductor, and insulator, are used in TFTs. Like a crystalline silicon MOS transistor, a TFT consists of source and drain regions that are doped with impurities, and a gate electrode. The gate bias, applied through the gate insulator, controls the current that runs between source and drain. Either *n*-channel or *p*-channel TFTs can be made by selecting *n*-type impurities (phosphorus or arsenic) or *p*-type impurities (boron), respectively. This makes CMOS circuits possible by using both types of TFTs.

The most important feature of the TFTs is that they are built on an insulating substrate, typically glass or fused quartz. This allows optical transparency of the device structure that is essential in most of their applications. Moreover, it allows use of much larger substrate sizes than those possible with crystalline semiconductor substrates. TFTs have been successfully used in active-matrix–addressed liquid-crystal displays, in which each pixel is addressed by a TFT (see DISPLAY TECHNOLOGY).

The electrical properties of semiconductor thin films and the semiconductor–gate insulator interface are the two main factors that determine TFT performance. Efforts have been made to achieve high-quality semiconductor thin films by optimizing the deposition conditions in both amorphous and polycrystalline silicon TFTs.

Field-effect mobilities achieved in amorphous-silicon TFTs are in the range of 0.5–1 $\mathrm{cm^2/V \cdot s}$. These mobilities are two to three orders of magnitude lower than that of crystalline silicon MOS transistors. However, such mobilities in amorphous silicon TFTs are sufficient for current active-matrix display applications.

In polycrystalline silicon TFTs, on the other hand, field-effect mobilities over 50 $\mathrm{cm^2/V \cdot s}$ have been achieved, enabling high-speed performance in TFT integrated circuits. In laser-annealed polycrystalline silicon TFTs, a mobility of 382 $\mathrm{cm^2/V \cdot s}$ has been reported (Serikawa *et al.*, 1989). This mobility is about half of the mobility in crystalline-silicon MOS transistors. Such high mobilities in polycrystalline silicon TFTs have been achieved mainly by reducing the trap state density at grain boundaries.

Levinson *et al.* (1982) formulated an expression for the drain current of a polycrystalline-silicon TFT using a carrier-transport model at the grain boundary first given by Seto (1925). The following equation shows the drain current I_D as a function of the gate voltage V_G and the drain-source voltage V_D:

$$I_D = \mu_{GB}(W/L)(C_{OX})V_G V_D \exp(-V_B/kT), \qquad (27)$$

where μ_{GB} is the carrier mobility inside the grain, W is the channel width, L is the channel length, C_{OX} is the gate capacitance, and V_B is the potential barrier height at the grain boundary [Levinson *et al.*, 1982, Eq. (21)].

Equation (27) shows that the drain current is determined by the mobility inside a grain and the grain-boundary trap density

N_t. This is a natural consequence of the premise that the grain boundaries are the dominant factor that distinguishes polycrystalline silicon TFTs from crystalline-silicon MOS transistors.

5. CONCLUSION

The electrical properties of thin films are greatly affected by the existence of the surfaces and defects. In conductor thin films, the carrier transport is affected by the scattering at the surfaces especially when the thickness is smaller than the mean free path of an electron. In amorphous-semiconductor thin films, the carrier transport is dominated by the defects and the energy-state distribution originating from the lack of long-range order. In hydrogenated amorphous-silicon thin films, the electrical conduction can be controlled by doping impurities. In the case of polycrystalline semiconductor thin films, the potential barrier at the grain boundary plays a dominant role. Carrier transport in insulator thin films under high electric field occurs through the energy states in the band gap. There are a few current mechanisms in insulator thin films. One or more of the mechanisms dominate depending on the temperature and electric field.

Thin-film technologies have been the basis of microdevices that achieved the electronics revolution in the latter part of the twentieth century. There is no doubt that they will continue to be the key technologies in the future. There seem to be two major goals in thin-film applications. One is to further scale down the existing microdevices to achieve not only even higher density integration but superior performance. The other is to create novel microdevices with new functionalities. To these ends, control of electrical properties in thinner and more finely patterned thin films, and in thin films of new materials, must be studied taking full advantages of state-of-the-art deposition methods and related science and technologies.

GLOSSARY

Annealing: A process to provide energy (usually thermally) to a material to improve its quality by reducing defects.

Chalcogenide: A group of materials that contain one or more atoms of S, Se, or Te.

Complementary Metal-Oxide–Semiconductor (CMOS) Circuit: A circuit consisting of *p*-type and *n*-type MOS transistors in which low power consumption performance is achieved due to complementary operation of serially connected *p*- and *n*-type transistors.

Field-Effect Mobility: A mobility measured in a field-effect transistor structure reflecting the conduction at the insulator–semiconductor interface.

Grain Boundary: The boundary between adjacent grains, where defects concentrate.

Hall Effect: A phenomenon in which an electric field arises when a magnetic field is applied perpendicular to a current flow in a material.

Ion Implantation: A method to incorporate atoms into a solid-state material by accelerating ions by high electric field.

Metal-Oxide–Semiconductor (MOS) Transistor: A field-effect transistor with a stacked structure of metal-oxide insulator and semiconductor.

Passivation: A technique to protect a thin film that is vulnerable to exposure to air by covering the thin films using a stable insulator thin film.

Thin-Film Transistor (TFT): A field-effect transistor built using a semiconductor thin film that is originally deposited on an insulator substrate.

Very Large-Scale Integration (VLSI): Circuits composed of transistors, capacitors, and resistors integrated on a semiconductor (usually silicon) chip.

INTRODUCTION

In general, the properties of any solid-state material, either bulk or thin film, are determined by the arrangement of the constituent atoms, the nature of the chemical bonds between the constituents, and the elementary excitations occurring in the system. Consequently, the distinction between electronic and nonelectronic properties is somewhat artificial since the electronic structure of the material is one of the fundamental ingredients determining the physical properties of matter. However, based on the generally accepted terminology, the following distinction is used as a guideline: electronic properties—all properties that are determined by charge transfer within the system; nonelectronic properties—all properties not dominated by charge transfer.

According to this definition, this article reviews the basic phenomena of mechanical and optical properties of thin films, and treats the analysis of structure and chemical composition as well as the analysis of mechanical and optical properties. Since film properties are substantially affected by surface effects, a brief survey of relevant surface analytical techniques is included, irrespective of the fact that they are not used for thin-film analysis exclusively. To deduce the nonelectronic properties of thin films from first principles determining the atom arrangement and to treat the specific relationship between the microstructure and the physical properties deserves other articles in this volume of the Encyclopedia, and the reader is referred to them (especially the chapters dealing with electron structures in Volume 5 and the article THIN FILMS, ELECTRONIC PROPERTIES in this volume). Consequently, a rigorous treatment of the substrate precon-

ditioning, thin-film nucleation, growth mechanisms, and microstructure evolution is not included here. Furthermore, not covered in this article are nonelectronic thin-film phenomena that are determined by charge transfer such as mechanical stability changes due to electromigration, dielectric properties, and thermal-transport properties.

In science and technology, the mechanical and optical properties of thin films play a vital role. The mechanical properties such as hardness, wear, durability, adhesion, and cracking of thin films are major topics to be considered in all applications associated with microelectronics and microsystem technology. Hard, wear-resistant and protective coatings are used in improving the lifetime of metal-forming tools, cutting tools, and all areas where tribological properties of materials have to be improved—e.g., in bearings and gears.

Thin-film optics is a topic of invaluable importance. The application of thin films as antireflecting coatings in everyday consumer products is obvious. All sorts of optical devices have been improved or even made possible by the application of thin films and thin-film multilayers. In recent years the application of thin-film technology suitable to fabricate optical devices for x-ray optics has experienced a breakthrough. Optical systems such as monochromators, mirrors, and focusing mirrors are available now.

There is a myriad of diagnostic tools suitable for thin-film analysis. The general trend, however, is the development of element-specific, nondestructive techniques with high lateral resolution. Systems based conceptually on the scanning tunneling microscope (near-field characterization probes) (see TUNNELING MICROSCOPY AND MICROANALYSIS) with a lateral and vertical resolution in the atomic range will be indispensable tools for thin-film analysis in the years to come.

1. MECHANICAL PROPERTIES OF THIN FILMS

1.1 General Comments

The mechanical properties of thin films—similarly to the optical, magnetic, and electrical properties—depend mainly on the material-specific intrinsic characteristics as determined by the type of chemical interactions of the atoms involved, resulting in the chemical bonding, crystal structure, and electronic band structure. Superimposed are extrinsic features arising from film growth and microstructure evolution. For a fundamental description of the mechanical properties of thin films, it is therefore mandatory to correlate the observed behavior with their microstructure. The microstructure is well known to depend on substrate selection, substrate preconditioning, and the deposition method itself (classified, e.g., by the kinetic energy of impinging atoms and/or molecules) as well as deposition rate, substrate temperature, and residual gas composition and pressure. Adsorption, desorption, and diffusion of the particles impinging at the substrate site are the fundamental processes to be controlled. Adhesion, e.g., is determined by nucleation as well as by the early stages of film growth. Other properties like hardness, internal stress, and fracture depend on the subsequent growth and resultant crystallographic type (amorphous, polycrystalline, textured, and single crystal) of the film.

A rigorous treatment of the mechanical properties of thin films therefore has to be based on an atomistic description of the arrangement of atoms as determined by the film-forming processes and the interaction of the atoms involved. Instead of this rigorous treatment, in this section a more pragmatic concept is used, describing especially those mechanical properties of thin films that are relevant for applications, such as hardness, stress, adhesion, fracture, and delamination. For simplicity reasons atomistic bonding concepts are used to pave the way for a fundamental understanding of thin-film hardness. For the description of thin-film stress as well as adhesion, fracture, and delamination processes based on stress issues, the atomic structure is mostly ignored, and the properties are explained in terms of continuum mechanics and thermodynamics.

1.2 Hardness of Thin Films

Hardness of thin films is defined by the ratio of the peak load and the projected contact area in a microindenter experiment (see details in Sec. 3.4.2). The properties of materials depend on the bond within the solid-state matter; mechanically hard materials including thin films, therefore, can be classified by their bonding types:

1. metallic hard materials,
2. hard materials with covalent bonding, and
3. hard materials with heteropolar bonding (ionic character).

Since the classification of bond holds only in extremes, a sharp separation is not always possible.

Metallic hard thin films are the carbides, nitrides, silicides, and borides of group-IIIA–VIA transition metals as well as some of the group-VIIA and group-VIIIA transition metals that form interstitial solid-solution structures. Typical values for the Vickers hardness (HV) are 1500–3000 HV (as a reference, diamond has 8000 HV). These films have low ductility, a high coefficient of thermal expansion, and good electrical conductivity. To this category belongs WC, the first artificially synthesized hard material. From the application point of view, TiN and TiAlN are the most widely used thin films of this category, especially in the cutting tool industry, tribological (bearings and gears), as well as decorative applications (e.g., substitution for gold). In TiAlN an increasing Al content causes a more wear-resistant coating; commonly the composition $Ti_{0.5}Al_{0.5}N$ is used. The main advantage of TiAlN is its superior performance at elevated temperatures due to the enhanced oxidation temperature (700 °C compared to 500 °C for TiN).

Among the covalent hard materials—diamond as well as the carbides and nitrides of group-III and group-IV elements B, Si, Al—cubic BN as well as B_4C are important as the second and third hardest materials known. *c*-BN coatings, however, are difficult to synthesize because of the competition of the mechanically soft hexagonal modification *h*-BN in the deposition process. Plasma chemical vapor deposition (PCVD) as well as pulsed-laser deposition (PLD) are the techniques of choice to prepare these films. On account of the unique properties of diamond (hardness, thermal conductivity, chemical inertness, wide energy band gap, dielectric constant), thin films are of great technological importance. Thin films are mainly deposited using plasma-assisted or hot-filament–assisted CVD.

Heteropolar hard thin films are represented by the oxides; they have the advantage of high strength at high temperatures and—naturally—no oxidation problems. Furthermore, they are interesting as diffusion barriers and thermal barrier coatings.

Table 1 compiles a selection of the mechanical properties of materials from these three categories. For details in thin-film

Table 1. Properties of different hard materials.

Phase	Density (g/cm^3)	Hardness (HV/100)	Young's modulus (kN/mm^2)	Resistivity (Ω cm)	Thermal expansion ($10^{-6}/K$)

preparation of hard and protective materials, the reader is referred to a recent review by Knotek and Schrey (1995).

1.3 Internal Stress of Thin Films

The formation of heterophase boundaries such as film/substrate or film A/film B as well as homophase boundaries such as grain, twin, and domain boundaries are the main sources for internal stress occurring in thin films. In layered structures generally two types of internal residual stress occur whose physical origins are quite different: thermal stress and intrinsic stress.

Thermal stress is due to the constraint imposed by the film–substrate bonding and is produced by the thermal mismatch between layers of different thermal expansion coefficients, α. In the approximation for an isotropic thin film on a thick substrate, biaxial stress conditions are present and, provided there is no change in microstructure and no phase transition between deposition temperature and measurement temperature, the total thermal strain ϵ_{therm} is simply

$$\epsilon_{\text{therm}} = \int (\alpha_{\text{film}} - \alpha_{\text{sub}})dT = \Delta\alpha\Delta T, \qquad (1)$$

where $\Delta\alpha$ corresponds to the difference in the linear expansion coefficients of film and substrate, and ΔT to the difference of deposition temperature and measurement temperature. Combined with Hooke's law, we get for the thermal stress

$$\sigma_{\text{therm}} = \frac{E_f}{1 - \nu_f}\Delta\alpha\Delta T, \qquad (2)$$

where E_f corresponds to the Young's modulus and ν_f to the Poisson ratio of the film. Typical values for α (in units of 10^{-6}/°C) are 8 for glass, 10–20 for many metals, and 30–40 for alkali halides. If ΔT and $\Delta\alpha$ are positive, a tensile stress arises; for negative ΔT and positive $\Delta\alpha$ compressive stress is found.

The second contribution, the intrinsic stress, summarizes all contributions to the total residual stress that are not of thermal origin. They depend on a variety of experimental parameters such as film material, structure, thickness, deposition technique, deposition rate, deposition temperature, cooling rate, etc. Generally, several of these parameters are not measured quantitatively in conventional deposition experiments; hence tables for data of intrinsic stress for various combinations of substrate/film materials have to be treated with caution. For deposition experiments performed at room temperature, typical values for the intrinsic stress range from 10^9 Pa (iron on mica) to nearly zero (tin on glass). A variety of mechanisms produce intrinsic stress in different types of films.

1.3.1 Thin Discontinuous Films

Surface tensions are the main source, and, with increasing coverage (coalescence of islands), compressive stress can change sign to tensile stress. Since $\sigma \sim 1/t$, only very thin films show appreciable stress $>10^8$ Pa.

1.3.2 Epitaxial Single-Crystal–Type Thin Films

Differences in the substrate and film lattice parameters are the main reasons for intrinsic stress, which may be either tensile or compressive. When the elastic energy of a coherently distorted lattice is larger than the energy required to create misfit dislocations, a dislocated incoherent interface is formed. Figure 1 compares the lattice planes of film and substrate in cases with perfect lattice-matched epitaxy with a coherently strained lattice-mismatched interface and a relaxed one. In Fig. 1(a) an epitaxial film is grown upon a substrate with the same crystal structure and lattice parameter; in principle, in this case there is no driving force leading to elastic energy accumulation and thus dislocation formation. In Fig. 1(b) an epitaxial

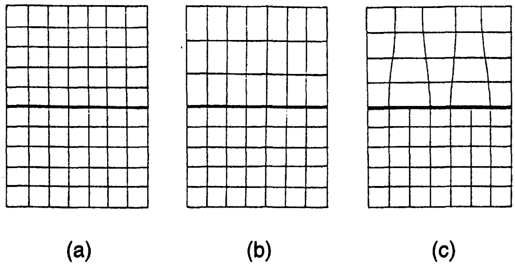

FIG. 1. Schematic representation of the lattice planes of film (top) and substrate (bottom) in (a) a lattice-matched heteroepitaxy, (b) coherently strained lattice-mismatched heteroepitaxy, and (c) relaxed lattice-mismatched heteroepitaxy. At a critical thickness configuration (b) converts to configuration (c).

film is grown upon a substrate with different lattice parameter. For thin layers, up to a critical thickness t_c, the difference in lattice parameter can be accommodated by a biaxial stress in the interfacial plane causing a distortion along the growth normal. If the film thickness exceeds t_c, this elastic strain is relaxed by the formation of misfit dislocations [Fig. 1(c)]. In an energy-balance consideration, the elastic energy is calculated as a function of lattice mismatch, film thickness, and dislocation density. By minimizing this energy, the dislocation density can be calculated as shown by Hull and Bean (1992).

1.3.3 Continuous Polycrystalline Films

A general thermodynamic principle states that atomic disorder is usually accompanied by an increase in volume, and any relaxation to a more ordered state causes a decrease in volume. This principle can be used as a guideline to judge whether stress is tensile or compressive. Tensile stress is expected in films whose deposition temperature is larger than room temperature. This holds especially for thin films deposited via vacuum evaporation. In the presence of impurities, however, this tensile stress can convert into compressive stress. On the other hand, sputtered thin films are usually found in a state of compressive stress. Atom bombardment (peening), whether from energetic depositing atoms or deliberate ion bombardment, creates this compressive stress. Models based on the theory of radiation damage in solids can explain the development of compressive stress. A detailed analysis of stress in sputtered films shows that the normalized momentum $P^* = \vartheta\sqrt{ME}$ (ϑ = flux of energetic particles/atomic flux, M = atomic mass, E = energy of impinging atoms) is the appropriate scaling factor. In Fig. 2 an idealized stress–momentum curve is given, depicting the variation of the intrinsic stress with P^* for any sputtering or ion-assisted deposition process. At low P^*, porous films are deposited unable to support high tensile stress; as the momentum increases, densification occurs as voids collapse, and the tensile stress reaches a maximum. At moderately high momentum, the tensile stress decreases, as compensating compressive stress becomes operative caused by the atomic bombardment mechanisms. When the microstructure becomes fully densified, a conversion to compressive stress takes place that scales with $\sqrt{E}$ as expected theoretically by the forward sputtering cascade model. In the high-momentum region, plastic flow is commonly observed as the yield strength of the film is exceeded, and thus the compressive stress is reduced. Problems associated with internal stress formation have been reviewed by Windischmann (1992).

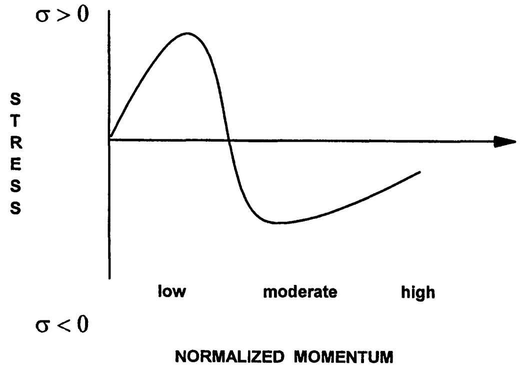

FIG. 2. Idealized intrinsic stress of a film vs normalized momentum P^* for sputter deposition (after Windischmann, 1992). Details are explained in the text.

Furthermore, recrystallization occurring upon cooling from deposition temperature to room temperature in polycrystalline thin films can give rise to microstructural changes, e.g., of grain size D_0 to $D > D_0$; and thus a strain

$$\epsilon = (\Delta - \alpha)(1/D_0 - 1/D) \qquad (3)$$

occurs with $\Delta - \alpha$ being the grain-boundary relaxation length (values around 0.1 nm are typical). Volume changes due to phase transitions and polymorphous transitions are further examples for thickness-independent mechanisms for stress generation.

1.4 Stress Relaxation

The residual stress in thin films, either extrinsic or intrinsic, can be quite large; typical numbers are 0.1–1 GPa. A stress of this magnitude corresponds to about 1% strain in many materials and is comparable to the yield strength of most bulk materials. When film peeling does not occur (shear stress < adhesion for peeling), several mechanisms will lead to stress relaxation: dislocation generation and gliding, dislocation climbing, and diffusion creep. For low temperatures, $T < 0.4T_m$ where T_m is the melting temperature, and small values for stress, $\sigma \leq \sigma_c$ (σ_c: critical shear stress), there is an elastic distortion, only. Dislocation gliding occurs for $T < 0.4T_m$, when

$$\sigma \geq 2\mu b/t_f = \sigma_c \tag{4}$$

(μ, shear modulus; b, Burgers vector; t_f, film thickness). Typical values for σ_c are 4×10^8 Pa for lead and 10^9 Pa for Ta thin films of thickness 100 nm. For $\sigma \leq \sigma_c$ and temperatures around $\frac{1}{2}T_m$, dislocation climbing (the dislocation moves perpendicular to the glide plane) is the dominant process, which is associated with point-defect diffusion, especially the diffusion of vacancies.

For high temperatures, $T > 0.4T_m$, and small values for σ, diffusion creep occurs. The rate $\nabla_t \epsilon$ is proportional to σ and depends on the temperature in a complicated way. A classical review of diffusion creep is given by Gibbs (1966). To get an overview of the different mechanisms as a function of temperature and acting stress, the introduction of deformation maps has been proven to be a practical tool. Murakami (1984) reviews the essential features of deformation maps.

1.5 Adhesion of Thin Films

For the adhesion of dissimilar materials with atomically flat surfaces, a variety of mechanisms can be responsible, ranging from covalent bonding to van der Waals attraction, and can include capillary adhesion, electrostatic attraction and mechanical interlocking.

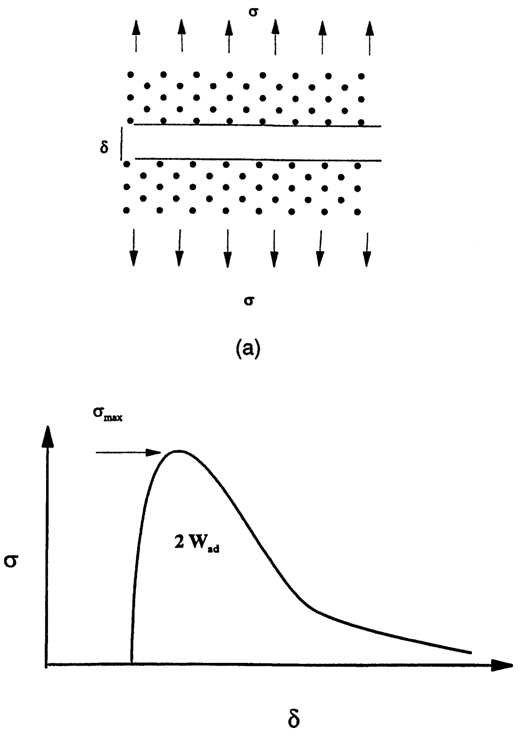
Practically, the adhesion is generally determined by the properties of an interfacial region, which can be structurally as well as chemically different from the bulk phases involved. The properties of these interfacial layers can be modified by physical—e.g., diffusion processes—or chemical—chemical reactions—methods or artificially introduced intermediate layers. In cases of film/substrate couples that have no bulk chemical affinity (e.g., metals on ceramics), a stable bonded interface must be created that will intrinsically link the materials involved by formation of chemical complexes.

Quantitatively, the energy of adhesion is defined by the work W_{ad} required to separate a unit area of the bonded surfaces:

$$W_{\text{ad}} = \gamma_f + \gamma_s - \gamma^*, \tag{5}$$

where γ_f and γ_s correspond to the surface free energy of the film and the substrate, respectively, and γ^* to the interface free energy.

Another quantity that characterizes the strength of bonding across the interface is the theoretical strength of the interface, $\sigma_{\text{max}} = f_c/A$, where f_c is the load required to remove the film of area A. In an idealized experiment, the displacement δ and the load σ are measured [c.f. Fig. 3a] during the uniform separation of two bonded materials. The form of the plot of applied stress vs displacement is represented schematically in



(a)

(b)

FIG. 3. Idealized stress-displacement plot for the definition of W_{ad} and σ_{max}. (a) Uniform separation of an interface by an applied stress results in (b) a stress/displacement plot, defining the theoretical strength of the interface σ_{max} and the thermodynamic work of adhesion $2W_{\text{ad}}$. (After Thouless, 1994)

Fig. 3b; here the area under the curve gives the thermodynamic work of adhesion, and the peak stress, $\sigma_{\max}$, gives the theoretical strength of the interface.

The strategy to improve adhesion derived from Eq. (5) is to lower the surface energy of the interlayer in order to maximize W_{ad}. An example for the implementation of a reactant layer to accomplish adhesion is the commonly used technique of bonding metals to glass via a Cr/Cr-oxide intermediate layer. Often, simply disorder introduced at a crystallographically perfectly terminated substrate surface is sufficient to induce new chemical bond configurations. Plasma modification of polymer surfaces is a standard technique for adhesion improvement. Other techniques to create well controlled, low-energy, chemically stable interfacial layers consist in the different methods of using energetic ions. Table 2 summarizes several different strategies for the enhancement of film adhesion as suggested by Baglin (1994). Presputtering in vacuum using inert species such as Ar will clean the surface from contaminants. Furthermore, this procedure will break up surface-bond chains from a polymer substrate or the terminating layer of a metal oxide and thus activate surface bonding sites. Ion-assisted deposition may be used to bombard the receiving surface with energetic particles. The increased kinetic activity at the receiving surface causes removal and/or separation of surface contaminations in addition to the formation of denser films. Generally, dense films have reduced intrinsic stress, which in turn lowers stored stress energy and thus improves adhesion. Ion implantation is a method for adding reactive species in a controlled way even in the vicinity of an already formed film/substrate interface. Modifications in a graded way are accessible using the dependence of the straggling range of ions on the kinetic energy of the impinging ions. In ion-beam stitching techniques, energetic, inert ions pass through a film and the interface and into the substrate. Each ion creates a sheathlike collision cascade within the solid. During the short period of high atomic mobility, a substantial rearrangement of the atoms within the cascade can occur, resulting in substantial layer interdiffusion. Adhesion is improved by the reconfiguration of the interface structure, interface roughening, and contaminant dispersion.

1.6 Fracture Mechanisms and Thin-Film Delamination

Cracking and, as a result, thin-film delamination occurs when the elastic energy of a film of thickness t and unit area equals a characteristic energy, W_f, required to form a free surface. In a descriptive way the formation of a dislocation network can be imagined that leads to weakening the adhesion and results finally in delamination. The energy balance

$$E^*\epsilon^2 t = W_f \tag{6}$$

(E^*, average Young's modulus; ϵ, total strain) results in a "phase diagram" for the different phenomena as a function of film thickness (cf. Fig. 4). In this figure, the phase boundaries are given in a stress/thickness representation, separating the areas where the different mechanisms are occurring. It is worth noting that the strain scales with $\epsilon \sim \sqrt{1/t}$ as long as γ can be regarded to be thickness independent. The empirical rule that the me-

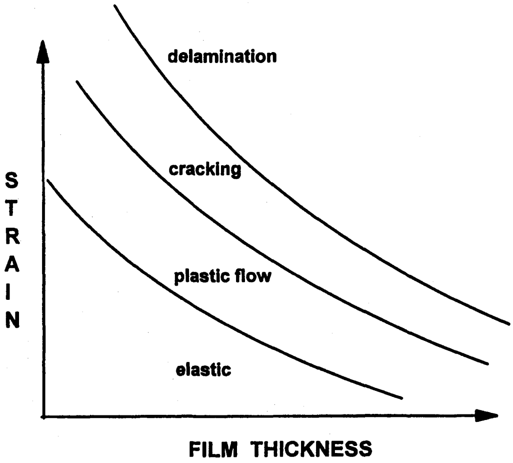

FIG. 4. Schematic "phase diagram" separating the areas of elastic, plastic, cracking, and delamination processes in thin films.

chanical stability of thin films decreases with increasing film thickness is based on this.

The typical mechanism leading to delamination is crack growth by breaking of bonds in a highly strained region of the material. The driving force for crack growth, F_c, is

$$F_c = (\partial/\partial A)(W_{ex} - U), \qquad (7)$$

with W_{ex} being the work done by external forces and U the elastic energy stored in a unit volume.

Delamination occurs independent of whether the stress is compressive or tensile. Compressive stress causes buckling-driven delamination; tensile stress results in a bending momentum around the neutral axis acting at the interface of film and substrate. A comprehensive treatment of problems associated with thin-film adhesion, friction, and delamination has been published by Thouless (1994).

2. OPTICAL PROPERTIES OF THIN FILMS

2.1 Basics of Thin-Film Optics

The fundamental properties investigated by thin-film optics are reflection R, transmission T, and absorption A of light at various wavelengths λ and angles of the incident beam, Φ_0. The phenomenological description of reflection, transmission, and consequently absorption (through the law of energy conservation) is given by macroscopic electrodynamics based on Maxwell's equations. For details the reader is referred to the corresponding articles of this Encyclopedia.

The macroscopic optical properties of an isotropic medium conventionally are characterized by the complex refractive index

$$N = n - ik, \qquad (8)$$

where the real part n usually is called refractive index and the imaginary part k is known as the extinction coefficient. Using the description with the refractive index, the rigorous treatment of calculating reflection, transmission, and absorption based on macroscopic electromagnetic theory is reduced to the determination of the steady-state amplitudes of the electrical- and magnetic-field vectors at the interfaces arising from an incident light wave of certain characteristics.

For parallel-sided, nonabsorbent thin films of refractive index n_1 supported by a substrate with refractive index n_2 and incident beam from a medium (e.g., air) with n_0 at angle Φ_0, the reflectance and transmittance are readily obtained by summing multiple reflected beams (cf. Fig. 5):

$$\begin{aligned} R &= \frac{r_1^2 + r_2^2 + 2r_1r_2\cos\delta}{1 + r_1^2 + r_2^2 + 2r_1r_2\cos\delta}, \\ T &= \frac{n_2 t_1^2 t_2^2}{n_0(r_1^2 + r_2^2 + 2r_1r_2\cos\delta)}; \\ \delta &= 2\pi\nu n_1 t_1 \cos\Phi. \end{aligned} \qquad (9)$$

Here, r_1, r_2, t_1, and t_2 correspond to the Fresnel reflection and transmission coefficients (for the electric vector either perpendicular or parallel to the plane of incidence) for the air/film (index 1) and the film/substrate (index 2) interfaces, respectively. δ is the phase difference between successive beams.

These general expressions show an oscillatory variation with film thickness (see Fig. 6). Written in terms of the refractive index, they are rather complicated; for the special case of normal incidence and nonabsorbent films and $n_0 < n_1 < n_2$, however, these expressions reduce to

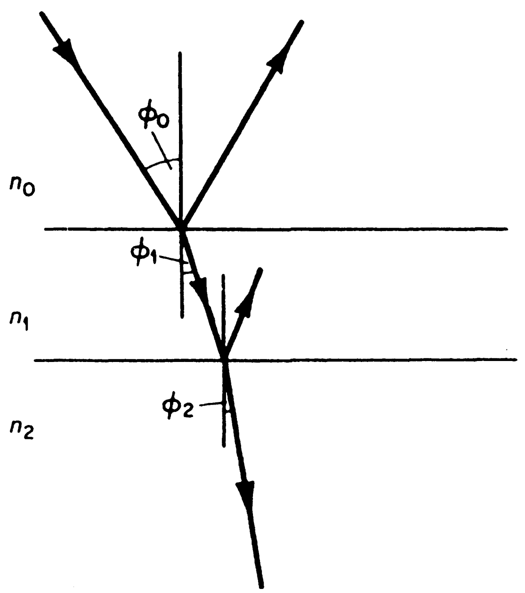

FIG. 5. Ray diagram of a light beam incident at angle Φ_0 on a plane, parallel-sided film of thickness t, and refraction index n_1 supported by a substrate of refraction index n_2.

$$R_{\max} = [(n_2 - n_0)/(n_2 + n_0)]^2 \quad \text{and}$$

$$R_{\min} = [(n_1^2 - n_0 n_2)/(n_1^2 + n_0 n_2)]. \qquad (10)$$

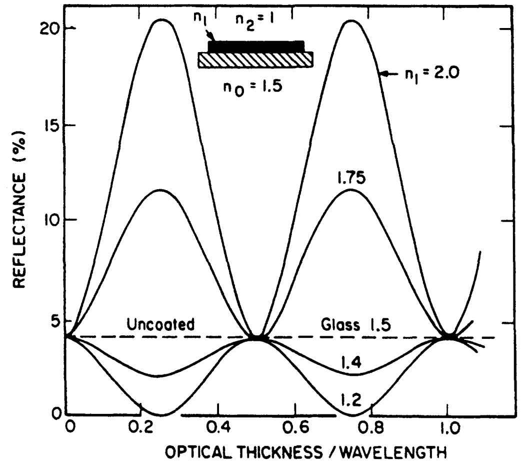

FIG. 6. Theoretical variation of reflectance with normalized film thickness for films with different refractive indices on a glass substrate with n_0 = 1.5.

The evaluation of Eqs. (9), which are valid for any type of film and substrate media, is cumbersome especially when stacks with alternating absorbing and nonabsorbent films are treated. For nonnormal incidence the s and p components of nonpolarized light have different amplitudes, and at a certain angle of incidence (Brewster's angle, ϕ_B) unpolarized light is reflected plane polarized:

$$\tan\phi_B = n_0/n_1. \qquad (11)$$

In case of absorbing thin films, both the amplitude and the phase of originally linearly polarized light change, and consequently the incident light beam is reflected elliptically polarized (see Fig. 7). The phase change of E_s relative to E_p, Δ (E_s and E_p being the field components of the electrical-field vector parallel and perpendicular to the plane of incidence, respectively), and the amplitude change Ψ are related to the sample complex reflection coefficient for light polarized parallel (R_p) and perpendicular (R_s) to the plane of incidence:

$$\tan\Psi \exp(i\Delta) = R_p/R_s = \rho(\lambda,\Phi). \qquad (12)$$

For a bare substrate with no overlayer and a perfectly smooth surface, R_p and R_s are simply the Fresnel reflection coefficients and ρ is readily converted into the dielectric function of the substrate. If the substrate is covered by a film and the same procedure is done, the pseudodielectric function $\langle\epsilon(\omega)\rangle$ is obtained,

$$\langle\epsilon\rangle = \sin^2\Phi\left[1 + \frac{1-\rho}{1+\pi}\tan^2\Phi\right]. \qquad (13)$$

The ratio R_p/R_s includes the refractive indices of a film (or stack of films), the corresponding thickness, angle of incidence, and light wavelength. The complete mathematical treatment of the electromagnetic theory of reflection and transmission in general cases is given in textbooks of optics, e.g., by Born and Wolf (1972).

The discussion of optical properties of absorbing materials is similar; however, the refractive index n has to be replaced by the complex refractive index N. It can readily be seen that the computation of reflectance and transmittance in the case of complex refractive index is not simple, and the reader is referred to the corresponding literature—e.g., Levi (1968).

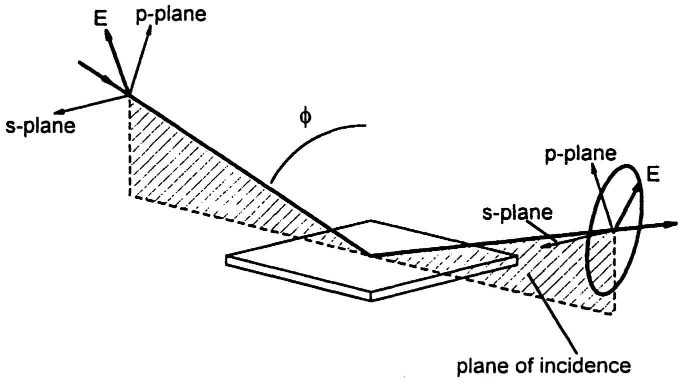

FIG. 7. Change in polarization state of a linearly polarized light beam incident on a sample at oblique angle Φ_0 (basic principle of an ellipsometer).

2.2 Optical Constants of Thin-Film Materials

The dielectric susceptibility $\chi(\omega)$ and the dielectric function $\epsilon(\omega)$ are macroscopic average quantities. Microscopically, these quantities are derived from the summation over the local ones; thus, the average functions $\chi(\omega)$ and $\epsilon(\omega)$ depend on their atomistic counterparts and the way in which atoms are arranged and bonded with the crystal. Consequently, the microstructure, by determining the local arrangement of atoms, influences the dielectric function and thus the real and imaginary parts of the refractive index. The microstructure, in turn, is strongly related to the deposition method and the corresponding deposition parameters. Condensing species deposited by thermal evaporation usually have insufficient kinetic energy to migrate into equilibrium positions after sticking at the substrate or the growing film surface. This causes a reduced mechanical density of the film as well as reduced real part and enhanced imaginary part of the refraction index. Heating the substrate provides additional thermal energy to enhance the diffusivity for surface migration of the evaporant, resulting in more dense films. Figure 8 gives an example showing the dispersion curves of sapphire thin films deposited at different substrate temperatures T_s. The increase of T_s results in an increase of n; the bulk value ($n = 1.76$ for $\lambda = 0.5$ μm), however, is not reached. Thermally evaporated coatings usually show a columnar microstructure with discrete columns of material extending from the substrate/film interface to the film surface. The columns are separated by voids, which can absorb water vapor when the deposition system is vented, and especially in higher humidity atmosphere, these voids may be filled with water molecules in an unpredictable manner. Reactions due to the enlarged inner free surface affect not only the optical properties but also the chemical stability of the films. Most of the materials used for optical coatings are compounds; many of them are either susceptible for preferential sputtering of the anion or decompose when thermally evaporated. Both effects result in nonstoichiometric deposits. Precise stoichiometry control, however, is mandatory to achieve low-loss optical coatings. Compared to thermal or electron-beam evaporation, the sputtering technique provides more dense films mainly because of the higher kinetic energy of the

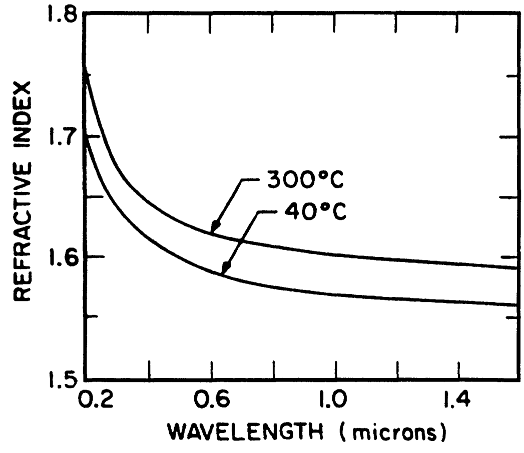

FIG. 8. Refractive index of Al_2O_3 thin films evaporated at different deposition temperatures, as a function of wavelength.

Table 3. Refractive indices for representive materials for optical coatings.

Material	Refractive index	Wavelength for measurement [μm]	Spectral range for transparency [μm]
CaF_2	1.24	0.546	0.15–15
CeF_3	1.65	0.55	
Si	3.3	2.0	>1.0
Ge	4.4	2.0	1.7–20
InAs	3.4	3.8	>7.3
InSb	4.0	7.3	>7.3
KBr	1.56	0.589	0.6–30
MgF_2	1.35	2.0	0.23–10
Na_3AlF_6 (cryolyte)	1.36	0.57	0.2–10
NaCl	1.54	0.589	0.2–>15

SiO	1.55–2.0	0.55	0.5–8
ZnS	2.35	0.55	0.4–14

adatoms (1–10 eV) impinging on the substrate and growing film. These films, however, suffer from compressive stress depending on the deposition parameters used (see Sec. 1.3). To circumvent these problems, ion-beam–assisted evaporation is a widely used technique for industrial applications; here, the thermally evaporated material is exposed at the substrate side to an energetic ion bombardment. Increased packing density, reduced permeability to water, and changes in the film crystal structure result from ion-beam bombardment. Typical ion energies range from 30 to 500 eV. In the case of oxide thin films an oxygen ion beam not only provides the kinetic energy required to form thin films with a density close to the bulk; it also furnishes activated oxygen to achieve stoichiometric thin films. A further parameter affecting the film properties is the ion-beam current density. There is a critical value for achieving a maximum in the refractive index; ion-beam current densities larger than the critical value cause film degradation due to nonstoichiometry, creation of closed isolated voids, or incorporation of gas bubbles into the film. As a result of the dependence of the refractive index on the actual deposition process as well as on the deposition parameters, the data collected in Table 3 therefore can only be treated as representative figures.

2.3 Multilayer Optical Systems

The derivation of the expressions of reflectance and transmittance of multilayer systems is rather straightforward. The usual electromagnetic boundary conditions are applied at each interface, and the amplitudes of the waves in any layer are written in terms of the adjacent layers; the successive operations reveal the amplitude of the waves emerging from either side, expressed in terms of the incident wave. There are several methods for the mathematical treatment to solve this problem, and the reader is referred to the special literature, e.g., Born and Wolf (1972).

Typical examples for multilayer optical systems include antireflecting coatings, high-reflectance nonmetallic mirrors, interference filters, and bandpass and blocking coatings. High-reflectance nonmetallic mirrors consist of a stack of layers with equal optical thickness and alternating refractive index. For the wavelength λ_0 and layer thickness $\lambda_0/4$, all multiple-reflected beams are in phase for perpendicular incidence. At λ_0 the system has a high reflectance and a flat top for a large number of layers; Fig. 9 represents an

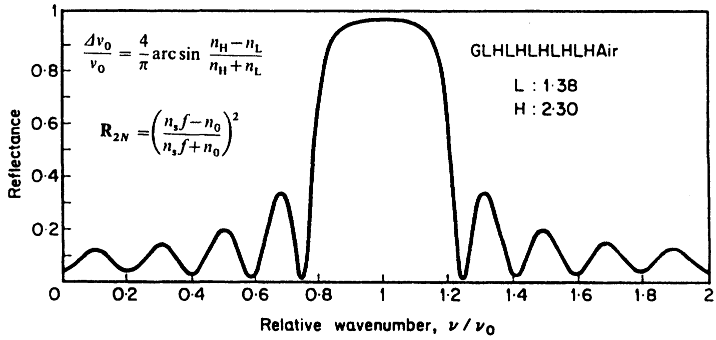

FIG. 9. Reflectance band of a quarter-wave stack on glass (G) with n = 1.51. The low-index material (L) has a refraction index n = 1.38, the high-index material, n = 2.3. The formulas (left upper part) give the width of the reflection band ($\Delta\nu_0/\nu_0$) and the reflectance at ν_0. In the right upper part the stacking sequence is given.

example of a quarter-wave stack with ten layers. The width of the reflection band and the reflectance at λ_0 are determined by the refractive indices of the individual layers and the number of layers according to the equations given in the inset in Fig. 9.

Antireflecting coatings, on the other hand, consist in the application of at least one single layer of optical thickness $\lambda_0/4$ and refractive index $\sqrt{n_s}$, which reduces the reflectance of a surface of index n_s to zero at λ_0. To achieve a low reflection over an extended range of wavelengths, suitable stacks of dielectric layers have to be used. An example for a four-layer antireflecting system is given in Fig. 10. The construction parameters of such antireflection coatings depend on the refractive indices of the substrate and the ambient medium as well as on the width of the spectral region over which the reflection is to be reduced. Dobrowolski and Sullivan (1996) review design methods that yield optimum solutions to the antireflection problem for a given pair of coating materials and for a given overall thickness of the multilayer.

In the past decade a particular class of optical multilayers has been developed especially for soft x rays (100 eV–3 keV, i.e., λ = 12.4–0.41 nm) and extreme UV (15–100 eV, i.e., λ = 80–12.4 nm). These systems consist of a periodic layered microstructure (superlattice) of materials with significantly different scattering powers for x rays. Model calculations using a Fresnel multilayer computational code allowing the optimization of multilayer structure and composition for maximum reflectivity show, for normal incidence, peak reflectivities in the range of 40–80% for λ = 0.6–10 nm. The best material pairs for these purposes will be those that form smooth layers with compositionally abrupt interfaces and have high optical contrast with low absorption in the frequency range required. Selection criteria are therefore not only the optical constants but also the ability of the materials involved to form continuous smooth layers, low interdiffusivity, low chemical reactivity, and low chemical affinity to the residual gases of the deposition system (especially hydrogen, oxygen, water vapor, and carbon oxides). Material combinations typically used for soft x-ray mirrors include Mo, Ru, Rh, or W as high–electron-density layers and C, Si, B, or Be as low–electron-density layers, depending on the wavelength used. Practically, the achieved peak reflectivities for normal incidence are lower than the calculated ones but still as high as 66% for λ = 13.4 nm in Si/Mo multilayers. The degradation of the peak reflectivity is mainly due to the fact that superlattices are not in a thermodynamic equilibrium, and thus the structure is sensitive to preparation methods and growth conditions. Interfacial roughness between the layers, compositionally graded interfaces, scatter in the period of the superlattice, and problems with substrate surface flatness are the main reasons for the degradation of the peak reflectivity. The physics, fabrication, and applications of these types of multilayered structures have been reviewed by Spiller (1994).

3. ANALYSIS OF NONELECTRONIC PROPERTIES OF THIN FILMS

3.1 Analysis of Structural and Chemical Composition

Standard x-ray diffraction analysis of thin films has the advantage of relative ease and convenience and makes possible the accurate determination of film properties such as orientation, phases present, and lattice parameter. In the commonly used Bragg–Brentano configuration (Θ–2Θ scan), the Bragg condition of diffraction,

$$n\lambda = 2d\sin\Theta, \tag{14}$$

gives the position of the diffraction peaks when the angle between the incident beam and the film plane is scanned (λ is the x-ray wavelength, n the order of reflection, d the lattice spacing, and Θ the angle of incidence). The diffraction pattern represents the average through the film, and usually the simultaneous display of the diffraction patterns of the film and the substrate is observed. Texture analysis is accomplished when in addition to the Bragg angle the polar angles ω and Φ are scanned; the mosaic spread (or tilt) of domains in the films can be investigated by scanning the angle ω around $\omega = 0$, while Θ is set to Bragg conditions. The rotation of the film domains around the surface normal (Φ scan with Θ in Bragg conditions) gives the in-plane orientation. Furthermore, a quantitative analysis of the full width at half maximum of the diffraction peaks allows the determination of the mean grain size $\langle s\rangle$ of thin film according to the Scherrer formula

$$\langle s\rangle = \lambda/[\Delta(2\Theta)\cos\Theta], \tag{15}$$

with $\Delta(2\Theta)$ being the angular broadening of the diffraction peaks. X-ray analysis has been refined recently by Fullerton *et al.* (1992) to such extents that detailed structural information like disorder, chemical interdiffusion, and lattice strain—even in the case of superlattices—can be revealed, when the diffraction intensities are measured quantitatively and compared with model calculations.

Complementary to x-ray diffraction techniques, Raman scattering (inelastic photon–phonon scattering) has been proven to be a powerful diagnostic tool, which can provide answers to questions such as

1. state, quality, and phase of thin films, crystallinity, polycrystallinity, microstructures, etc.;
2. residual strains following material treatment (implantation, thermal or laser annealing, polishing, etching) in thin films, heterostructures, and superlattices.

The power of light-scattering spectroscopies for thin-film analysis results from the rather stringent selection rules that arise from the conservation of the wave vector in the scattering process. The probing depth depends on the penetration depth of the light used, and structural as well as compositional peculiarities can be investigated even for thin films with thickness below 100 nm as demonstrated by Zhang *et al.* (1996). Details, like the presence of foreign phases, film orientation, degree of epitaxy, and in some cases details of the degree of oxygenation in thin-film oxides, can readily be revealed from Raman spectra. As an example for a quantitative determination of the degree of epitaxy, Fig. 11 compares the x-ray (103) pole figures with the Raman spectra of an epitaxially grown $YBa_2Cu_3O_{7-\delta}$ thin film with two different settings of the polarizer and analyzer of the Raman-scattering experiment. The x-ray pole figure—basically a three-dimensional representation of the scattered x-ray intensity for a given Bragg angle Θ while scanning the polar angles ω and Φ—demonstrates the fourfold symmetry in the pole density, suggesting in-plane epitaxy. From the intensity ratio of the Cu–O in-plane vibration (at 340 cm^{-1}) for the two settings, the degree of epitaxy of the film is determined to be 0.91, i.e., more than 90% of the grains are aligned with respect to the substrate (in this case strontium titanate) as demonstrated by Thomsen *et al.* (1992).

Several methods are applicable for chemical analysis. The most simple consist in removing the thin film by a solvent and analyzing the solution by chemical techniques. Emission spectroscopy is one of the methods capable of quantitative elemental analysis.

Nondestructive techniques like electron microprobe analysis (EMA), electron spectroscopy for chemical analysis (ESCA), or Rutherford backscattering (RBS) are favored, especially since RBS is capable of quantitative analysis of composition, thickness, and depth profile of thin films. RBS is the energy analysis of ions backscattered from the surface. Ions with low mass (e.g., He^+) are accelerated toward the sample and are backscattered with an energy E_1 at an angle Φ_0 resulting from the energy and momentum

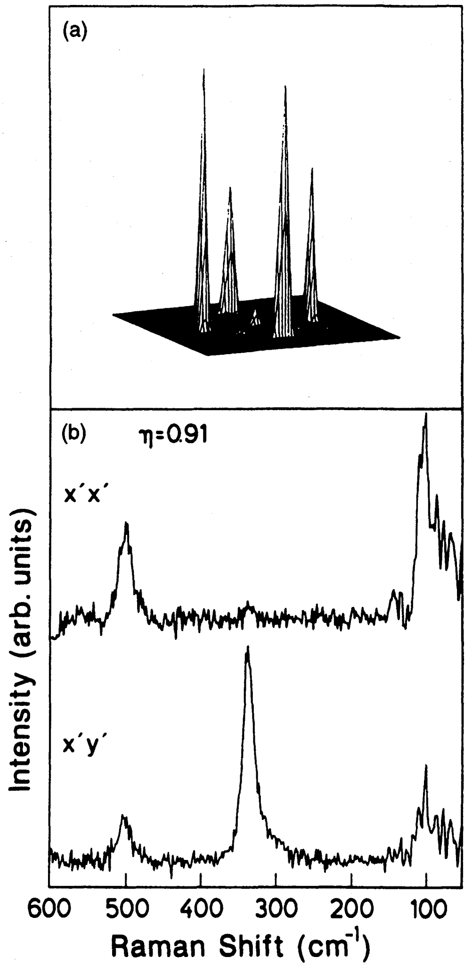

FIG. 11. X-ray (103) pole figure and Raman spectra of an epitaxially grown Y-Ba-Cu-O thin film measured in two different polarization configurations to determine the degree of epitaxy.

conservation laws for scattering. The concept of close-impact scattering collisions implies that it is independent of features of the electron shell and the chemical bonding; thus RBS is not sensitive to the electron configuration and bonding states. This simple scattering concept allows RBS to sort out the various masses of a sample and thus determines the sample composition. Applications include compositional analysis, depth profiling, and interdiffusion studies. A rigorous treatment of RBS is given by Chu *et al.* (1978). Recently, Chu and Langouche (1993) gave a review on quantitative RBS analysis in thin films including channeling phenomena to analyze lattice disorder as well as the location of impurity atoms.

Electron microprobe analysis is based on the detection and measurement of characteristic x rays of material excited by energetic electrons. The essential feature is the localized excitation of a small volume of the sample with a finely focused electron beam and the detection of the x rays as demonstrated in Fig. 12. When suitable standards are available, even a quantitative analysis can be carried out. Feldman and Mayer (1986) give a comprehensive introduction into the details of microprobe analysis.

3.2 Analysis of Mechanical Properties

3.2.1 Stress Measurements There are three categories of measurements used in practice for stress measurements:

1. measurement of substrate bending,
2. mechanical resonance techniques, and
3. x-ray or electron-diffraction techniques.

In static methods based on substrate bending, the thin film of thickness t is deposited on a substrate in the form of a rectangular strip or a square plate. When the substrate of length L and thickness d is fixed at one end (cantilever beam), the stress in the film causes a strain in the substrate, and a displacement of the free end, δ, occurs that is measured by interferometric, electromechanical, or capacitive techniques. The stress is calculated from the displacement, and for cases where the film thickness is much less than the substrate thickness, the stress σ is determined by the Stoney equation

$$\sigma = E_s d^2 \delta / 3(1 - \nu) L^2 t, \qquad (16)$$

where E_s is the Youngs modulus for the substrate and ν the Poisson's ratio for the substrate.

Mechanical resonance techniques rely on the fact that the resonant frequency of a membrane is a function of both its mass density and its stress, which together determine the speed of sound in the membrane. The resonant frequency f of a film/substrate combination is given by

$$f = \frac{C}{R} \left\{ \frac{\sigma_f t + \sigma_s d}{\rho_f t + \rho_s d} \right\}^{1/2}. \qquad (17)$$

Here, C is a constant related to the mode of vibration, R is the radius of the circular membrane, and ρ_i the mass densities of film and substrate, respectively.

Electron-diffraction and x-ray diffraction methods can be used to measure changes in lattice spacing and hence stresses in thin films. In cases where the crystallite sizes are less than 100 nm, the diffraction lines are broadened as described by the Scherrer formula [see Eq. (15)], and a distinction between crystallite size broadening and stress-induced broadening is complicated. Hoffman (1966) has published an extensive review of the literature dealing with stress measurement, and the various methods for macrostress and microstress determination are examined critically. A more recent review by Clemens and Bain (1992) especially treats problems associated with stress measurements by x rays.

3.2.2 Measurement of Thin-Film Hardness Hardness of a material is defined as the resistance to deformation and is usually measured as the permanent deformation of a surface by a specifically shaped indenter under a given load. Usually micro- or nanoindentation is used; here, a diamond indenter is driven into and removed from a film while the load on and displacements of the indenter are measured. Figure 13(a) shows schematically the physical processes involved. As the indenter is driven into the film, both elastic and plastic deformations occur. The plastic deformation results in a permanent impression with the contact

depth h_c. The elastic deformation during the exertion of the load causes the bending of the film surface at the edge of the contact by h_s. In a load–displacement curve [see Fig. 13(b)] the relevant quantities $P_{\max}$ and $h_c = h_0$ are revealed. This allows the determination of the hardness as defined by

$$H = P_{\max}/A. \tag{18}$$

The contact area A is determined by evaluating the area function $A = F(h_c)$ at the depth h_c. A recent review by Pharr and Oliver (1992) highlights physical and practical problems with nanoindentation.

3.2.3 Measurement of Thin-Film Adhesion On a microscopic level the removal of a film from the substrate consists in breaking of the bonds of individual atoms of the film and the substrate. The macroscopic adhesion is therefore a summation of the individual forces. There are a large number of adhesion tests available, as reviewed by Mittal (1987), ranging from tape methods—classical "Scotch-tape test"—to tensile pull tests using wires bonded to the film to be tested, scratch tests, abrasive, and deceleration methods in an ultracentrifuge. Whereas the simple Scotch-tape test reveals only qualitative information, especially for poor adhesion, the tensile pull test allows a more quantitative access to the adhesion forces. A good survey of test methods and their limitations is given in the article of Campbell (1970); Mattox (1994) recently gave a comprehensive review of adhesion measurements.

3.3 Analysis of Optical Properties

Optical probes for analyzing film properties [interferometry (see INTERFEROMETERS AND INTERFEROMETRY), reflectometry, ellipsometry (*q.v.*), and light scattering] have the advantage of directly measuring the complete film/substrate system. Additionally, they are often used as *in situ* real-time analytical probes during the deposition process.

Ellipsometry, e.g., is widely used to characterize the optical properties correlated with the pseudodielectric function $\langle\epsilon\rangle$ (cf. Sec. 2.1). The components of the complex refractive index, n and k, as well as the film thickness can be determined from the measurements of the ellipticity. Furthermore, in spectroscopic ellipsometry where $\langle\epsilon(\omega)\rangle$ is measured, the dispersion of $n = n(\omega)$ as well as $k = k(\omega)$ is accessible. In practice, problems arising from inhomogeneous thin films, rough surfaces, or film stacks on a substrate can be solved by the variation of film parameters and minimizing the deviations from the measured ellipsometric curves. A comprehensive recent review of *in situ* ellipsometry is given by Irene and Woollam (1995) as well as by Snyder (1995).

In contrast to spectroscopic ellipsometry for thin-film analysis, other techniques like Fourier-transform infrared spectroscopy (FTIR), photoluminescence (PL), and Raman spectroscopy play a less dominant role. In FTIR the measured absorption sensitively depends on the presence or absence of impurities in the thin film. A classical example is oxygen in silicon, where the 9-μm band absorption is the fingerprint of interstitial oxygen in the material. In the case of diamond-like amorphous carbon (DLC) films, whose hardness and electrical insulation are believed to depend on the ratio of sp^2 to sp^3 bonding structures, FTIR is an extremely valuable tool to determine the absorption lines of the corresponding stretching bonds.

Photoluminescence is a simple nondestructive technique for the evaluation of the optical properties of semiconductors. Here, electrons are photoexcited from the ground state in the valence band to the conduction band, and a combination of thermalization and radiative recombination occurs, revealing details of the band structure as well as the position of defect levels in the band gap—as long as the transitions are radiative. Impurity-level determination and impurity identification are the most prominent applications of this technique, as reviewed by Nishino *et al.* (1985).

3.4 Surface Analysis

3.4.1 Diffraction Methods In addition to the x-ray diffraction techniques already covered in Sec. 3.1, special cases of x-ray diffraction such as grazing-incidence x-ray diffraction (GIXRD) are used for surface-specific analysis. The techniques based on GIXRD require a bright x-ray source and, usually, access to a synchrotron facility.

Electron-diffraction techniques, on the other hand, can be used as *in situ* real-time analytical tools and do play a much larger role in thin-film analysis. Low-energy electron diffraction (LEED) and reflection high-energy electron diffraction (RHEED) require UHV environment. In LEED electrons of energy 30–150 eV impinge on the sample at normal incidence; the backward-diffracted electrons provide information on the atomic geometry of the top layers of the film. In many ways LEED is analogous to the classical XRD with the addition of high surface sensitivity. It is important to recognize that LEED patterns reveal the periodicity of atoms at the surface as well as the overall symmetry of the surface and not the detailed atomic position. Changes in periodicity of the atom arrangement at the surface result in changes of the diffraction pattern that are easily observable and can readily be interpreted in terms of the new two-dimensional symmetry.

RHEED, on the other hand, is a grazing-incidence reflection technique with a primary electron beam of 10–40 keV. The diffracted pattern is formed on a screen opposite to the electron gun. It is worth mentioning that the probing depths of the two techniques, RHEED and LEED, are quite comparable. This is because the energy E_p normal to the surface to be analyzed is $E_p = E_0 \sin\phi$, with ϕ being the angle of grazing incidence. In addition to the detection of the atomic configuration of the crystalline surfaces, RHEED has the advantage of being able to provide information on surface disorder, defects, and surface topography including roughness, surface facets, and step arrays. Since RHEED is sensitive to topography, it can be used to distinguish between three-dimensional island clustering and two-dimensional layer-by-layer growth in an *in situ* experiment. In the past years RHEED has been the indispensable diagnostic tool for *in situ* deposition control for atomic layer-by-layer molecular-beam epitaxy for semiconductor superlattices, high-temperature superconductors, and colossal magnetoresistance materials. Superstructure modulation, occurrence of twinning, and time-dynamic features such as structural phase transitions can be revealed by RHEED. Bozovic and Eckstein (1995) recently reviewed the application capabilities of RHEED for the analysis of growing films of complex oxides. Lagally and Savage (1993) treat the possibilities and limitations of quantitative electron diffraction by thin films.

3.4.2 Scattering Methods In contrast to the diffraction methods, where the wave nature of particles is applied, in scattering methods, the particle character is used. Some inconsistencies—especially in texture analysis and determination of degree of epitaxy—in comparisons of different methods—e.g., x-ray diffraction and Raman scattering—can be explained by this. Methods sensitive to probing the structure and composition of the surface of a film are based on the interaction of a particle beam (photons, electrons, ions) with the material to be analyzed and the detection of energies and intensities of the emitted beam. The penetration depth of the incident beam together with the escape depth of the emitted particles determines the surface sensitivity. The energy provides the signature of the scattering atoms; the intensity gives the amount of atoms probed. The concept of physics used in these techniques is the inner–electron-shell vacancy formation by irradiation [x-ray photons for x-ray photoemission spectroscopy and x-ray fluorescence (XRF) spectroscopy, electrons for Auger emission spectroscopy (AES) and electron microprobe analysis]. The excited atoms release their energy either by radiative transitions with the emission of x rays (XRF, EMA) or by nonradiative transitions with the emission of electrons (AES). In general, these techniques are extended probe-beam techniques; however, several of them are available as scanning-beam techniques capable of spatial resolutions down to the micron size. There is an impressive multitude of techniques available for thin-film surface analysis. Nearly all combinations of particles are used, and a myriad of acronyms can be found in the literature. The main methods generally used in thin-film analysis can be classified into two categories:

1. identical particles for incident and emergent beam, and
2. incident beam is different from scattered beam.

In Table 4 the most popular of these are listed, indicating the processes involved and giving some average values for probing depth

Table 4. List of volume-averaging techniques for surface analysis, indicating the effective probing depth and surface monolayer sensitivity.

Method	Particle in	Particle out	Acronym	Effective probing depth	Monolayer sensitivity
Auger-electron spectroscopy	Electron	Electron	AES	2 nm	10^{-1}
Rutherford backscattering	Ion (α-particle)	Ion (α-particle)	RBS	~10 nm	10^{-4}
X-ray fluorescence spectroscopy	X ray	X ray	XRF	~1000 nm	none
Photoelectron spectroscopy	X ray	Electron	XPS	~3 nm	10^{-1}
Electron microprobe analysis	Electron	X ray	EMA	~1000 nm	none
Secondary-ion mass spectroscopy	Ion	Target ion	SIMS	~1 nm	10^{-5}

and surface sensitivity. For thin-film analysis AES, Rutherford backscattering (RBS) (see Sec. 3.1), and secondary-ion mass spectroscopy (SIMS) are the most widely used techniques.

In AES the Auger-electron transitions appear as small features superimposed on a background of secondary electrons; consequently, derivative techniques are used to generate a function $dN(E)/dE = f(E_0)$, with E_0 being the energy of the impinging electron beam. Typical values for E_0 are several keV; the detection limit for AES is around 0.1 at.%. AES is widely used for studying surface reactions, surface contaminations, and depth profiles. For this purpose a sputtering gun has to be implemented into the system for layer sectioning. One of the advantages of AES is its sensitivity to low-mass atoms, e.g., carbon, nitrogen, and oxygen, which are typical contaminants at surfaces and interfaces.

Secondary-ion mass spectroscopy is based on the erosion of the sample by energetic ion bombardment, and the relative abundances of the sputtered species give a direct measure of the composition of the layer removed. SIMS (as well as its advanced counterpart secondary neutral mass spectroscopy, SNMS) is used for surface and depth concentration analysis of thin films and superlattices. The problem in all depth-profiling techniques using film sectioning by sputtering is the accurate determination of the depth axis, which is usually done by measurements of the resulting crater depth and converting a time scale to a depth scale. It is beyond the scope of this article to review these methods critically in further details; the reader is referred to the book of Feldman and Mayer (1986) and special monographs like the article of McGuire (1994).

3.4.3 Scanning Probe Microscopy The methods mentioned above cannot detect surface inhomogeneities over atomic distances. Scanning probe microscopy based on the scanning tunneling microscope (STM) invented by Binnig *et al.* (1982) closes the gap to atomic resolution. An atomically sharp tip biased with respect to the sample is positioned in a proximity distance of less than 1 nm from the surface of the sample. Electrons from the tip can tunnel into empty states of the sample, and a tunneling current is generated, increasing exponentially with decreasing distance. This exponential dependence is controlled by piezoelectric transducers; a three-dimensional set of piezoelectric transducers allows the corresponding movements with a resolution of around 0.1 nm. This method allows a two-dimensional representation of the sample surface with atomic resolution. The method relies on the fact that electrons can tunnel into empty states in the film to be analyzed. This is fulfilled in the cases of metals and most semiconductors, but not for insulators. For surface analysis of insulators with a resolution close to the atomistic, repulsive, and/or attractive forces exerted from the film to the tip are used. This type of instrument is called atomic-force microscope (AFM) since its functional principle makes use of van der Waals forces between tip and film. This concept is realized when the tip is fixed on a cantilever, whose deflection upon scanning is measured either by an STM—this was the original version of Binnig, Quate, and Rohrer—or by optical systems using deflection techniques. Tremendous progress has been made in developing other noncontact near-field surface characterization techniques in the past ten years.

For thin-film analysis the superior capabilities of scanning tunneling microscopies have been recently added to the more volume-averaging techniques discussed in the previous sections. These microscopies extend the resolution range beyond high-resolution scanning electron microscopy while adding the capability of obtaining three-dimensional atomic or unit-cell details without extensive and destructive sample preparation required, e.g., for transmission electron microscopy (TEM).

For film growth and surface morphology as well as tribology and hardness/friction studies of thin films, STM analysis is a vital tool because of its combination of extremely high vertical resolution and local nonaveraged details. In fundamental studies of film growth (e.g., high-temperature superconductors, ferroelectric as well as colossal-magnetoresistance thin films), STM and AFM analysis of the substrate surface and the early stages of film deposition play a crucial role in closing the gap between fundamental understanding at an atomic scale and macroscopic properties. Raistrick and Hawley (1994) review recent results of studies of the microstructure of Y-Ba-Cu-O thin films deposited on various oxide substrates and relate the nucleation and growth process to film properties. Special growth-related features, known as growth spirals—a terrace-type layered structure with unit cell height—have been demonstrated to affect the physical properties (e.g., transport, flux pinning) of the films dramatically. Recently, Haage *et al.* (1996) have demonstrated a substrate-mediated defect tailoring in Y-Ba-Cu-O thin films by a careful STM investigation of the relation of substrate preconditioning and film growth.

Scanning probe techniques for thin-film analysis will be one of the indispensable diagnostic tools in the future to bridge the gap between fundamental understanding of substrate conditioning, thin-film nucleation, and film growth on an atomic scale and macroscopic thin-film properties.

GLOSSARY

Adhesion: Ability of a film to stick mechanically on top of a substrate. The thermodynamic work of adhesion, defined as the energy to separate unit area of the two bonded surfaces, and the theoretical strength of the interface (maximum stress in a stress/displacement curve) are used for a quantitative description of adhesion.

Antireflecting Coatings: Reduction of the optical reflection of a substrate (e.g., glass) by depositing one or several dielectric thin films with alternating high and low refractive index materials.

Deformation Map: Stress/temperature diagram identifying the different regions where a particular strain relaxation mechanism (e.g., grain-boundary diffusional creep, dislocation climbing, dislocation gliding) is dominant.

Delamination: Peeling of thin films due to localized breaking of bonds in highly stressed regions of the film/substrate interface; typically at the tip of a propagating crack.

Dielectric Function: In cases where the tensor nature of the complex, second-rank dielectric tensor $\epsilon_{ij}(\omega)$—which couples the electrical-field vector to the Fourier transform of the electric-displacement vector—is not important, $\epsilon_{ij}(\omega)$ reduces to $\epsilon(\omega)$; $\epsilon(\omega)$ is known as dielectric function.

Epitaxial Thin Films: Single-crystal–type thin films grown on a single-crystal substrate with crystallographic relations between substrate and film.

Hardness: Ratio of the peak load and the projected contact area in a microindenter experiment. The measurement method consists of the continuous recording of the indentation load and displacement in a complete cycle of loading and unloading.

Intrinsic Stress: Summarizes the mechanical stress in thin films not due to the difference of thermal expansion coefficients of film and substrate. In general they have a microstructural origin. Examples are interfacial stress in heteroepitaxy, stress due to phase transitions occurring between deposition temperature and room temperature.

Microstructure: Structure of a material at the atomic level including compositional ordering, chemical bonding, presence/absence of impurity atoms as well as point (vacancies, interstitials), line (dislocations), and planar (grain, tilt, twist boundaries) defects.

Polycrystalline Thin Films: Thin films with a random orientation of the crystallites.

Pseudodielectric Function: Dielectric function of a complex, film-covered surface. In contrast to the dielectric function, the pseudodielectric function includes effects due to differences in film density, surface roughness, composition, and microstructure.

Raman Scattering: Inelastic scattering of photons by elementary excitations such as optical phonons, magnons, or plasmons.

Refractive Index: Complex quantity used to describe the macroscopic optical properties of an isotropic medium. The real part is usually referred to as the refractive index; the imaginary part is usually called extinction coefficient.

Textured Thin Films: Films where one crystal axis of the grains show a crystallographic relation with the substrate, while the others are random.

Thermal Stress: Mechanical stress in thin films arising during variations of temperature due to the difference in thermal expansion coefficients of film and substrate.

X-ray Optical Components: Development of optical components (mirrors, lenses) for extreme UV and soft x rays using material combinations with high and low electron density.

INTRODUCTION

Thin-film deposition is the process of placing a thin layer of one substance on another in order to modify the properties of the second material—e.g., to increase hardness—or to change electrical conduction or to modify the optical properties of the underlying material referred to as the substrate. The film itself may also have useful properties of electrical conduction, optical reflectivity or absorption, or corrosion resistance. Thin films have become a significant part of microelectronic circuitry by virtue of their small size, i.e., their nearly two-dimensional nature, and, of course, this permits the fabrication of very small device structures, or microcircuits. However, thin films have many features other than size that make them useful in electronic applications; viz., a large variety of methods for deposition exist that can be quite efficient in the usage of material. Also, many of these deposition methods utilize a vacuum environment, which allows very high purity to be obtained in the resulting film; and finally, it is fairly straightforward to deposit multiple layers of different materials to produce composite films with properties not possessed by any of the components alone. In some very important cases, the high purity of the deposition environment combined with cleaning of the substrate permits the films to be deposited with a single-crystalline structure that "fits" on the crystal structure of the substrate, a process called "epitaxial growth."

We begin by defining more specifically what is meant by a thin film. In electronic applications distinction is made between "thin" and "thick" films. A thin film is a layer of material that is typically less than a few micrometers in thickness, while a thick film could be as much as a millimeter in thickness. The principal distinction, however, lies in the deposition process. Thin films are deposited by the addition of atoms or molecules to the substrate, while thick films are deposited as particles, usually contained in a liquid suspending medium. Thick films are typically applied by painting or spraying, which might be followed by a firing process to decompose or fuse the binder material. In this discussion we consider only thin films. Thin films are most often applied in a closed chamber, frequently under vacuum conditions, either by a physical process such as thermal evaporation of the film material or by a chemical process in which a vapor species is chemically or thermally decomposed

on the surface to be covered. We also consider some methods of thin-film deposition from liquid solutions.

Films may be amorphous in structure or display varying amounts of atomic order, at least locally. They are often composed of microcrystals and in some cases may consist of very large (in two dimensions) single-crystal grains. Films with crystalline order may have a structural relationship with the substrate on which they are deposited. A polycrystalline film that shows an ordering of the microcrystals with respect to the crystalline structure of the substrate is often called an ordered polycrystalline film as opposed to a randomly ordered film. For many electronic applications where the film may be carrying an electrical current, the scattering of carriers at grain boundaries may be intolerable, and consequently it is necessary to minimize the scattering centers by constraining the film to grow as a large, thin single crystal.

In semiconductor devices, thin films are used to form the conducting lines connecting individual devices, as well as the contact pads to which are bonded the wires that connect the circuit to the packaging structure. They are also used to form insulating layers to isolate conducting films from the underlying device structure. In many cases, part or all of the active device may be composed of a single crystal of semiconductor material deposited epitaxially on the underlying supporting substrate, in order to provide semiconductor material with properties not available from the bulk substrate crystal. In brief, thin-film technology is an essential component of microcircuit fabrication, and advances in circuit complexity have progressed in step with advances in our understanding of how to control the deposition and properties of thin films. See Smith (1995) and Campbell (1996) for a more complete discussion.

Thin films have been extremely important in developing an understanding of surfaces and interfaces. Because of the essentially two-dimensional nature of films, many of the properties are dominated by the proximity of interfaces. Consequently, films have provided experimental access to changes in the surface environment. Perhaps one of the most dramatic demonstrations of thin-film science has come from the electronic properties of "quantum wells," i.e., the properties of thin films that have one or more dimensions smaller than the wavelength of the electrons in the film. These "low-dimensional structures" show clearly the transition from a continuum of energy states to discrete, quantized electronic states in the optical and transport properties (Allan *et al.*, 1986).

Much of the recent scientific interest in films has come from the increasingly sophisticated and powerful array of analytical techniques for examining the atomic structure of thin films. Electron, ion, and photon spectroscopic techniques, discussed by Feldman and Mayer (1986), identify the chemical composition and bonding state of atoms in films with extremely high spatial resolution, while the new tunneling probe microscopies display the atomic microstructure. These techniques have provided a much better understanding of the nature of thin films and have played a crucial role in optimizing the methods for their deposition.

The present discussion is limited to an overview of methods for depositing thin films, with an emphasis on those used in the fabrication of electronic devices. The properties of films will be considered only as they are influenced by the method of deposition. Readers wishing more detailed discussion are encouraged to consider the suggestions in the Further Reading list appended to this chapter.

1. ESSENTIALS OF VACUUM TECHNOLOGY

Before considering deposition *per se,* we discuss some elementary aspects of vacuum technology, since the vacuum environment is essential to most methods of deposition (O'Hanlon, 1989). Except in a few notable instances that are discussed, high-purity films are deposited in vacuum, and, most generally, in ultrahigh vacuum (UHV), which we define as a pressure lower than 1×10^{-7} Torr. The reasons for this are evident from a discussion of elementary gas kinetics.

Since a typical solid contains $\sim 10^{22}$ atoms/cm^3, a surface has an atomic density of $\sim 3 \times 10^{14}$ atoms/cm^2, i.e., the volume density raised to the $\frac{2}{3}$ power. It can be shown from fundamental gas-kinetic theory that the number n of gas atoms impinging on unit area of surface in unit time is

$$\frac{dn}{dt} = \frac{P}{\sqrt{2\pi mkT}}, \tag{1}$$

where P is the gas pressure, m is the atomic mass, k is the Boltzmann constant, and T is the absolute temperature. Equation (1), the Knudsen equation, is extremely important in thin-film physics, because it permits a comparison of the rate of deposition with the rate of contamination from the residual gas in a vacuum system. For example, if the vacuum pressure P is measured in Torr and if the atomic mass m is converted to molecular weight M in grams, then Eq. (1) becomes

$$\frac{dn}{dt} = 3.5 \times 10^{22} \frac{P}{\sqrt{MT}} \quad \mathrm{cm}^{-2}\,\mathrm{s}^{-1}. \tag{1a}$$

For a typical residual gas molecular weight of 40 g and a temperature of 25°C, the rate of gas arrival is $3.2 \times 10^{20} P(\mathrm{Torr})$, and for a pressure of 10^{-6} Torr the arrival rate is $3.2 \times 10^{14}\ \mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. In other words, the arrival rate at 10^{-6} Torr is just about equal to the number of atoms in a square centimeter of surface. Thus it takes only a second to completely cover an initially clean surface with residual gas, assuming all of the arriving atoms or molecules remain on the surface. The pressure of 10^{-6} Torr is a fairly representative ultimate vacuum attained in typical diffusion-pumped systems that are opened frequently to insert substrates for film deposition—for example, bell-jar systems used for thermal evaporation of metal films for circuit metallization. The cautionary point is that the rate of deposition must be orders of magnitude faster than the contamination rate in order to avoid impure films. This requires either better vacuum or high rates of supply from the film source.

In order to improve the vacuum, we need to consider what limits the vacuum in a system. The rate of change of pressure in a continuously pumped chamber is given by

$$V\frac{dP}{dt} = -PS + G \quad \mathrm{L\ Torr/s}, \tag{2}$$

where P is the pressure in Torr, V is the volume of the chamber, S is defined as the speed of the pumping system, and G is the generation rate of gas from various sources within the system. When G is small compared to P, e.g., at the beginning of the pump-down cycle, Eq. (2) predicts that the pressure will decrease exponentially with time with a time constant V/S. The ultimate pressure limit is reached when the rate of removal of gas, PS, is equal to the generation of gas, G, and the ultimate pressure is

$$P = G/S. \tag{3}$$

Obviously, reducing the generation rate G and increasing the pumping speed S will both act to lower the ultimate pressure obtainable.

The need for improved vacuum in thin-film technology has been a major driving force in the development of improved pumping systems. Today there are many choices of pumping schemes, including diffusion pumps, ion pumps, turbomolecular pumps, and cryopumps, for achieving vacuum less than 10^{-6} Torr (see VACUUM TECHNOLOGY AND INSTRUMENTATION). Cryopumps in particular feature very high pumping speeds, since they are based on the principle of providing a large cold surface that effectively condenses all arriving gas molecules. One application of cryopumps is in the coating of automobile bumpers with chromium or aluminum films. In this instance, the vacuum system is designed for very high throughput of material—essentially a moving assembly line—and large cryopumps provide the extremely high pumping speed to deal with the heavy gas load. Each type of pumping technology has advantages and disadvantages, and the reasons for the possible choices are discussed in detail in references in the Further Reading list.

The other approach to improved vacuum lies in reducing the gas generation rate. There are two ways in which to accomplish this. The straightforward approach is to raise the temperature of the entire vacuum chamber for a prolonged "bakeout" to desorb gas from all the interior surfaces of the vacuum system, and this is essential to achieve pressures in the 10^{-10}–10^{-11} range. Once the internal walls of a vacuum system are clean, it is possible to insert and remove substrates without recontaminating the system by the addition of a vacuum interlock system in which an intermediate chamber is used to load, pump down, and outgas the substrates prior to insertion in the hard vacuum. This approach requires additional hardware, valves, and pumps but is increasingly useful in the electronic industry where rapid throughput and high vacuum standards are both necessary (Hablanian, 1990).

The question of the vacuum necessary to avoid contamination of thin films from the residual gas depends to a great extent on what level of contamination can be tolerated. For instance, an Al film used for metallization of an integrated circuit might be evaporated onto a substrate in a vacuum of 10^{-6} Torr at a rate of 0.33 μ/min, which is about 20 atom layers per second. From the discussion above, we might expect that as much as 5% impurity might be found in the film, since about one atom layer of impurity per second comes from the residual gas. Actually, since much of the residual gas in the deposition system would consist of fairly inert species such as N_2 that do not adsorb readily, it is highly unlikely that the impurity content would be this great, but even if it were, this would not seriously affect the quality of the film, since the metallic conduction would not be drastically impaired. On the other hand, deposition of a semiconductor film under similar conditions would be impossible because that level of contamination would completely overwhelm the desired semiconducting properties of the film. We know that a good semiconducting film should have an impurity level $<10^{-6}$. To decrease the impurity level by a factor of 5×10^4 means a similar reduction in background pressure to less than 10^{-10} Torr. Thus while high vacuum may be adequate for the deposition of metals, UHV will be necessary for semiconductors.

2. TECHNIQUES FOR DEPOSITION OF THIN FILMS (Ohring, 1992; Campbell, 1996)

Methods for the deposition of thin films can be conveniently divided into two classes: physical deposition techniques, in which atoms or molecules of the source material are vaporized by physical processes such as thermal evaporation or by bombardment from an energetic beam of electrons, photons, or ions; and chemical deposition techniques, which rely on a chemical reaction involving one or more vapor species incident on a substrate to produce a film of the desired composition. Physical deposition is typically carried out in vacuum to avoid contamination of the film by the ambient atmosphere, while chemical deposition often utilizes an inert carrier gas, and may even be carried out at atmospheric pressure.

The steps of film deposition are as follows:

1. Generation of a supply of atoms or molecules from a source, which may be solid, liquid, or vapor. This is accomplished by supplying energy to the source in the form of heat or incident energetic particles or from chemical reaction.
2. Transport of the constituent atoms or molecules to the substrate. From a technological point of view, this is a crucial part of the deposition, because the manner of transport will determine the uniformity of coverage of the substrate. In integrated-circuit fabrication, uniformity of thin films becomes much more difficult to achieve as the size of the substrate wafer increases. The deposition geometry that provided 2% uniformity across a 100-mm wafer is not adequate for the new 300-mm wafers just coming into production.
3. Deposition of atoms or molecules on the substrate. The condition of the substrate surface is the key issue in this phase of the process. If the substrate surface is contaminated with a fraction of a monolayer of impurity atoms, the surface mobility of the arriving film atoms may be reduced to an extent that the crystal orientation of the film bears little relationship to that of the substrate, and the film is polycrystalline. Conversely, if the substrate surface is essentially clean, the arriving film atoms are likely to adsorb in sites related to the substrate orientation, and the film may be oriented or even epitaxial.
4. Postgrowth treatment. In this phase of the process, a prolonged annealing of the film at elevated temperatures may yield a film with superior properties as a result of crystal grain growth in the film.
5. Postgrowth analysis. Modern film analytical techniques have been critical in improving the deposition parameters to in-

crease the quality of the film, in terms of either structure or purity, or both.

3. PHYSICAL METHODS OF DEPOSITION

Physical deposition is a process for transferring atoms or molecules from a source to a substrate that relies on physical methods to produce the vapor species. We consider some typical physical deposition processes along with their advantages and disadvantages. For the time being, we will not be concerned with the ordering of the deposited film, since for a large number of applications, a polycrystalline film is entirely adequate and generally is much simpler and more inexpensive to produce.

3.1 Vacuum Evaporation

Vacuum evaporation is possible for a large range of materials, particularly metals, except for the refractory metals with very low vapor pressures. By heating the material source, such as a crucible containing an Al charge, the vapor pressure of the charge is raised to the point that sublimation or evaporation occurs, depending on whether the charge is solid or molten. The relevant physical constraints are that since the deposition usually occurs in a conventionally pumped vacuum chamber where the base pressure is ~10^{-6} Torr, and since the deposition rate should be large compared to the rate of contamination from the background, the vapor pressure must be large enough to provide a sufficient flux at the substrate; i.e., the pressure of the source material at the substrate must be ~10^{-5} Torr. (We note that in fact there is not an equilibrium pressure of atoms at the substrate but rather a unidirectional flux; however, for simplicity we describe the flux in terms of an effective pressure.) It can easily be shown by geometrical argument that the effective pressure at a substrate a distance L from a source of area A is related to the vapor pressure at the source P by

$$P_{\text{eff}} = PA/4\pi L^2; \tag{4}$$

consequently, for a 1-cm^2 source 10 cm from a substrate, the pressure at the substrate is reduced by a factor of more than 1000. Thus the source temperature should be high enough to provide a vapor pressure of $>10^{-2}$ Torr. From data on the vapor pressure of Al given by Honig (1969), this would require an evaporation temperature of ~1200 °C.

While the discussion above suggests that rather high deposition rates are required to obtain adequate purity of metal films, in actual fact a metal such as Al is highly reactive, and the film deposition occurs over a large area of the vacuum chamber. The reactive Al film acts as a "getter pump" and quickly reduces the reactive gas concentration in the system. Consequently, adequately pure films can be obtained at lower growth rates; however, for convenience it is desirable to have growth rates of ~0.1 to 1 μm/min.

The rate of deposition can be obtained from Eqs. (1) and (4); and using the fact that the increase in thickness per unit area, R_t, is just the rate of mass increase divided by the density ρ leads to

$$R_t = \sqrt{\frac{M}{2\pi k\rho^2}}\left(\frac{P_c}{\sqrt{T}}\right)\frac{A}{4\pi L^2}, \tag{5}$$

where P_e is the equilibrium vapor pressure at the temperature T and M is the molecular weight. Written in this way, it is evident that the first term is material dependent, the second term is temperature dependent, and the third term is geometry dependent. From Eqs. (1a) and (4), with vapor pressure in Torr, this simplifies to

$$R_t = 4.62 \times 10^{-3}\frac{\sqrt{M}}{\rho}\frac{P_e}{\sqrt{T}}\frac{A}{L^2} \text{ cm/s}. \tag{5a}$$

For Al at 1200 °C with a vapor pressure of 10^{-2} in the geometry described above, this results in a deposition rate of 5×10^{-5} cm/s or 3 μm/min. The example is somewhat unrealistic because the distance between source and substrate would be significantly larger in a production evaporator, with a consequent reduction in deposition rate.

Uniformity of film thickness is an important issue in the production of integrated circuits. There are two physical limitations to consider. The first limitation is indicated in Eq. (4), namely, that for a point source of atoms, the flux decreases as the square of the distance. The second limitation is that for a source with a finite area, the flux decreases as the cosine of the angle from the normal to the source; i.e., the substrate "sees" a smaller area of source. In a technology in which many wafers are coated simultaneously, the configuration of source and substrates must be arranged so that all the wafers receive the same deposition flux. This can be accomplished by placing the substrates and the source crucible at positions corresponding to points on the circumference of a sphere, the "planetary configuration." In this configuration the substrates that are closer to the source are also located at increasing angle from the normal to the source, so that the distance and angle effects exactly compensate. Rotation of each substrate then insures that the average flux across the wafer is uniform. Runyan and Bean (1990) provide a good discussion of the methods for uniform deposition.

As the diameter of Si wafers increases, the thickness uniformity of films across a wafer becomes the important issue. This may be improved by rotation of the wafer during deposition and by using multiple deposition sources. However, some effort must be taken to determine empirically the exact angular distribution of atom flux from the sources.

A further issue of considerable importance is the step coverage. An integrated circuit is typically etched into mesas and steps, and the metal interconnects must pass over these features without significant reduction in thickness. Without wafer rotation during deposition, shadowing at step edges will cause thinning. Even more of a problem is the coating of holes with high aspect ratio (defined as the depth-to-width ratio). Shadowing is unavoidable in these structures, and the only way to achieve sufficiently uniform coverage is to rely on surface migration of the deposited atoms to regions of lower coverage. As a result, heating of the substrate during deposition is beneficial to improving the coverage; however, for high–aspect-ratio features it is necessary to use other deposition techniques more suitable for filling holes, as is discussed below.

Some metals have such low vapor pressures that they are difficult to evaporate from a resistively heated crucible. Electron-beam evaporators utilize the energy of a beam of high-energy electrons to heat a small portion of a metallic charge held in a water-cooled hearth to a high temperature. In effect, the molten charge is contained in an unmolten container of the same material, a phenomenon sometimes referred to as "skull melting." While this does solve the crucible problem for these metals, nevertheless, the thermal energy radiated from the hot center of the charge can be excessive.

3.2 Sputter Deposition (Vossen and Cuomo, 1978)

In order to evaporate a material it is necessary to heat it to a temperature where it has a significant vapor pressure. Many materials of interest for electronic films have low enough vapor pressures that it is not practical to attempt to evaporate them, as discussed above. For example, the radiant power emitted by a hot source can cause problems with organic films such as the photoresist films used in lithography. Furthermore, increasing the distance between source and substrate is not useful because both the emitted radiant thermal flux and the deposition flux decrease as the inverse square of the distance.

An alternative method of deposition that avoids these problems is the ejection of atoms or molecules from a target bombarded by energetic ions, a process known as sputtering (*q.v.*) (Anderson and Bay, 1981). In the simplest form, sputtering is obtained by generating a beam of inert-gas ions, accelerating the beam to energies of a few keV, and directing the beam at a target composed of the material to be deposited. Atoms or molecules from the target are ejected onto the substrate (Wehner, 1956, 1957). Sputtering can also be accomplished in a diode configuration where the target is biased negatively to attract the positive ions from a glow discharge. Figure 1 shows these two configurations.

Sputtering has a number of advantages:

1. Nearly any thermally stable material can be sputtered, including compounds or alloys where one component may have a much larger vapor pressure than the other. While the evaporated flux from such a material would have a composition very different from the source be-

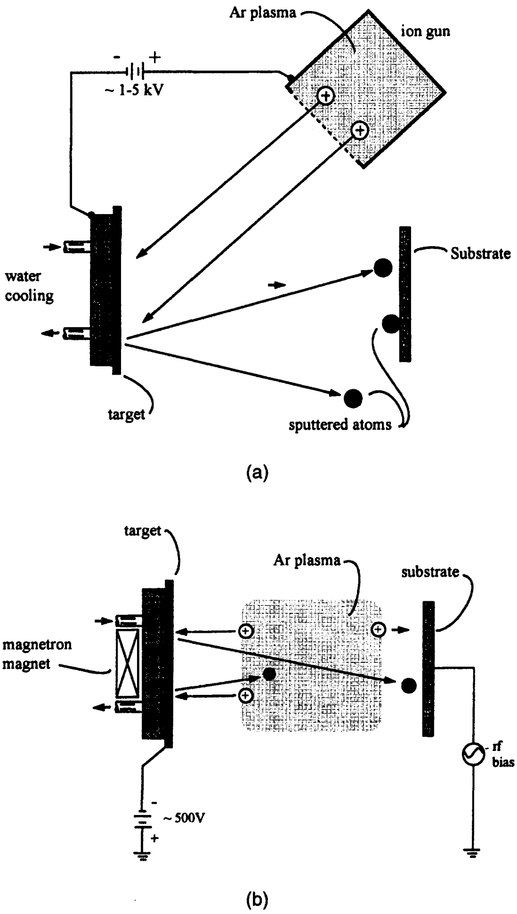

FIG. 1. System configurations for sputter deposition of thin films. (a) Direct ion-beam bombardment configuration. (b) Magnetron diode configuration.

cause of the disparate vapor pressures of the constituents, the sputtered flux from this material after a surface equilibration time will have the same composition as the source target, as shown by Westwood (1989) for example. A simple explanation for this arises from the fact that the sputtering yield from a surface depends only on the immediate surface composition, while the vapor pressures are much more a function of the bulk composition.

2. While the target is heated by the incident ion beam, the power radiated to the substrate is much less than from a hot evaporating source.
3. The arriving atoms or molecules typically have higher kinetic energies than evaporated atoms, which improves step coverage; furthermore, in some methods of sputtering, there may be resputtering of film material on the substrate, which aids in improving step coverage.
4. Particularly for refractory metals or oxides, where evaporation rates are quite low, sputtering can produce reasonable deposition rates.
5. Sputtered films tend to have a finer grain size than do evaporated films.
6. Sputtering targets are readily fabricated by hot-pressed powder sintering; consequently, the composition can be easily controlled.
7. Ion bombardment of the substrate often enhances adhesion of the film.

There are also some disadvantages to sputter deposition of films compared to evaporation:

1. Sputtering requires an inert gas, which must be highly purified to avoid contamination of the film.
2. Sputtered films nearly always contain inclusions of the sputtering gas.
3. There may be ion-bombardment damage of the substrate.
4. Impurities from the fixtures within the system are also sputtered and may be incorporated into the film.

A variety of sputtering configurations are possible, depending on the application, ranging from the ion source–target–substrate configuration discussed above to a parallel-plate configuration of target and substrate where the ions are formed in a glow discharge, as shown in Fig. 1. Most common in manufacturing because of the greater charge density and consequent faster sputtering rate is the planar magnetron, in which the plasma is confined by a magnetic field parallel to the target. Older systems may use a cylindrical magnetron geometry.

A further modification often used to deposit insulating films is called reactive-ion sputtering (Molarius and Orpana, 1991). For example, if a Ta target is sputtered in a mixture of inert gas and N_2, a film comprised of Ta and/or Ta_2N and TaN is produced (Tsai *et al.*, 1992). The exact composition of the film depends reproducibly on the gas composition; thus this technique can be used to produce films of varying electrical resistivity. Reactive sputtering is commonly used to deposit oxides, carbides, and nitrides. It is particularly useful in the deposition of the oxynitrides of Ti, Ta, and Si, where the controlled addition of both oxygen and nitrogen can be used to minimize the tensile stress in the insulating film.

3.3 Ion Plating

Various hybrid techniques combining the best features of both evaporation and sputtering are also common. In one of these, called ion plating by Mattox (1973), a flux of high-energy ions bombards the substrate at the same time that deposition by evaporation is taking place. The ion bombardment assists in cleaning the substrate surface and aids in improving adhesion; at the same time, the "throwing power" or coverage over nonplanar features on the substrate is improved because the evaporating flux is scattered by the inert-gas ambient. The major use of ion plating has been to coat steel and other metals with very hard films for abrasion resistance.

3.4 Ion-Beam Deposition (Harper, 1978)

While less commonly used in manufacturing of integrated circuits, the direct deposition of ion beams onto a substrate has some very useful applications. By ionizing the material to be deposited, focusing the ions into a fine beam, and then directing the beam electrostatically to a desired location, it is possible to deposit small amounts of film material at very precise locations, i.e., to carry out direct "writing" of features. A useful characteristic of this technique is that as the ion-beam energy is increased, the operational mode changes from deposition to ion-beam etching. (At still higher energies, the incident ions become implanted into the target.) Focused–ion-beam systems using field-enhanced ionization from sharpened tips combine the versatility of localized etching or deposition with the optical simplicity of a high-brightness point source of ions. These systems are most generally used for the repair of photomasks or in prototype IC failure analysis. In some cases the ion beam is used to decompose a precursor vapor containing the metal to be deposited as described by Puretz and Swanson (1992).

A different form of ion deposition known as ionized-cluster beam deposition (ICB) has been studied for a number of years by Takagi (1987). In this process an evaporation cell with a small aperture is used to generate a flux of atom clusters, reportedly consisting of as many as 100 metal atoms each. The atom clusters are given a negative charge by a beam of electrons and are accelerated toward the substrate, with the result that each cluster has significant kinetic energy on arrival. It is suggested that this normal kinetic energy is converted to translational kinetic energy on impact, with the result of greater surface mobility and the creation of nucleation sites. While the concept of ICB is interesting, there is much that is not yet clear about the process, including the actual number and size of the proposed clusters, and it has not yet achieved much general acceptance.

3.5 Liquid-Phase Deposition—Langmuir–Blodgett Films (Ulman, 1991; Roberts, 1990)

A very different type of physical deposition takes place when a substrate is dipped into a liquid, usually aqueous, that contains an organic film on the surface. The substrate will adsorb a layer of the film as it is lowered into the solution and a second layer as it is withdrawn. Organic layers that are transferred in this manner from the liquid–gas interface to a solid surface are described as Langmuir–Blodgett (LB) films. The organic molecules that are used in this type of deposition contain two types of functional groups, with one end of the hydrocarbon chain containing an acid or alcohol group, which is soluble in water (hydrophilic), and the other end containing insoluble hydrocarbon groups (hydrophobic). As a result, the molecules form a film on the surface of water (a Langmuir film) with the hydrophilic end at the water side and the hydrophobic end at the air side. Pockels showed that such a film could be compressed to form a continuous monolayer on the liquid (Pockels, 1891; Rayleigh, 1899). Blodgett (1935) subsequently showed that the film adheres to a solid surface passing through the air–water interface.

A unique feature of LB films is the ability to form an ordered structure on a solid surface from a noncrystalline material. When a substrate is passed from the water phase through the film to the air phase (emersion), the hydrophilic group will bond to the solid surface. When the coated substrate is then passed back into the water phase (immersion), the hydrophobic tails in the surface film will bond to the hydrophobic tails exposed on the substrate. This process can be repeated to add additional layers in a head-to-head, tail-to-tail configuration. This type of deposition is described as Y-type. However, if a hydrophobic surface—clean Si is hydrophobic—is passed from air to water, the hydrophobic tails will bond to the surface. The apparatus can be designed to remove the substrate from an uncovered part of the water and reimmerse it in the covered part of the water, thus creating a sequence of head-to-tail layers on the substrate. This method is described as X-type. The significant features are first, that the mode of deposition is easily controllable; second, that the film thickness is precisely controllable in steps of the length of the molecule; and finally, that the X-type depositions are noncentrosymmetric, which has important implications for nonlinear optics applications, as discussed by Gaines (1966). Figure 2 shows the process of Y-type deposition.

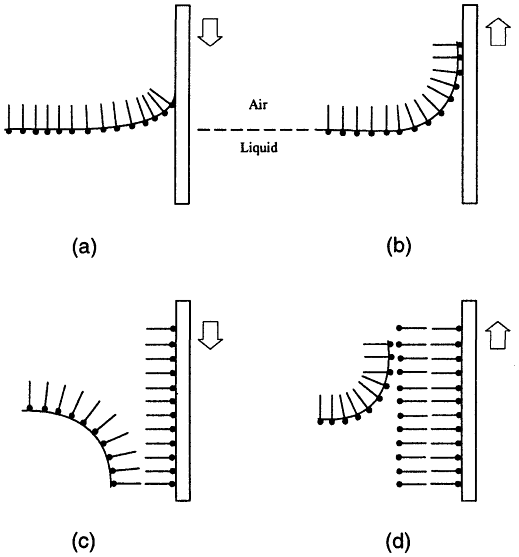

FIG. 2. Deposition of monolayers by the Langmuir–Blodgett method: (a) first immersion, (b) first withdrawal, (c) second immersion, and (d) second withdrawal.

While LB films have a number of potential applications for semiconductor devices, at the present time they are not used in conventional IC manufacturing because they compete with much more mature device systems and processing tools. Questions of long-term reliability have yet to be answered. Applications for which LB films seem to have significant potential include the following:

1. Photoresist technology. LB films can be rapidly and uniformly deposited over large wafer areas at much smaller thicknesses than can conventional spin-on photoresist polymers. Particularly as wafer diameters increase and lithographic features decrease, this could solve problems in photoresist uniformity and resolution.
2. Sensor applications. LB films can incorporate functional groups on the hydrophobic end that react with specific organic or bio-organic molecules. Such films could be incorporated into insulating gates on field-effect transistors or onto quartz crystal oscillators for sensitive measurement of mass change.
3. Flat-panel display applications. LB films have been used in electroluminescent film devices and offer the ability to tailor insulator thickness for optimum performance.
4. Optical devices. A wide range of nonlinear optical materials can be conveniently deposited on appropriate semiconductor substrates by LB techniques. It is easy to envision second-harmonic–generating films on light-emitting diodes and lasers.

The potential applications and recent experiments in this rapidly expanding field are discussed in the book edited by Roberts (1990).

4. CHEMICAL METHODS

Chemical methods of deposition involve a chemical reaction between vapor species containing the element or elements comprising the film. The reaction takes place on a suitable substrate, which may be involved in the reaction. In many cases the substrate acts primarily as a catalyst to mediate the energy involved in the reaction. The energy to initiate the reaction may be thermal or may be provided by rf or optical radiation. Chemical deposition can take place in vacuum or in an ambient consisting of the reactant gases and an inert carrier gas.

4.1 Chemical Vapor Deposition

Chemical vapor deposition (CVD) of thin films occurs when the reacting gas species come in contact with a heated substrate that catalyzes the reaction [see CVD (CHEMICAL VAPOR DEPOSITION)]. The substrate may supply the heat used to pyrolyze the reactant(s), or the entire reaction chamber may be heated. For example, the pyrolysis of silane can be used to deposit Si films (Sherman, 1987):

$$SiH_4(\text{gas}) \leftrightarrow Si(s) + 2H_2(\text{gas}). \tag{6}$$

In fact, this reaction is commonly used in LPCVD (low-pressure CVD) systems operating at ~600 °C and 1–10 Torr to deposit polycrystalline Si used for IC interconnects (Adams, 1985). Deposition rates of some hundreds of angstroms/minute are typical. To make the polysilicon conducting, gases such as diborane, phosphine, or arsine are added to dope the film with B, P, or As, respectively.

Other important CVD reactions are

$$SiH_4(\text{gas})\ O_2 \rightarrow SiO_2(s) + 2H_2 \tag{7}$$

and

$$3SiH_4 + 4NH_3 \rightarrow Si_3N_4(s) + 12H_2 \tag{8}$$

for the deposition of dielectric films.

Refractory metals are difficult to evaporate and are more readily deposited by a CVD process (Schmitz, 1992):

$$WF_6 + 3H_2 \rightarrow W + 6HF. \tag{9}$$

Since CVD reactions are normally carried out at pressures in the range 0.5 to 10 Torr, gas-flow dynamics play a significant role in determining reaction rates and uniformity of the resulting films. A large variety of chamber designs have been used to minimize turbulence and to facilitate the removal of undesirable reaction products (Kern, 1989). We have more to say about CVD under the topic of epitaxial growth. Figure 3 shows some generic reactor schematics.

4.2 Plasma-Enhanced CVD (Lucovsky *et al.*, 1986)

Plasma-enhanced CVD (PECVD) is used extensively to deposit a large variety of films, especially insulators on integrated circuits. Silicon nitride is an important dielectric material used extensively in IC fabrication. At later stages of processing, the circuits are not able to withstand high temperatures. By using a rf plasma to aid in the decomposition, reactions such as that in Eq. (8) can take place with no additional heating of the substrate. Heating by the plasma alone will typically keep the substrate below 300 °C. With the addition of small amounts of N_2O or H_2O, the composition of the dielectric Si_3N_4 can be modified to an oxynitride to minimize the stress in the film.

A recent related approach is to supply energy to the gas mixture by electron cyclotron-resonance (ECR) plasmas, which has the desirable effect of gaining efficient ionization of the source gas at lower pressures, typically 10^{-5}–10^{-3} Torr. This allows efficient deposition with lower power input to the substrate (Herak and Thomson, 1990).

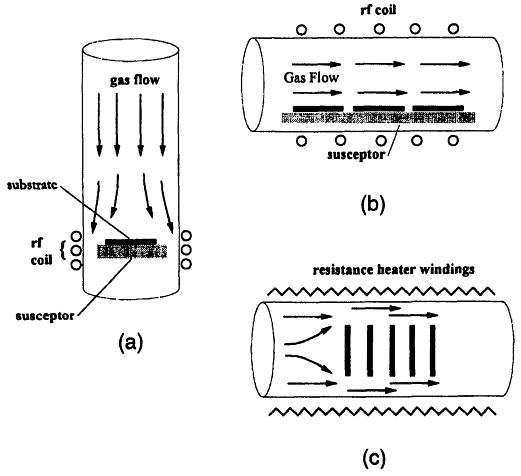

FIG. 3. Generic CVD reactor types: (a) axisymmetric with flow impingement normal to surface, (b) tube furnace with flow parallel to wafer surface, and (c) tube furnace with axial flow.

Finally, decomposition of the reactant gases can be accelerated by use of a focused laser beam, either by a pyrolytic process, in which the substrate is heated by the laser beam, or by a photolytic process, in which the reactants are directly dissociated by energetic photons. This technique is useful for direct "writing" of deposits—e.g., metal lines on prototype circuits. Because direct writing is a slow process, this is not yet a common technique in industry for IC production.

5. EPITAXIAL DEPOSITION

Epitaxy describes the extended single-crystal growth of a film on a crystalline substrate. In early work, the formation and ripening of crystalline nuclei on various substrates such as rock salt was observed and was described as epitaxial growth by Royer (1928); however, such films were highly imperfect on account of defects such as twins formed when the nuclei coalesced into a continuous film. Modern epitaxial films can be extremely perfect depending on the quality of the substrate on which they are grown. For example, growth on whole wafers can be carried out such that the lateral dimensions of the single-crystal film are a few inches while the thickness is only a few monolayers! Epitaxial layers are extremely important in semiconductor devices, because they can be produced with greater purity than bulk material and can provide carrier or potential profiles that are not possible to obtain by other technologies.

Two types of epitaxial growth can be distinguished: *homoepitaxy*, in which the film is grown upon a crystalline substrate of the same material, and *heteroepitaxy*, in which the film and substrate are different. Homoepitaxy has the obvious advantage that the substrate and film have the same lattice constant; provided that the substrate surface is initially clean of contamination, it can serve as a template to facilitate growth of the film as a single crystal. Homoepitaxy is most useful for semiconductor-on-semiconductor growth, in which the film has different properties from the substrate because of a different doping impurity content. For example, the film might have a much lower doping concentration than the substrate. This is not possible to achieve in a diffusion process without carrier compensation, since diffusion must be driven by a larger concentration at the surface.

Heteroepitaxy almost invariably involves mismatch between film and substrate. However, a clean, ordered substrate provides a strongly orienting template for deposited atoms even though this may introduce strain in the film. Various film structures occur depending on the amount of lattice mismatch and the resulting interfacial strain. If the mismatch is small, <0.2%, epitaxial growth can occur without serious difficulty. For larger lattice mismatch, the growth will initially often be "pseudomorphic," in which the film grows with the lattice constant of the substrate, resulting in strain in the plane of the interface. As a pseudomorphic film increases in thickness, the strain energy increases to a point at which misfit dislocations can be generated, leading to a relaxation of strain, with many defects introduced into the film. Frequently, strain relaxation causes the flat, planar epitaxial growth to become rough on an atomic scale. For lattice mismatch >5%, the growth is likely to be relaxed or even polycrystalline (Freund, 1992); however, some growth schemes have been used to accomodate larger mismatch. Figure 4 shows a diagram of the types of epitaxial configurations ranging from lattice matched [Fig. 4(a)] to relaxed mismatched [4(b)] to pseudomorphic mismatched [4(c)]. The pseudomorphic growth [4(c)] also demonstrates the uniaxial compression or expansion in the strained film that occurs normal to the growth direction.

As film thickness increases, so does the total strain energy in a strained film. At

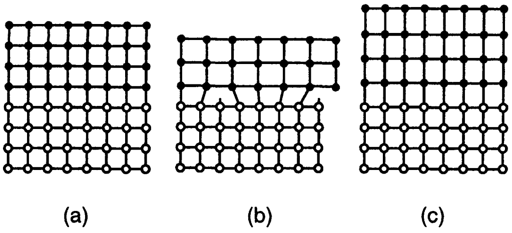

FIG. 4. Schematic cross section of epitaxial growth with varying mismatch: (a) commensurate growth with lattice matching, (b) strain-relaxed incommensurate growth, and (c) pseudomorphic growth with uniaxial expansion normal to growth interface.

some thickness, this energy is reduced by the spontaneous formation of misfit dislocations, as in Fig. 4(b). Calculations and experimental measurements have established the limits for strained growth as a function of film thickness. Figure 5 shows limits of defect-free growth in the Si–Ge system measured by Bean (1986). The solid line is based on calculations originally by Matthews (1975).

The modern key to epitaxial growth has been the clean, ordered substrate on which the film is grown. In the previous sections on deposition, we have avoided much discussion of substrate cleaning, and indeed, evaporated or sputtered films are usually deposited on oxidized semiconductor surfaces that have no long-range order. Here we define "cleaning" as, first, the removal of damage by polishing and etching, followed by removal of *all* impurities that influence the surface ordering. The combination of substrate processing under UHV conditions and the inclusion of surface-analysis tools in growth apparatus has made it possible to prepare and characterize atomically clean substrates, and to preserve the pristine state until growth can occur (e.g., see Fenner *et al.*, 1989).

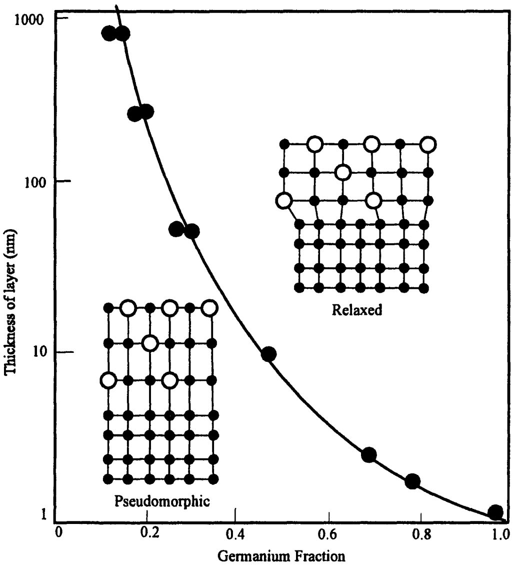

FIG. 5. Experimentally determined thickness limits for defect-free strained-layer epitaxy of Ge_xSi_{1-x} growth on Si. The mismatch is proportional to the Ge fraction, with a maximum of 4.2% at $x = 1$.

5.1 Molecular-Beam Epitaxy (Cho and Arthur, 1975)

Molecular-beam epitaxy (*q.v.*) (MBE) is conceptually the simplest epitaxial process and is also arguably the best understood. MBE occurs by the interaction of beams of atoms and molecules with a clean substrate surface contained in UHV and is discussed more thoroughly in another article in this Encyclopedia; nevertheless, since MBE is a prototypical epitaxial process, we describe it briefly here. Typically the beams are generated by the thermal evaporation of the constituent elements contained in refractory crucibles so arranged that the beams can be turned on or off by opening or closing shutters in the line of sight to the substrate. This allows the growth of a specific material to be initiated or terminated extremely rapidly. The UHV environment prevents contamination of the surface when growth is not taking place and also allows a variety of analytical tools to be available in the vacuum chamber for surface analysis, beam-flux measurement, and film-structure studies. This *in situ* analysis capability has been a major factor in developing an understanding of the process.

Two features of MBE make it especially powerful in the growth of heterostructure devices consisting of thin layers of different semiconductor materials. The UHV environment protects the quality of the growing surface so that contamination does not occur even at low growth temperatures and growth rates. This allows the use of growth temperatures low enough to minimize bulk diffusion processes and thus preserves the abruptness of heterointerfaces grown in the structure. The ability to turn both constituent and dopant beams on and off abruptly with the shutters also facilitates the growth of layered structures where composition or doping level change abruptly across a heterointerface. See Fig. 6 for a schematic view of the MBE growth chamber.

We have mentioned the need for atomically clean substrates for good epitaxial growth. The incorporation of sensitive surface tools such as the Auger-electron spectrometer (AES) in the MBE system makes it possible to determine when the desired state of cleanliness has been achieved. Each substrate material is likely to require a different method of preparation to allow cleaning in

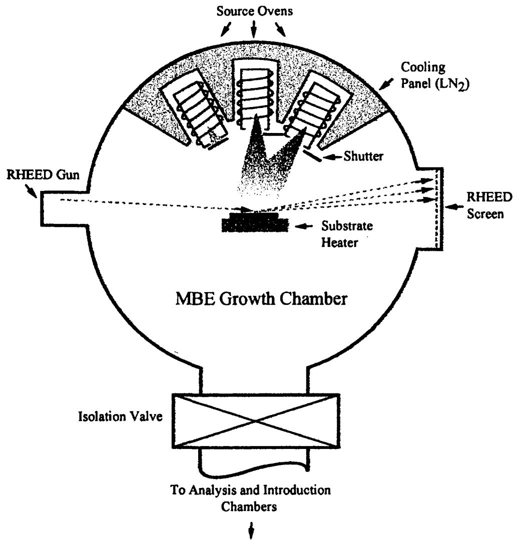

FIG. 6. Schematic top view of an MBE growth chamber showing the source ovens, substrate and heater, RHEED gun and screen, and mass spectrometer.

the growth system. Typically, these include washing in a sequence of etching solutions applied before introducing the substrate into vacuum, followed by a heating cycle to evaporate the residual oxide and to order the clean surface.

Nearly all commercial MBE systems today include equipment for displaying a RHEED (for reflection high-energy electron diffraction) pattern of the substrate to provide an indication in real time of the ordering of the surface. The RHEED pattern thus not only shows when the surface oxide is removed (since it is amorphous) but also shows the improvement in the surface ordering that occurs with the subsequent annealing (Cohen *et al.*, 1986). Clean semiconductor surfaces are reconstructed into a geometric configuration that minimizes the energy of electrons in localized bonds at the surface; this reconstruction is evident in the RHEED patterns as diffraction features positioned between the bulk diffraction spots. The presence of these "fractional order features" provides a qualitative measure of the long-range ordering of the surface (Chadi, 1989).

The most important usage of RHEED information, however, has come from the inference of the mechanism of film growth obtained from the time dependence of the intensity of the diffraction features. On a properly cleaned and annealed (therefore flat) substrate, as growth occurs, the intensity of the diffraction features oscillates in time. Joyce (1985, 1990) has suggested that this is strong evidence for a growth mechanism in which the growth of each atom layer is largely completed before the next begins, i.e., a layer-by-layer growth mechanism (see Frank and van der Merwe, 1949). See Fig. 7 for a schematic explanation of this observation. This growth mechanism is also supported by cross-sectional high-resolution TEM images of the interface between, say, Si and a Si–Ge alloy, which show the interface to be essentially atomically abrupt. Thus it appears that under the best conditions, MBE growth produces nearly ideal interfaces by virtue of the simple 2D layer growth mechanism originally proposed by Burton *et al.* (1951) (BCF). The ideas proposed by BCF have been substantiated with amazing agreement by elegant studies of the MBE growth of Si (Mo *et al.*, 1990) and GaAs (Biegelsen *et al.*, 1990) using scanning tunneling microprobe (STM) analysis.

MBE was initially used for the growth of III–V compound films, specifically GaAs and GaP, where the constituent elements have drastically different vapor pressures; the intent was to solve the vapor-pressure incompatibility with the use of separately controlled sources. In fact, it soon became apparent that the reaction between the metallic and nonmetallic source beams was nearly self-correcting. The vapor pressure of the group-V element was much lower over the stoichiometric compound than over an excess of nonmetal adsorbed on the substrate surface. Hence, a stoichiometric film was obtained by maintaining a slight excess of nonmetal beam flux over the metallic beam flux. The excess group-V element simply re-evaporated. It quickly became apparent that MBE offered a major advantage by virtue of the UHV environment that made possible the inclusion of surface analysis tools such as RHEED for real-time analysis of the growth process. At first it seemed that the semiconductor growth systems were unique in the layer-by-layer growth process that the RHEED analysis indicated. However, in subsequent studies of a wide range of film materials, from semiconductors to metals, RHEED studies indicate that layer-

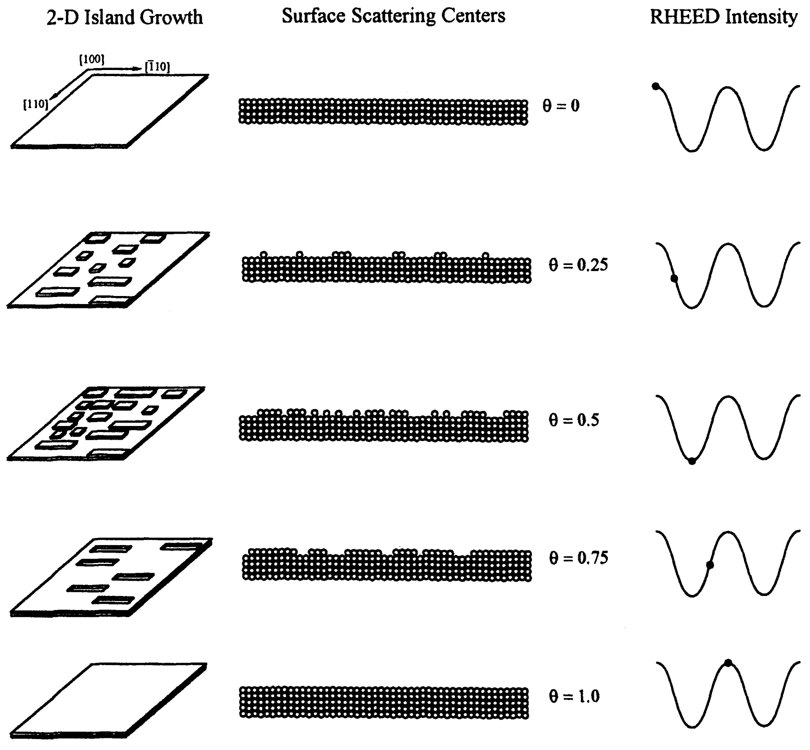

FIG. 7. Real-space representation of the growth of one monolayer, with the corresponding RHEED signal intensity.

by-layer growth is common on clean, low-index crystal faces.

One of the important consequences of the 2D growth is the ability to produce structures consisting of one or more very thin layers of one semiconductor material surrounded by layers of a different material. For device purposes, it is frequently of most interest that the center layer have a band gap smaller than the band gap of the cladding layers. If the thickness of the narrow-band gap center well is much less than the wavelength of electrons in the material, in the range from a few to tens of atom layers, the electron energy levels are discrete in the well, i.e., "quantized," and the structure is described as a quantum well. A structure composed of a periodic sequence of quantum wells is a superlattice. Quantum wells and superlattices are of great interest because the electronic and optical properties are quite different from these of bulk semiconductor material. Many of the theoretical predictions of solid-state physics have been precisely confirmed in these devices; e.g., tunneling of electrons can occur between quantum wells separated by a thin potential barrier of a few hundred angstroms thickness.

Much of the early work on superlattices and quantum wells was based on the material system GaAs-$Ga_xAl_{1-x}As$ because the Al content in the alloy increases the band gap, and yet the two materials have nearly the same lattice constant. The MBE process, at least in principle, should make possible the growth of selected ternary and quaternary III–V alloys, since the composition of the film can be controlled by the relative beam fluxes. Figure 8 shows the lattice constant vs band gap for III–V binary materials and their ternary alloys. It is evident that the lattice constant varies widely for the various alloys. If one is restricted to binary compound substrates, the mismatch between ternary film and binary substrate can be substantial. Thus the issue of growing strained layers is extremely important in order to have access

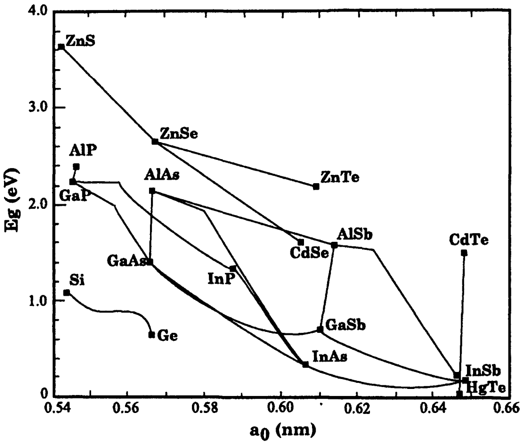

FIG. 8. Relationship between band gap and lattice constant for alloys in the InGaAsP and AlGaAsP systems. Also shown is the wavelength of light associated with the band gap energy.

to the full range of materials and properties offered by the III–V alloy family, as well as other families, notably, Si–Ge.

5.2 Vapor-Phase Epitaxy (Houng, 1992)

Vapor-phase epitaxy (VPE) and the related process, MOCVD, discussed below are chemical deposition processes as opposed to the physical process of MBE. VPE has evolved from the CVD of Si on Si substrates. The chloride process has been extensively used in industry:

$$SiCl_4(gas) + 2H_2(gas) \leftrightarrow Si(solid) + 4HCl(gas). \qquad (10)$$

This reaction is typically carried out at ~1200 °C and is reversible, which means that if the carrier gas—N_2, for example—that initially enters the chamber contains some HCl, the Si surface will be etched to clean the substrate prior to growth. VPE has been used from the early days of Si device processing to prepare thin layers of silicon with properties superior to those of the bulk substrate material; a typical application has been to grow lightly doped Si on a heavily doped substrate.

CVD is typically carried out at pressures in the range from a few Torr to atmospheric pressure. This has the advantage of simplifying the apparatus and increasing the growth rate; however, the complex fluid flow of reactant gases at these pressures is difficult to model. Furthermore, a large number of intermediate molecular species are actually involved in the reaction, as shown in Fig. 9. Thus CVD is mechanistically more complex than the UHV growth processes. An excellent discussion of these issues is given by Hess *et al.* (1985) and is also covered in CVD (CHEMICAL VAPOR DEPOSITION).

Meyerson (1986, 1990) has developed a UHV CVD process that has enabled the growth and fabrication of Si–Ge heterostructure devices with exceptional performance. These devices depend on the electronic properties of Si–Ge alloy quantum wells contained within Si barriers. This process illustrates that with care, it is possible to grow state-of-the-art films in a system designed for production.

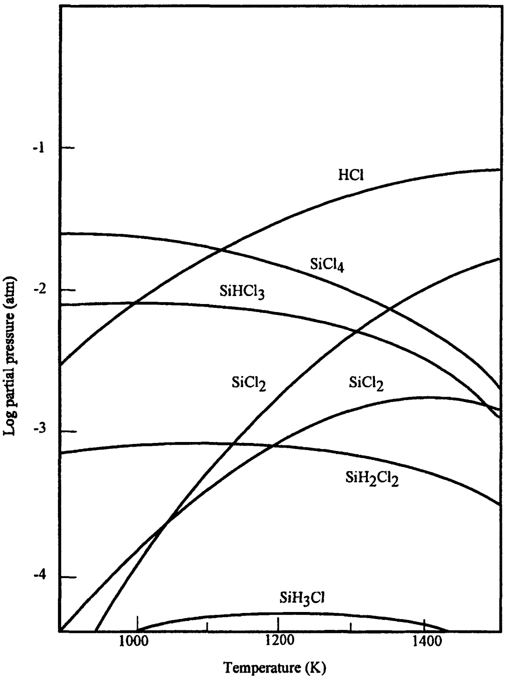

FIG. 9. Equilibrium partial pressures in the Si–Cl–H system at 1 atm and a Cl-to-H ratio of 0.06. The figure indicates the chemical complexity of CVD growth.

5.3 Metal-Organic CVD (Stringfellow, 1989)

Metal-organic CVD (MOCVD) is a process for the growth of III–V semiconductors that combines some of the best features of MBE and CVD. Rather than relying on an elemental source to provide the metal constituent, MOCVD utilizes a volatile organic compound to provide a vapor source that does not require the high-temperature cell used in MBE. Typically, organometallic compounds such as trimethyl gallium are used. The volatility of these species reduces the thermal load in the vacuum system and provides larger fluxes for faster growth; and, since the metal organic is introduced from a source outside the vacuum chamber, there is no need to open the system for replenishing the supply of metal. MOCVD also has made control of the composition of ternary and quaternary materials easier, since it is easier to control the partial pressures of several metal-organic sources than to control the temperature of elemental sources. A variation of MOCVD uses vapors of nonmetal compounds as well; for example, AsH_3 has been used as a source of As in the growth of GaAs (Panish, 1980). With beam sources that rarely need replenishing and an interlock system that allows substrate entry and exit from the growth chamber without impairing the vacuum, the MOCVD system can operate for very long periods without down time.

While MOCVD was first used in the late 1960s with systems operating at atmospheric pressure that were essentially identical to CVD systems of the period, present systems are much more closely related to MBE systems and operate at reduced pressure, or even at UHV in a molecular-beam mode. It has been possible to include RHEED display in UHV growth systems, and the observations of RHEED oscillations during growth are nearly identical to those observed in MBE and suggest a similar layer-by-layer growth mechanism.

Since hydrocarbons are normally to be avoided in UHV systems because of the difficulty in removing C contamination from clean surfaces, it is not surprising that early MOCVD films were rather heavily contaminated with C. It has since been found, however, that the C contamination can be essentially eliminated by adjustment of the group-V beam intensity. As a result, MOCVD produces very high quality III–V films, with the advantage of high throughput due to the faster growth rates possible.

5.4 Liquid-Phase Epitaxy (Nakajima, 1985)

Liquid-phase epitaxy (LPE) involves the growth of an epitaxial film on a substrate that is placed in contact with a saturated solution of the film material. In some cases the solvent may be one of the film constituents; e.g., GaAs films are grown from a saturated solution of As in molten Ga. When the solution is cooled very slightly it becomes supersaturated and growth occurs on the substrate. LPE is essentially an equilibrium process, where knowledge of the thermodynamic parameters allows a prediction of the composition of the film. Cleaning of the substrate surface is accomplished by raising the temperature of the solution briefly to make it unsaturated with respect to the substrate material causing some etching prior to growth. The advantages of LPE are the following:

1. Simplicity. The growth chamber is typically glass, and no complex pumping or valving is involved since growth occurs at or near atmospheric pressure in an atmosphere of purified H_2.
2. Near-equilibrium growth. Since diffusion rates in solution are rapid, LPE growth is rapid, >0.1 μm/min; consequently, fairly thick films can easily be deposited.
3. Films grown from a liquid-metal solution can be extremely pure because the distribution ratio of impurities between the solid (film) phase and the reactive liquid is low; in effect the liquid "getters" impurities, and the resulting films are quite pure, even though not grown in a clean vacuum environment.

However, there are enough disadvantages that LPE is not much used industrially:

1. Only small substrates can be used. Whole-wafer growth is not normally possible, and this limitation keeps LPE a research technique.
2. The composition of the film depends on the concentration of material in the liquid solution. Typically small volumes of solution are used, and the concentration of

film material may be small enough so that composition of the film changes as the liquid is depleted of solute.

3. Control of film thickness is difficult since the growth rate is an extremely sensitive function of solution temperature; as a result, interfaces between layers can be rough.

LPE played a very significant role in the development of III–V devices in the 1960s, and it is still used for research applications because of the high optoelectronic quality of the layers produced; however, the film uniformity and thickness are not sufficiently under control for modern device fabrication.

5.5 Solid-Phase Epitaxy

Solid-phase epitaxy describes the regrowth of a polycrystalline or amorphous film on a crystalline substrate at an elevated temperature. The most common example of solid-phase epitaxy is the regrowth of a semiconductor that has been ion implanted to an extent that the surface has been amorphized by the ion flux. Annealing causes regrowth from the unimplanted region outward. Other instances can involve the use of scanned laser beams or other optical sources to carry out a rapid annealing of the surface of a wafer on which a noncrystalline layer has been deposited. In most cases, solid-phase epitaxy is a homoepitaxial process, to recrystallize the surface of a semiconductor.

5.6 Atomic-Layer Epitaxy (Suntola, 1989)

Atomic-layer epitaxy (ALE) is a variation of MBE but with some unique modifications. In the II–VI family of semiconductors, e.g., ZnS, the vapor pressure of each of the pure elements is considerably higher than the partial pressure of each over the compound. ALE makes use of this fact to obtain stoichiometric growth by exposing the heated substrate alternatively to beams or vapors of the constituent elements. The substrate is heated to a temperature hot enough to evaporate the elements but not hot enough to vaporize the compound. Thus an exact monolayer of each element is adsorbed during each half cycle, sufficient to react with the monolayer below. ALE has been shown to produce very good-quality II–VI films, particularly for luminescent devices. However, the ALE process is often utilized in nonepitaxial film growth because it provides excellent conformal growth; i.e., the coverage over steps and in wells is not dependent on line-of-sight beam flux from a source, which can cause shadowing effects. Rather, the higher pressures of vapors used in the process penetrate into holes on nonplanar surfaces, and yet the stoichiometry of the film is preserved by the physics of the process.

6. SURFACE SCIENCE AND THIN-FILM DEPOSITION

The importance of the relationship between our understanding of surfaces and the technology of thin-film deposition cannot be overstated. The tools for studying surfaces developed during the past 25 years have played a crucial role in moving from polycrystalline films to epitaxial semiconductors that are more perfect than their substrates. In particular, the spectroscopic methods for determining surface composition—e.g., AES, XPS, SIMS—and the structural characterization tools, RHEED and now the STM, have opened the door to an understanding of how the various deposition methods influence the films that they produce (Czanderna, 1975). Figure 10 is an STM image of the stepped

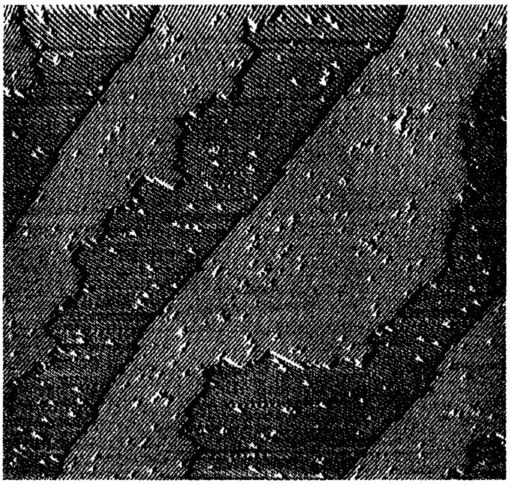

FIG. 10. STM image of stepped Si surface after MBE growth. Surface is oriented slightly off the [100] direction (~1°). Note the alternating irregular and smooth step edges.

surface of a Si layer that has been grown by MBE on a Si substrate oriented slightly off the [100] direction. The striking feature is how closely the actual surface, with its steps and nearly uniform terraces, resembles the idealized model proposed by Burton, Cabrera, and Frank some 45 years ago (Burton *et al.*, 1951).

GLOSSARY

AES: Auger-electron spectroscopy.

Aspect Ratio: The ratio of vertical dimension to lateral dimension of a feature on an integrated circuit.

Chemical Deposition: The process of depositing a thin film involving a chemical reaction.

Cryopump: A vacuum pump that condenses gas molecules on cryogenically cooled walls. Has a high pumping speed for condensable gas species and can be used to below 10^{-10} Torr.

Diffusion Pump: A vacuum pump that entrains gas in a vapor stream derived from the boiling pump fluid. Normally used down to $\sim 10^{-7}$ Torr, although lower pressures can be achieved.

Electroluminescent Film: A semiconducting film structure that emits visible light when excited by an electric field, typically from an alternating voltage.

Epitaxy: The growth of a thin film with an ordered relationship to the substrate.

Evaporation: The process of transferring material by the vaporization of a source at high temperature to a substrate at lower temperature.

Heteroepitaxy: Epitaxial growth of a film on a substrate of dissimilar material.

Homoepitaxy: Epitaxial growth of a film on a substrate of the same material.

Hydrophilic: Attracted to water; describing that portion of an organic molecule that is soluble in aqueous solution.

Hydrophobic: Describing the hydrocarbon tail of an organic molecule that is insoluble in aqueous solution.

Ion Pump: A vacuum pump that ionizes gas molecules and drives them into the pump electrodes. Useful down to $\sim 10^{-11}$ Torr.

Lattice Mismatch: A measure of the difference between the lattice constants of film and substrate. Defined as $f = [a_0(\text{sub}) - a_0(\text{film})]/a_0(\text{film})$, where a_0 represents the lattice constant of film or substrate.

Light-Emitting Diode: A semiconducting diode structure that emits band-gap light when electrically driven in the forward direction.

Low-Dimensional Structure: A thin film containing one or more layers that produce quantum wells with carrier confinement in one, two, or three dimensions; i.e., having one or more dimensions of the order of the electron wavelength.

Mesa Etching: Chemical etching during the processing of integrated circuits to leave a mesa structure on the semiconductor wafer. Typically done to electrically isolate a single device in the mesa.

Metallization: The process of covering a substrate with a metallic thin film.

Monolayer: A thin film that is exactly one molecule thick. For most materials this amounts to about 3×10^{14} molecules/cm^2.

Photolytic: Dissociated by the energy of incident photons.

Photoresist Film: An organic film that is light sensitive and that is used to define a region on an integrated circuit using photolithography.

Physical Deposition: The process of depositing a thin film by physical means, such as evaporation.

Polysilicon: A nearly glassy form of polycrystalline silicon with very small microcrystals.

Pseudomorphic Growth: Heteroepitaxial growth of a film on a substrate in which the film assumes the lattice constant of the substrate.

Pyrolytic: Dissociated by a thermal process.

Quantum Well: A thin film containing a region that confines carriers in a potential well whose dimensions in at least one direction are comparable to the wavelength of an electron or hole in the region.

Reactive-Ion Sputtering: Sputtering in the presence of a gas that reacts chemically with the sputtered particles.

RHEED: Reflection high-energy electron diffraction.

SIMS: Secondary-ion mass spectroscopy.

Sputtering: The process of using high-energy ions to remove material from a target. In many cases, the material removed is transferred to a substrate; however, in some cases sputtering is used simply for etching the target.

STM: Scanning tunneling microscopy.

Substrate: The solid material on which a thin film is deposited. It may be crystalline or not.

Superlattice: A film structure consisting of a periodic stacking of dissimilar films, with spatial dimensions of the order of the electron mean free path.

TEM: Transmission electron microscopy.

Torr: A unit of pressure equal to 1 mm Hg or to 133.3 Pa.

UHV (ultrahigh vacuum): A vacuum in which the pressure is considerably less than 10^{-7} Torr.

XPS: X-ray photoelectron spectroscopy.

INTRODUCTION

The recent explosion of research on ferroelectric thin films has led to significant advances in the processing and properties of these materials. A major driving force for this research is the advantages that accrue from integrating ferroelectric elements with integrated circuits (ICs) (especially silicon-based electronics). In particular, ferroelectric films can be optimized for high dielectric constants, hysteretic polarization behavior, and pyroelectric, electromechanical, or electro-optic properties. In this article, the potential uses of ferroelectric films, the structure and properties of ferroelectrics, the deposition methods for films, the properties of ferroelectric films on silicon, and the current status of research around the world are reviewed.

1. NEEDS FOR FERROELECTRIC FILMS ON SILICON

1.1 DRAM Applications

One crucial need for next-generation high-density memory circuits is the development of high–dielectric-constant, low-leakage films that are compatible with silicon circuitry for ultracompact charge storage. Until recently, the standard capacitors used in integrated circuitry were either SiO_2 or silicon oxynitride thin films. However, the dielectric constants of both of these materials are quite

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

low ($\epsilon_r \sim 4$ and ~ 9, respectively). Thus, as the linewidths of active devices have decreased, it has been hard to achieve a comparable reduction in capacitor size, even through the use of extremely thin layers or trench geometries. The situation is particularly severe in dynamic random-access memories (DRAM). Consequently, it is becoming imperative to integrate higher–dielectric-constant materials with Si circuitry. As a first attempt at this, several companies have switched to Ta_2O_5 ($\epsilon_r \sim 18$–25), but for extremely high integration levels, an even higher dielectric constant will eventually be required. For this purpose, considerable research is now being directed at development of low-loss paraelectric thin films.

1.2 FRAM Applications

The possibility of developing a high-density nonvolatile ferroelectric random-access memory (FRAM), in which the polarization state of the ferroelectric thin film is used to store information, has been one of the major drivers for the explosion of effort in ferroelectric thin films. Because intrinsically the switching in ferroelectric films is extremely fast (<100 ps) (Larsen, 1995), a ferroelectric-based memory might ultimately challenge existing technologies for computer applications. In the short term, however, FRAMs are becoming competitive with other nonvolatile information storage systems on silicon such as EEPROM (electrically erasable programmable read-only memory). Potential large-volume markets include the information storage systems on "smart cards."

1.3 IR Thermal Imaging

In ferroelectric crystals and films the strong temperature dependence of the spontaneous electric polarization leads to the possibility of very strong pyroelectric effects, as the pyroelectric coefficient p is defined by

$$p = \frac{\partial P_s}{\partial T}, \tag{1}$$

where P_s is the polarization and T is the temperature.

For a thin sheet of crystal or ceramic, poled normal to the sheet and blackened on one surface, absorbed long-wavelength infrared radiation will change the temperature, and the pyroelectric current may be used to monitor the radiation level. Such current-mode detectors can be very fast and are usable as power meters for pulsed CO_2 lasers working at 10 μm. If the radiation is chopped at a frequency $\omega \sim 30$ Hz, and the element is thin and very well thermally isolated, the thermal sensitivity is given by

$$\frac{\Delta T}{W} = \frac{\eta}{(g^2 + \omega^2 c^2 t^2)^{1/2}}, \tag{2}$$

where ΔT is the temperature rise for incident IR energy W, a fraction η of which is absorbed by the detector chip; g is the effective thermal conductance to the environment; c is the volume specific heat; and t is the detector thickness. For high sensitivity the cardinal importance of low g and very small t for any given frame frequency ω is clearly apparent.

In isolated point detectors it is easy to provide excellent thermal isolation by mounting the element on an ultrathin polymer "drum head," and very inexpensive, high-sensitivity thermal IR detectors made from a wide range of ferroelectric materials are commonly used in industry.

For imaging, where the individual element is down to a pixel size of ~25 μm, the conflicting requirements of electrical interconnection and refined thermal isolation provide challenging problems. Present systems use hybrid technology in which the detector plane is a very thin sheet of poled ferroelectric ceramic, bump bonded to the silicon integrated interrogation circuit. With an $f1$ lens system, such imaging systems give resolution of 0.07 K in the object plane (Kulwicki *et al.*, 1992).

Currently, there is a strong push to move to integrated systems using microelectromechanical technology to form air-bridge or diaphragm thermal isolation on the silicon chip itself (Shorrocks *et al.*, 1995; Kohli *et al.*, 1995; Watton, 1994). Major problems concern the conflicting processing needs of ferroelectric films and silicon microcircuits, but the prize would be a system that could be fitted in automobiles to provide drivers with useful night vision.

1.4 Mechanics

Piezoelectricity and electrostriction entail a coupling between electrical and mechanical energy in materials. That is, if a stress is applied to the material, it responds with an electrical polarization. Conversely, if an electric field is applied, the material undergoes a strain. Piezoelectric materials find widespread use in both sensor and actuator applications. A significant research effort is now being directed toward miniaturization of piezoelectric devices for microelectromechanical systems (MEMS). For these applications, the capability of processing thin-film piezoelectrics such as $Pb(Zr_xTi_{1-x})O_3$ (PZT) on platinum-coated silicon allows for the integration of the active sensing or actuator elements directly with on-chip driving or receiving electronics (including all of the necessary amplification). This can significantly increase the sensitivity of devices such as microphones and hydrophone detectors (Kim, 1990; Kim and Muller, 1987). From the standpoint of actuation, it is clear that as devices are miniaturized, piezoelectric devices permit comparatively higher energy densities, compared to other means of generating displacement. Thus, as active elements are integrated, electromechanical devices become progressively more attractive.

1.5 Packaging

Ferroelectrics are widely used as high–volumetric-efficiency capacitors in the bulk form. Thus, it is not surprising that there is interest in developing thin-film ferroelectrics as decoupling capacitors for integrated-circuit applications (Schwartz *et al.*, 1994). In particular, in some applications it is possible to replace chip capacitors with higher-density thin-film integrated capacitors in order to decrease circuit noise. For example, Matsushita has reported use of $Ba_{1-x}Sr_xTiO_3$ films in GaAs MMICs for portable telephones and in conjunction with CCDs for VCRs and camcorders (Shimada *et al.*, 1995). Required properties for films used in these applications are a high dielectric constant at the use frequency, a low dielectric loss, and a high resistivity.

1.6 Microchemistry

A specialized area of MEMS that is receiving rapidly increasing interest is that associated with chemistry and biochemistry on a chip. For a number of important liquid-phase chemical reactions, there are accessible regions of the boundary conditions where the reactions can become unstable and uncontrollable. By splitting the reactants into very small reaction chambers that can be replicated by inexpensive semiconductor technology and where sensing and control circuits may be on the same chip, control time constants are drastically shortened ensuring better control, but even in the extreme case of a "runaway," the volumes involved ensure that the result is not catastrophic (Jensen, 1996).

For many biological problems it is essential to work with microliter volumes and below, so that the micropumps and microvalves accessible in MEMS become essential components. DNA sequencing by electrophoretic capillary separation is just one example where widespread use in the criminal justice system is pressing toward massive markets (Sonnenschein, 1996).

In the microchemical–biochemical systems the piezoelectric/electrostrictive components are primarily for mechanical actuation (pumps and valves), pressure flow, and temperature sensing.

2. FERROELECTRIC MATERIAL SYSTEMS

2.1 Properties of Bulk Materials

Ferroelectricity is a property of crystals; there are no ferroelectric glasses or liquids. The appearance of a polarization vector in a crystal will certainly modify the point symmetry and create a new phase. If the resulting phase is to be ferroelectric, there must be more than one equivalent equilibrium orientation for the polar vector, and it must be switchable between states by a realizable electric field.

The electrical consequence of the reorientable spontaneous electric polarization is the appearance of dielectric hysteresis in the relation between dielectric polarization and applied electric field at higher field levels

(Fig. 1). This behavior is strongly reminiscent of the ferromagnetic hysteresis between intensity of magnetization and magnetic field and led to the adoption of the name ferroelectric for these materials. From the hysteresis loop, the terms remanent polarization and coercive field are defined (Fig. 1) also by analogy with the magnetic systems. As with magnets, many ferroelectrics exhibit a phase change to a nonferroelectric (paraelectric) form at higher temperature, and the transition point is defined as the Curie temperature (T_c). Similarly above T_c one of the diagonal elements of the permittivity tensor often follows a Curie–Weiss relation of the form

$$\epsilon_{ii} = c/(T - \theta), \qquad (3)$$

where θ is the Curie–Weiss temperature. However, in the dielectric case, the Curie constant c is 5 to 7 orders of magnitude larger than in the corresponding magnetic case, indicating the much "softer" ordering (weaker interaction) in the ferroelectric and leading to very high values of dielectric permittivity in the paraelectric phase above T_c. Also, unlike magnetism, the remanent polarization of a ferroelectric does not give rise to a strong permanent electric field in the surrounding medium, as the bound dipolar charge at the surface is always eventually compensated by the free charges that are available in the electrical case.

2.2 Symmetry Considerations

All point symmetries other than 1, which has no symmetry to lose, may be prototypic (paraelectric) phases out of which ferroelectric species may occur. A complete cataloging of all possibilities has been given by Shuvalov (1970) and Aizu (1969), and compact notations have been presented for describing the state shifts. The tabulation for the cubic point groups is given in Table 1, adapted from Shuvalov. Taking, for example, one of the common species from point group *m*3*m*, the symbol

$$m3m\ (3)\ \mathrm{D4F}\ 4mm \qquad (4)$$

means that prototype *m*3*m* has a ferroelectric state (F) that will have three (3) equivalent orientations (six vector directions) which are definite (D) along the fourfold axis (4) giving rise to six domain states, each in tetragonal point symmetry 4 *mm*.

A consequence of the general symmetry

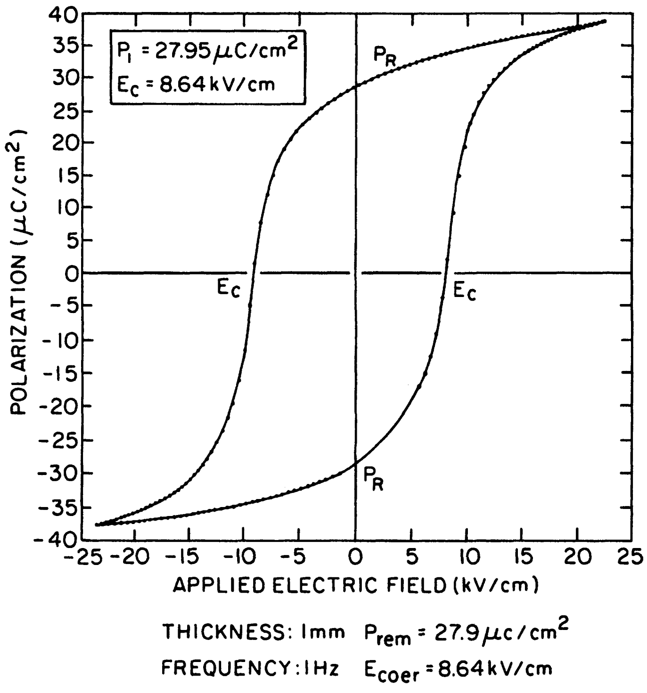

FIG. 1. Typical hysteresis between electric polarization and electric field in a ferroelectric material in its ferroelectric phase. P_r, remanent polarization. E_c, coercive field.

arguments was the realization that there could be ferroelectric species in which the polar vector is reorientable but not reversible. An example is in the cubic group $\bar{4}3m$, i.e., $\bar{4}3m$ (12/2) AmF m. Again $\bar{4}3m$ is the prototype group. In the ferroelectric species there are 12 vector directions for ferroelectric polarization; (12/2) indicates that the orientation is redirectable but not reversible; A indicates arbitrary, but in the plane of the mirror (m), and the ferroelectric phase has monoclinic (m) symmetry.

In Shuvalov's table the corresponding simple form is the solid surface that would be formed by the normals to the full family of polar directions. In the "nature of the phase change" column, Roman II indicates that the Curie transition may be either first or second order thermodynamically, Roman I indicates that the change must be first order (discontinuous). The small symbols at the end of the letter descriptors indicate whether the sublattices in the different domain states are parallel (‖) or canted.

It should be stressed that the symmetry classification is a tabulation of the possible; i.e., all actual ferroelectrics of any symmetry must fall within this grouping. However, whether any structure of a given symmetry is actually prototypic depends on details of its atomic architecture, which are not controlled by the crystal symmetry.

2.3 Domains and Polarization Switching

Only simple proper ferroelectrics from centric prototype (paraelectric) symmetries have so far been applied to thin films, and discussion of domains and switching is confined to such crystals. In these proper ferroelectrics, the appearance of polarization leads to significant shape change driven through the phenomenon of electrostriction; i.e., the strain induced from the prototype $x_{ij(s)}$ is given by

$$x_{ij(s)} = Q_{klij} P_{k(s)} P_{l(s)}, \qquad (5)$$

where Q_{klij} are the symmetry-permitted electrostriction constants and $P_{k(s)}P_{l(s)}$ are components of the spontaneous polarization vector in the ferroelectric domain. Einstein summation convection is assumed, and the expression is expanded for repeated subscripts to get the full family of equations.

Clearly for these centric prototypes, domain inversion will not change the shape; however, for non-180° changes, the domains are strain distinct, and acceptable planes joining such domains (domain walls) will be regulated by elastic as well as electric boundary conditions. The spontaneous strains $x_{ij(s)}$ are quite large, of the order of 1% in $BaTiO_3$ and from 2% to 6% in tetragonal PZTs, so that the elastic constraints are strong. A tabulation of strain-preferred walls has been given by Fousek and Janovec (1969).

For $BaTiO_3$ and PZT the phenomenological Gibbs free energy is known, and it is possible to calculate the field level required for intrinsic coherent polarization switching within the single domain. Such calculations yield values orders of magnitude larger than the observed coercive field. Thus it is generally agreed that in bulk crystals the switching is incoherent and occurs by the motion of domain walls.

For $BaTiO_3$ 180° switching has been extensively studied and has shown to be by nucleation and growth of new domains, preferentially against existing walls, and not by a true sidewise motion of the wall. The presence of non-180° walls in general appears to raise the effective coercive field, but shape-changing ferroelastic switching has been much less studied.

In the randomly axed polycrystal both 180° and ferroelastic shape-changing switching must be involved, and the process varies widely between different systems. For $BaTiO_3$ less than 30% of the single-domain spontaneous polarization is remnant, and the response is a strong function of grain size. For PZT compositions close to the morphotropic phase boundary at the 52:48 Zr:Ti ratios, good "square loop" switching is observed. From elementary electrostatic considerations, Arlt (1996) has shown recently that grain-by-grain switching in a ceramic is impossible and that the switching nucleus must be a larger entity. Given the fact that thin films often have appreciably different grain sizes and stress states than are characteristic of bulk ceramics, it is possible that the switching process in films will differ markedly from that observed in bulk materials.

2.4 Transport Properties

Comprehensive reviews of the electrical conduction mechanisms in ferroelectric materials have been given by Smyth (1994) and Waser (1994). As has been described there, the principal charge carriers in the perovskite oxides are electrons, holes, and oxygen vacancies. In most of the perovskites, nominally undoped materials contain an excess of acceptors from lower-valent impurities, and so act as acceptor-doped compounds. This is especially true for the lead-based materials, where lead vacancies also act as acceptor sites. These materials are insulating at room temperature on account of the existence of hole traps (Warren *et al.,* 1994). It is important to note, though, that either variations in the film stoichiometry or preparing films without sufficient oxygen present changes the defect chemistry and can lead to unacceptably high conductivity levels.

Upon application of a dc voltage to a ferroelectric capacitor, the capacitor passes a polarization current. Eventually, this transient dies away, and the current decays to the value determined by the leakage through the capacitor. At still longer times, if the applied dc field is high enough, the sample may undergo resistivity degradation and ultimately time-dependent dielectric breakdown (TDDB) (Chen *et al.,* 1994).

As has been shown by Waser and coworkers, the current initially follows the Curie–Von Schweidler law (Waser and Klee, 1992):

$$J \propto t^{-m}, \tag{6}$$

where J is the current density, t is time, and m is approximately 0.5 (actually 0.4 to 1) (Dietz and Waser, 1995). It then flattens out as the true leakage value is reached. It is important to note that the transition to the steady-state current can be quite slow ($>10^3$ s) (Chen *et al.,* 1994). Techniques for measuring this properly have been described by Dietz and Waser (1995). In particular, it has been demonstrated that stepped changes in the applied voltage (with appropriately long wait times between steps), where both charging and discharging currents are measured, are preferable to ramped voltage experiments in determining the true leakage currents. This is especially true at low temperatures (i.e., 25 °C).

2.5 Perovskite-Structure Systems

The simple cubic perovskite ABO_3 structure is the prototype structure for many useful ferroelectric materials. Fundamentally, it consists of large 12-coordinated cations such as Na, K, Rb, Ca, Sr, Ba, Pb, etc. at the corners of a unit cell, with a smaller cation such as Ti, Sn, Zr, Nb, Ta, or W at the unit cell center octahedrally coordinated to the anions at the face centers (see Fig. 2). These octahedral units form a three-dimensional array via corner linking. The resulting structure has a high symmetry (the point group symmetry is *m*3*m*). This high symmetry is extremely useful, as it implies that when the material distorts to form a ferroelectric phase, there are many equivalent differently oriented domain state polarization directions. As a result, it is possible in the randomly axed polycrystal to thread the polarization vector through the structure without major discontinuities. Consequently, large remanent polarizations can be developed, as well as substantial piezoelectric and electro-optic coefficients.

Among the technologically important materials possessing this crystal structure are the solid solutions $BaTiO_3$:$SrTiO_3$ (BST), $PbZrO_3$:$PbTiO_3$ (PZT), and $KTaO_3$:$KNbO_3$ (KTN). $BaTiO_3$ itself shows three ferroelectric phases as a function of temperature. At temperatures above ~135 °C, the octahedra are undistorted, and the material possesses symmetry group *m*3*m*. On cooling through the Curie point, however, the Ti^{4+} ion displaces closer to one of the adjacent oxygen along the [001] direction. This results in an elongation along the *c* axis, contraction along the *a* and *b* axes, and, most importantly, development of a spontaneous polarization along the ferroelectric *c* axis. This tetragonal structure is stable to ~5 °C, at which point the Ti^{4+} ion shifts again, along one of the [110] directions of the original cubic unit cell. This leads to an orthorhombic structure with the polarization oriented along the direction of Ti^{4+} displacement. Finally, at ~ -90 °C, the TiO_6^{8-} octahedra distort again, with the Ti^{4+} ion (and hence P_s) displacing along one of the original [111] directions. Each of these symmetry changes corresponds to a first-order displacive transition (see Fig. 3).

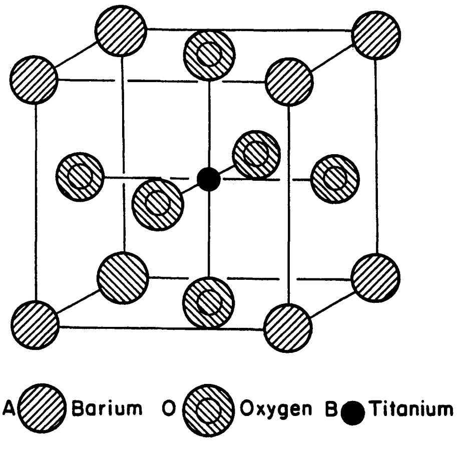

FIG. 2. Cubic form of the perovskite structure using barium titanate as a typical example.

Associated with each of the transitions in $BaTiO_3$ is a maximum in the low-field dielectric permittivity as shown in Fig. 4. Fundamentally, each transition marks a temperature where two phases are similar in energy. On application of an electric field, then, the material can be distorted between the two different polytypes. This, in turn, leads to high polarizability near transition temperatures. The high dielectric permittivity even between phase transitions in ferroelectric $BaTiO_3$ is tied to the presence of the spontaneous polarization and to the existence of domain walls.

$BaTiO_3$ and $SrTiO_3$ form a complete substitutional solid solution in which the ferroelectric–paraelectric transition temperature of the compound decreases nearly linearly with Sr composition. As a result, it is possible to tailor the transition temperature as well as the dielectric properties. For DRAM applications, paraelectric BST compositions are being widely investigated because of the combination of relatively high dielectric permittivity with low dielectric loss.

The most important of the piezoelectric ceramics are found in the lead zirconate–lead titanate solid-solutions series. PZT shows a temperature-independent morphotropic phase boundary between tetragonally and rhombohedrally distorted ferroelectric

phases at the Zr:Ti ratio of 52:48 as seen in Fig. 5. As a result of the large number of potential orientations for the spontaneous polarization, this material shows efficient poling and large enhancements in the dielectric and piezoelectric properties at this composition.

Potassium niobate, $KNbO_3$, is a monovalent/pentavalent analog of $BaTiO_3$ in essentially the same perovskite structure. It goes

through the same sequence of phase changes associated with the onset and reorientation of spontaneous electric polarization. In $KNbO_3$ the Curie point is at 420 °C, the tetragonal ⇄ orthorhombic transition is at 220 °C, and the orthorhombic ⇄ rhombohedral phase change is at −10 °C. Replacing Nb with Ta rapidly lowers T_c, and the sequence of change is similar to that induced in $BaTiO_3$ by Sr substitution.

At low concentration of Nb in $KTaO_3$ an interesting new phenomenon occurs, associated with the formation of small droplets of polar phase within the high-K tantalate matrix leading to massive dielectric maxima ($K \sim 100\,000$) with strong relaxation character, behavior in many ways compatible to the relaxor ferroelectrics discussed in Sec. 2.4.

Sodium niobate, like lead zirconate, is antiferroelectric at room temperature, and as in lead zirconate, the antipolar state can be destabilized under high–electric-field switch-

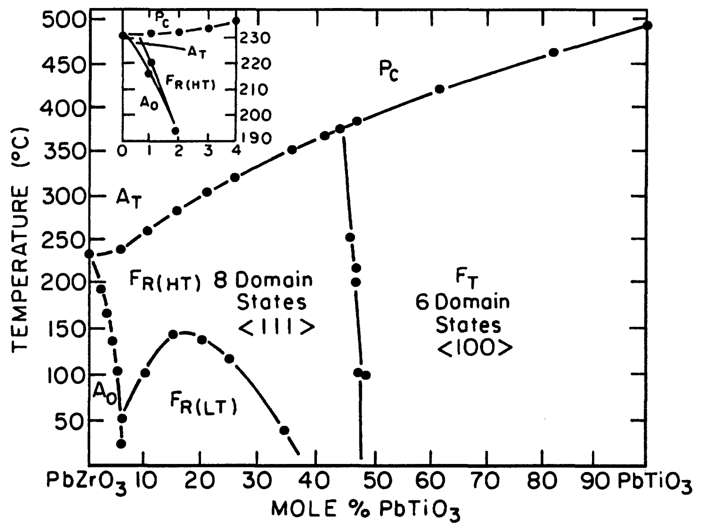

FIG. 5. Phase diagram for the $PbZrO_3$:$PbTiO_3$ solid-solution ferroelectric system. Note the almost vertical (morphotropic) phase boundary at the Zr/Ti 52/48 composition separating tetragonal and rhombohedral ferroelectric forms. P_c is the paraelectric prototypic cubic state. F_T is a tetragonal ferroelectric phase with six alternative domain states polarized along the ⟨100⟩ family of directions of the unit cube. F_R is a rhombohedral ferroelectric state with eight equivalent polar directions in its domain structure with polar vectors along equivalent ⟨111⟩ family of directions. The rhombohedral form has a simple high-temperature phase in which oxygen octahedra are in orthogonal array, and a low-temperature form in which the oxygen octahedra are slightly rotated about the ⟨111⟩ family of directions. A_0 is an orthorhombic antiferroelectric phase in which opposing polarizations occur on a unit cell scale.

ing to a strong ferroelectric form (Cross and Nicholson, 1955).

2.6 Bismuth Oxide Layer Structures

Particularly in the area of FRAMs, the family of bismuth oxide layer-structure ferroelectrics is also important. The bismuth oxide layer structures are made up of sheets of perovskite-like corner-linked oxygen octahedra separated by $Bi_2O_2^{2+}$ layers (Fig. 6) (Dorrian *et al.*, 1971). The prototypic symmetry is 4/*mmm* with the $Bi_2O_2^{2+}$ sheets normal to the *c* axis interleaved by from one to five perovskite-like layers. In the bulk crys-

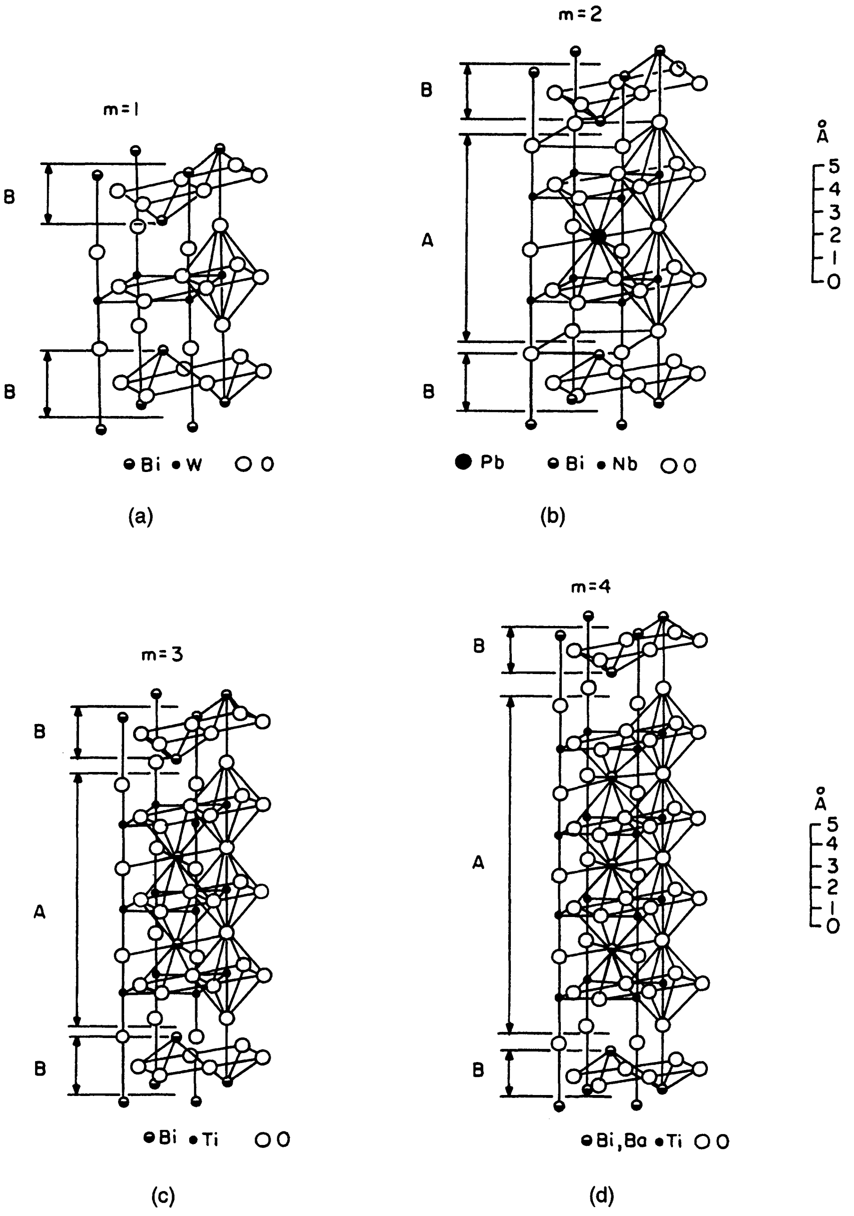

FIG. 6. Crystal structures for 1-, 2-, 3-, and 4-layer bismuth oxide layer-structure ferroelectrics. The figure shows one-half of the unit cell of (a) Bi_2WO_6, (b) $PbBi_2Nb_2O_9$, (c) $Bi_4Ti_3O_{12}$, (d) $BaBi_4Ti_4O_{15}$ (after Aurivillius). "A" denotes perovskite-like layers; "B" denotes $(Bi_2O_2)^{2+}$ sheets.

tals there are major differences both in structure and in properties between compositions with odd (1,3,5) and even (2,4) numbers of interleaving perovskite layers. Even-layer structures retain a mirror normal to the fourfold axis in the ferroelectric phases so that the polarization vector is confined to the plane of the perovskite sheet (Newnham *et al.,* 1971), while in the one- and three-layer structures the mirror is lost, and in $Bi_4Ti_3O_{12}$ the polarization tilts out of the perovskite plane. Similarly, in properties odd-layer compounds have a single phase change on cooling, leading to a prominent dielectric anomaly. Two- and four-layer structures go through two phase changes, only one of which carries the major dielectric anomaly (Diaz-Colon, 1973).

To date, the best studied thin films have been in the $Bi_4Ti_3O_{12}$ and $SrBi_2Ta_2O_9$ compositions. The latter is particularly important, as it appears that when fabricated with simple platinum electrodes it shows lower coercivity and much lower fatigue on repeated cycling than comparable PZT films. It is difficult to see why a randomly axed polycrystal film made up from crystallites with only four in-plane domain states should have low coercivity and quite high remanent polarization, and one suspects that the processing and consequent microstructure of the film may significantly modify the bulk symmetry and properties.

2.7 Alternative Systems

In addition to these compounds there are alternative normal ferroelectric systems that are, for the most part, somewhat less well studied in thin-film form. Examples include $LiNbO_3$ and its tantalate analog, the tungsten bronze systems, and some of the improper ferroelectrics. $LiNbO_3$ is widely used as a bulk single crystal for nonlinear optical applications and as a high-temperature piezoelectric (its ferroelectric transition temperature $T_c \approx 1200$ °C). Thin films are amenable to wave-guiding applications and so have been pursued for optical switches and second-harmonic–generation applications. In thin films, as in bulk crystal growth, maintaining the correct stoichiometry is problematic. The tungsten bronze family of ferroelectrics is based on a relatively complex crystal structure in which oxygen octahedra are the primary structural units (Lines and Glass, 1977). The multiple possibilities for cation disordering in these compounds, coupled with the large solid-solution regions, lead to widely tailorable dielectric, electro-optic, and electromechanical properties. Epitaxial $Sr_{5-x}Ba_xNb_{10}O_{30}$ (SBN) films have been grown on single-crystal substrates with different Sr:Ba ratios (Trivedi *et al.,* 1996). Among improper ferroelectrics such as $Gd_2(MoO_4)_3$, the primary order parameter is not the polarization, so that the ferroelectricity is a secondary consequence of a zone-boundary structural mode (Dvorak, 1971). A study of thin films of this material might be rather useful, given the strong effect that the elastic clamping of the film to the substrate is expected to have on the properties of most ferroelectrics. In $Gd_2(MoO_4)_3$, where the elastic effects should be much more important than the electrical boundary conditions, it may be easier to isolate the importance of the film stress state.

There are ferroelectric polymers of which the odd-number nylons and polyvinylidene difluoride (PVDF) are much the most widely researched. PVDF and its copolymer with polytetrafluoethylene (PTFE) is commercially produced in thick film sheet ($\tau > 10$ μm) and finds useful piezoelectric and pyroelectric application. The material is in fact a composite between a ferroelectric crystalline form and a flexible amorphous component. The polarization levels are more than an order of magnitude less than in PZTs, but the permittivity is also low so that voltage coefficients of piezoelectric and pyroelectric response are quite attractive for large-area, low-frequency sensors.

There are also large families of ferroelectric liquid crystals, which find major application in display technologies. Since, however, they are liquids, they take the form of the containment vessel and have not been widely explored in thin-film form.

2.8 Relaxor Ferroelectric Systems

In contrast to normal ferroelectrics, relaxor ferroelectrics demonstrate a diffuse phase transition and dispersion in the low-frequency dielectric properties. The broad temperature response, in conjunction with the high dielectric constants that can be achieved in bulk ceramics, make such materials attractive as relatively temperature-stable high–volume-efficiency capacitors. To date, thin films based on relaxor ferroelectric compositions such as lead magnesium niobate (PMN) or lead scandium tantalate (PST) show lower dielectric constants than do bulk materials, though they are still clearly high enough to warrant investigation as alternative capacitor compositions. Additional areas where thin-film relaxor ferroelectrics would be attractive include pyroelectric sensors and actuators based on either electrostrictive or biased piezoelectric response. Among the compositions available, solid solutions based on the PMN–$PbTiO_3$ and PST–$PbTiO_3$ systems look particularly good.

3. FERROELECTRIC FILM PREPARATION

3.1 Boundary Conditions for Films on Silicon

Most of the interesting ferroelectrics for integration on silicon come from the perovskite and the layered perovskite families. Unfortunately, in most cases when deposited directly on silicon, these materials react at the temperatures required for processing crystalline films. The lead-based compounds, in particular, form a lead silicate glass phase when processed directly on silicon or SiO_2, which leaches lead from the ferroelectric and acts as a low–dielectric-constant barrier layer between the ferroelectric and the semiconductor. As a result, reaction-blocking chemical barrier layers between the ferroelectric and the Si are required. Development of appropriate barrier-layer and electrode schemes is currently an area of intense research. This is particularly important in memory elements where the device capacitor is placed directly over the contact plug (often poly-Si). For such a geometry, a barrier layer is required to prevent the plug material from oxidizing or reacting with the dielectric during the capacitor processing.

There are also processing temperature restrictions that must be considered in integrating ferroelectric elements with Si-based semiconductor circuitry. All of the interesting ferroelectrics are multiple-cation compositions. While this is not inherently a limitation, the fact that many of the interesting compositions contain at least one volatile component, either Pb or Bi, limits the upper temperature to which the film can be exposed before appreciable changes in the film chemistry occur. As a result, the ferroelectric elements are typically introduced into the semiconductor after the majority of the CMOS processing has been completed. This, in turn, places restrictions on the temperature excursions allowed during the ferroelectric film processing, so that the silicon circuitry itself is not affected. This time–temperature limitation is expected to become progressively more restrictive as linewidths in the circuitry continue to fall. In order to minimize the thermal budget associated with the preparation of the ferroelectric element, rapid thermal processing (RTP) is preferred over conventional annealing for *ex situ* crystallized films. For films deposited at elevated temperatures so that they can be prepared in the desired crystalline form, routes that lower the deposition temperature are particularly attractive.

An additional parameter that must be considered, particularly for thick-film deposition, is the thermal expansion coefficient mismatch between the ferroelectric and the substrate. Since the thermal expansion coefficient of PZT does not match that of the underlying Si substrate, appreciable stresses develop during cooling from typical processing temperatures of 650 to 750 °C. Thus, particularly in thick films, the resulting stresses are large enough to cause film cracking and delamination. While this is unlikely to be a serious limitation in capacitor applications, for piezoelectric devices where large electrically induced displacements are required, larger thicknesses are necessary.

Some of the most important issues to be resolved in integrating ferroelectric (or paraelectric) capacitors into silicon-based circuitry are

1. development of appropriate electrode materials,
2. development of IC-compatible processing (including conformal coverage of nonplanar surfaces as well as all of the necessary etch chemistries), and
3. maintaining the required electrical properties through all of the processing steps required to form the device.

To date, the most important electrodes

have been Ti/Pt and RuO_2. Both retain good conductivity after firing in an oxidizing atmosphere at the temperatures required for crystallization of the capacitor. They do, however, suffer from problems. Pt, in particular, frequently undergoes significant stress relief during heating (which is often accompanied by hillocking) (Bruchhaus *et al.*, 1992) along with the migration of O and Ti through the Pt layer. PZT films electroded with Pt show much higher levels of fatigue than the same films on RuO_2. In addition, no good dry-etch chemistry has been developed for Pt. RuO_2, on the other hand, leads to improved fatigue behavior but degraded leakage current values in PZT. It also has a lower conductivity than Pt, which can lead to degradation in the high-frequency response of ferroelectric capacitors. Moreover, many of the volatile Ru compounds are toxic. Additional electrode materials that have been investigated include Pd, Ir, IrO_2, $SrRuO_3$, $CaRuO_3$, $La_{0.5}Sr_{0.5}CoO_3$, $YBa_2Cu_3O_{7-x}$, and TiN.

From an equipment standpoint, since the high volatility of Pb leads to appreciable diffusion during annealing steps, it will be necessary to develop secondary, contaminated, processing lines for the ferroelectric film processing in order to avoid contaminating the CMOS fabrication equipment. This is a significant additional expense.

3.2 Deposition Methods

There are a wide variety of deposition methods that have been used to prepare ferroelectric thin films, including chemical methods such as sol-gel or metal-organic decomposition (MOD), sputtering, laser ablation, metal-organic chemical-vapor deposition (MOCVD), reactive evaporation, molecular-beam epitaxy (MBE), and liquid-phase epitaxy. Factors that may dictate the techniques chosen for a specific composition and application include

- availability of appropriate precursors,
- uniformity of coverage,
- particulate generation,
- ease of composition control,
- growth temperature limitations,
- desired residual stress level,
- required thickness and deposition rate,
- step coverage, and
- compatibility with additional processing (especially semiconductor processing).

Since the literature is by now extensive enough that it is not possible to give a comprehensive review of each of the techniques, a short review is given in the following section. More complete descriptions are contained elsewhere (Myers and Kingon, 1991; Kingon *et al.*, 1992; Myers *et al.*, 1993; Tuttle *et al.*, 1994; Desu *et al.*, 1995). It is important that all of the methods described can be used to produce high-quality films, once problems associated with film composition and film microstructure are overcome.

3.3 Vapor-Phase Techniques

There are a host of vapor-phase techniques for preparing ferroelectric films, which differ primarily in the method for generating the vapor phase. Multiple texts are available that discuss the equipment requirements and deposition mechanisms for these methods. One factor that distinguishes vapor-phase production of ferroelectric films from deposition of other materials is the fact that most ferroelectrics are multiple-cation compounds that show large degradation in properties when made nonstoichiometric. This is especially problematic because many of the useful ferroelectric compounds contain cations with vastly different sputtering yields and vapor pressures (especially Bi and Pb relative to Ti, Zr, or Ta.). Consequently, in many of the vapor-phase deposition techniques, maintenance of the film composition is nontrivial. Of the vapor-phase techniques, Table 2 summarizes the advantages and disadvantages associated with each.

3.4 Liquid-Phase Techniques

Both sol-gel and MOD techniques rely on introducing an organometallic precursor into an appropriate solvent system. This liquid is then either spun, misted, sprayed, or dip-coated onto the substrate. Following solvent evaporation, the organic phase must be removed through a pyrolysis step and the film crystallized. While good results have been obtained with furnace annealing, a consensus is developing that RTP is preferable for integrated applications, given the vastly lower thermal budget. In principle, the stoi-

Table 2. Advantages and disadvantages of vapor-phase thin-film deposition techniques.

Method	Advantages	Disadvantages
Magnetron sputtering	High deposition rate possible. IC-compatible. Good compositional flexibility.	Target chemistry changes in reactive gas environment. Preferential sputtering/resputtering of multicomponent materials.
Ion-beam sputtering	Independent control of ion current density and ion energy. Atom/ion arrival ratios controllable.	Low deposition rates.
Laser ablation	Good target/film compositional fidelity. High deposition rate.	Boulder production. Poor thickness uniformity.
MOCVD	Excellent step coverage. Large area coverage possible. High deposition rate possible.	Appropriate precursors required. Precursor toxicity.
MBE	Layer-by-layer control.	Low throughput. Low coverage areas.

chiometry of the resulting film should be identical to that of the initial solution. It is clear, however, that compositional heterogeneities can arise during gelation, pyrolysis, or crystallization, any of which may lead to some segregation of cations from an originally homogeneous precursor. Procedures for solution preparation of high-quality lead zirconate titanate, as well as other perovskite films, are well documented for a variety of solvent–precursor systems (Tuttle and Schwartz, 1996). Similarly, several reports on the deposition of $Sr_2BiTa_2O_9$ films from solution precursors are available (Huffman, 1995). Some of the significant advantages of the sol-gel techniques are good compositional tailorability, even in multiple-cation systems, large area coverage, and the capability of building up films several microns thick (Chen *et al.*, 1996). In terms of integrated ferroelectric films, sol-gel materials have been used for most of the published work on MEMS. Debits include the fact that the liquid-phase techniques do not permit conformal coverage, and they are not compatible with high-density integrated-circuit processing.

4. CHARACTERIZATION OF FILM MICROSTRUCTURE

4.1 Introduction

Demonstration of good crystallinity in thin films is not, in and of itself, a guarantee of acceptable film properties. Equally important are the microstructure and the defect structure of the films. The role of defect structure has been discussed already. In this section, the use of microstructural characterization as an essential complement to structural and electrical characterization is described. Numerous articles describing microstructure–property relations in ferroelectric films are available in the literature (Tuttle *et al.*, 1995; Barlingay and Dey, 1992; Reaney *et al.*, 1994). Given the wide variety of data available, only generic features are covered here.

4.2 Direct Methods

Key microstructural features that can significantly affect the electrical properties include grain size, crystallite orientation, phase purity, density, and, in some cases, the depth profile of each of these parameters. In particular, the importance of phase purity and crystallographic orientation have been well described in numerous texts (Jaffe *et al.*, 1971; Herbert, 1985). Structure-sensitive probes such as x-ray diffraction and selected-area diffraction can be used to determine the phase content and to investigate the global and local crystallographic orientation, respectively. However, x-ray diffraction measurements alone are not a conclusive demonstration of single-phase films. Especially in the lead- and bismuth-based compounds, second phases can be present to levels as high as 15% before they appear in most x-ray patterns. High-resolution SEM, or TEM, particularly in conjunction with local composition probes, can be used to identify second phases such as PbO-rich pockets, or pyrochlore surface layers in $PbTiO_3$ and PZT films (Tuttle *et al.*, 1996; Reaney *et al.*, 1994; Fox *et al.*, 1992). Similarly, second-phase porosity can often be identified. Such microscopy studies have been instrumental in identifying the nucleation and growth processes in ferroelectric films. Similar studies are now coming out on the compound $SrBi_2Ta_2O_9$ (Scott *et al.*, 1996).

In interpreting the film properties, a knowledge of the grain size is also important. Electron microscopy and, to a lesser extent, atomic-force microscopy (AFM) can be utilized to determine the film microstructure, including the primary grain size, directly. In general, it cannot be assumed that grains in thin films are isometric, and so measurement in cross section is required. It is also important to note that lower-resolution SEM studies often identify cluster boundaries, which may be considerably larger than the primary grain size in the material.

TEM analysis also permits investigation of the domain structure in films. Several studies have demonstrated that PZT thin films tend to show relatively high domain densities, at least once the grains are above a certain size (Reaney *et al.*, 1994; Voight *et al.*, 1993). This is consistent with the observation in bulk PZT ceramics that the domain size drops with the grain size (Kim, 1994). It is not clear, however, that these twin walls are mobile in thin films (Tuttle and Schwartz, 1996; Trolier-McKinstry *et al.*, 1995a). Consequently, it may not be possible to rely, in thin films, on the extrinsic contributions to the dielectric and piezoelectric properties that are available in bulk materials.

4.3 Optical Methods

Optical methods, including wave-guiding experiments (Potter *et al.*, 1993), light scattering (Sinclair *et al.*, 1995), and spectroscopic ellipsometry (Trolier-McKinstry *et al.*, 1993; Trolier-McKinstry *et al.*, 1995b) can also be used to depth profile dielectric films nondestructively. These methods can be quite sensitive to small inhomogeneities in the density of the film through the film thickness. Such information is useful in electrical applications since introduction of a low-density (and hence low dielectric permittivity) layer leads to an appreciable decrease in the effective dielectric constant, piezoelectric coefficient, and electro-optic coefficient of the film. For optical applications, such as wave guiding, identification and elimination of low-density layers is essential, as the associated refractive index discontinuities lead to unacceptable optical scattering (Fork *et al.*, 1996). Similarly, scattering centers such as rough surfaces, grain boundaries, and domain walls can significantly decrease the distance over which light can be guided. The importance of these factors is best determined by optical measurements, as a microstructure-based technique will not necessarily be a complete predictor of the scattering losses.

5. PROPERTIES OF FILMS ON SILICON

5.1 High-Permittivity Films (DRAMs)

In the area of memory applications, the drive to incorporate paraelectric materials is predicated on the need for dielectrics that permit development of gigabit memories. A good review of the requirements for memory dielectrics is given by Jones *et al.* (1995). For DRAM applications, information is kept by storing charge on a capacitor and periodically reading and resetting it (typically, around ten times per second). In such a configuration, it is imperative that the charge be retained without excessive leakage during a cycle time, and it must be large enough that α-particle events do not change the logic state. This necessitates a capacitor of at least 50–75 fF (Jones *et al.*, 1995).

Until this point, SiO_2 and SiO_2/Si_3N_4 have been used as the capacitor material. However, as memory density increases beyond 256 Mbit, it is difficult to achieve sufficient capacitance per element with these materials. Ta_2O_5 films, with their higher relative permittivity, permit higher densities and may be adequate for 1-Gbit DRAM. Considerable simplification of the capacitor structure would, however, be facilitated by materials of higher ϵ_r. Potential candidates include $SrTiO_3$, $Ba_xSr_{1-x}TiO_3$, or paraelectric La-doped PZT (Jones *et al.*, 1995).

The primary materials parameters that must be optimized for DRAM applications are a high storage density, a low leakage current, little resistance degradation, and suppression of time-dependent dielectric breakdown (TDDB). Paraelectric compositions are preferred in these applications. Most dielectric films for DRAM applications show somewhat lower dielectric constants than their bulk counterparts, especially when prepared as layers <100 nm in thickness. However, several groups have demonstrated that it is possible to prepare films that meet the capacitance density, leakage, and breakdown strengths required for DRAMs. A listing of some of the reported efforts in DRAM manufacturing is given in Table 3. A discussion of some of the important processing integration issues is given below in the section on FRAM materials, since many of the issues are identical.

5.2 Hysteretic Films (FRAM)

In the design of ferroelectric nonvolatile memories, the polarization state of the film is used to store the ones and zeros of the binary code. In principle, such memories are nonvolatile since the remanent polarization state of the ferroelectric is not lost when power is cut off. Low-density FRAMs are attractive for applications such as smart cards and drop-in EEPROM replacements, while high-density FRAM could replace some Si-based memory in computing applications. FRAMs can be written quite rapidly, and so they offer significant advantages over other nonvolatile memories such as EEPROM. In practice, several barriers need to be overcome before the full benefits of a high-density, nonvolatile memory based on ferroelectric films will be viable. These include

1. fatigue, i.e., loss of switchable polarization associated with repeated polarization reversals over the lifetime of the device;
2. poor retention of the written polarization direction;
3. imprint, or development of a preferred polarization state; and
4. development of IC-compatible processing.

Significant progress has been made in each of these areas over the past few years.

At present, the two best-developed candidates for this application are PZT and $SrBi_2Ta_2O_9$. For FRAM applications, PZT is attractive because of its large switchable polarization ($2P_r$ around 45–55 $\mu C/cm^2$) and the lower temperatures required for crystallization. However, PZT films deposited on Pt electrodes suffer significant fatigue in the magnitude of the switchable polarization after the polarization has been reversed on the order of 10^7 times. This can lead to significant difficulties in distinguishing the memory state. While for a few applications this is acceptable, in computer memories it would be preferable to have 10^{12}–10^{15} polarization reversal cycles. Several years ago, it was demonstrated that fatigue could be eliminated in PZT films by using conductive oxide electrodes such as RuO_2, IrO_2, or LSCO (Au-

ciello and Ramesh, 1996; Nakamura *et al.*, 1994; Ramesh *et al.*, 1993). In some cases these electrodes also minimize imprint problems (Nakamura *et al.*, 1994). An alternative choice is to switch to one of the Bi-layer structure ferroelectrics like $SrBi_2Ta_2O_9$. While in polycrystalline films, the reversible polarization in this system is smaller than in the PZTs ($2P_r < 22$ $\mu C/cm^2$), they also show negligible fatigue out to 10^{12} cycles, even when deposited on Pt electrodes (Jones and Desu, 1996).

In addition to the materials requirements, there are many processing issues that must be addressed in order for paraelectric or ferroelectric films to be integrated into DRAM or FRAM. First, most groups are reporting memory capacitor structures similar to that shown in Fig. 7. Since the capacitor must be deposited over a 0.25–0.75 μm step in order to increase the element capacitance while maintaining a small feature size, a deposition process that enables conformal coverage is essential. For such applications, MOCVD is the method of choice. Second, each of the materials utilized must be patternable at the required feature size, which will probably require reactive ion etching (RIE). Third, the dielectric film properties must be retained throughout the entire processing cycle. As has been discussed elsewhere (Jones and Desu, 1996), this is a significant challenge. Especially problematic is the RIE (Pan *et al.*, 1994), which can result in degradation of the ferroelectric's hysteresis loop (for FRAMs). Additional degradation can be induced when the interlevel dielectric is deposited over the patterned capacitor. Moreover, any processing step that involves significant exposure to hydrogen can lead to reduction of the ferroelectric layer, with a consequent increase in the conductivity, and a decrease in the switchable polarization. A more complete review of these effects is given by Archard *et al.* (1995).

Research in both DRAM and FRAM memories is being conducted in Japan, the United States, Europe, and Korea. Table 3 summarizes recent publications in these areas.

5.3 Pyroelectric Films

As described in Sect. 1.3, thin-film pyroelectrics offer significant advantages in terms of integration with integrated circuitry and low thermal time constants relative to bulk materials (Shorrocks *et al.*, 1995). For pyroelectric applications, $PbTiO_3$, $(Pb,La)TiO_3$, $(Pb,Ca)TiO_3$, and PZT have been the most widely studied film compositions. Interest in the $PbTiO_3$-based compounds stems from its combination of a large polarization (around 80 $\mu C/cm^2$) and hence the potential for a large pyroelectric coefficient, and its relatively modest dielectric permittivity. Both factors are necessary for a substantial figure of merit (FOM). Ca or La doping serves the dual purpose of bringing the ferroelectric transition temperature closer to room temperature and increasing the electrical resistivity of the film. Taking p/ϵ_r as an approximate FOM for a pyroelectric detector, PZT films have been demonstrated with FOMs of ~0.7 $\mu C/(m^2\ K)$ (Shorrocks *et al.*, 1995; Kohli *et al.*, 1995), while $PbTiO_3$-based films have been reported with FOMs as high as 2.9 $\mu C/(m^2\ K)$ (Kamada *et al.*, 1995; Seifert *et al.*, 1996).

In terms of thermal isolation, two families of device geometries have been pursued: diaphragm structures prepared by bulk Si micromachining and air-bridge arrays (Shorrocks *et al.*, 1995; Polla, 1995) for higher-resolution imaging. Thin-film $(Pb,La)TiO_3$ pyroelectric sensors are now being used commercially in some Matsushita air-conditioning units so that the ventilation can be automatically adjusted on the basis of the number of heat sources in the room (Kamada *et al.*, 1995). There is considerable room in this field for optimization of detector properties based on both the film composition and microstructure as well as new device designs.

5.4 High–Energy-Density Transducers

The primary requirements for a thin-film transducer are that it demonstrate an appreciable controllable displacement and that it have a high energy density. Piezoelectric and electrostrictive materials are attractive from both standpoints, as large electrically induced displacements can be achieved. Moreover, on account of the high dielectric constant of most ferroelectrics, they have a significant advantage in energy density over electrostatic actuators. In addition, they show much higher piezoelectric activity as well as higher piezoelectric coupling coefficients than ZnO. For many years, ZnO has been the predominant piezoelectric transducer for thin-film applications, largely because oriented thin films could be sputtered reproducibly. However, the piezoelectric activity of ZnO is modest (typically 5–10 pm/V). As a consequence, in applications where large displacements and efficient electromechanical coupling are required, ferroelectric thin films (with d_{33} = 50–300 pm/V) offer significant advantages.

Among the ferroic candidates for actuator films, three distinct mechanisms can be utilized to generate a strain in the film: piezoelectricity, electrostriction, and phase switching. Fundamentally, the piezoelectric effect is the linear relationship between the applied electric field and the resultant displacement. Electrostriction, on the other hand, implies proportionality between the square of the electric field and the shape change, and is observed when piezoelectricity is absent. In practice, both of these relations are applicable over a limited electric-field range. For example, when a large alternating electric field is applied to excite piezoelectric displacement, hysteresis in the strain is observed due to domain-wall motion. While electrostrictive materials show much lower levels of hysteresis in the strain, it has been found that the strain is properly proportional to the square of the polarization rather than the square of the electric field at high field levels. Phase-switching compositions, on the other hand, rely on the electrically induced transition from an antiferroelectric phase to a ferroelectric phase. Since the volumes of the unit cells differ between the two, an appreciable surface displacement can be generated.

Thin-film actuators based on each of these mechanisms have been demonstrated over the past several years. Among the piezoelectric compositions, PZT-based materials have been the best studied. In most cases, PZT thin films show smaller effective piezoelectric coefficients than do bulk ceramics of the same composition (i.e., d_{33} ~ 70–140 pm/V for undoped PZT films where undoped bulk ceramic PZT shows a d_{33} of ~220 pm/V). Nonetheless, this represents a significant step up from ZnO-based devices. Comparable properties have been demonstrated by several groups, including some in the United States (Polla, 1995; Udayakumar *et al.*, 1992; Li *et al.*, 1994), Europe (Muralt *et al.*, 1995), and Japan (Fujii and Watanabe, 1996). In many cases, the piezoelectric coefficients of PZT thin films can be increased if the ac driving field is superimposed over a dc bias electric field (Udayakumar *et al.*, 1992; Muralt *et al.*, 1995). Thus far, a conclusive demonstration of soft PZT properties in thin films has not been reported in the literature, possibly as a result of either the small grain size or the stress state in films, either of which can restrict the domain-wall mobility (Shepard *et al.*, 1996; Damjanovich and Demartin, 1996). However, this may be obviated, at least in part, by the fact that thin films typically have high breakdown strengths (~1 MV/cm), and so they can be driven harder than a comparable bulk actuator.

Over the last few years, several types of MEMS actuators using ferroelectric films have been demonstrated, including micromotors (Udayakumar *et al.*, 1992; Muralt *et al.*, 1995; Flynn *et al.*, 1992), pumps (Polla, 1995), acoustic imaging devices (Bernstein *et al.*, 1996), AFM components (Fujii and Watanabe, 1996), and meanderline actuators (Polla and Francis, 1996). Outstanding issues in the field include the effect of the film stress state and the film microstructure on the piezoelectric coefficients, the aging of the properties, and the long-term reliability of the structures for large-amplitude devices.

Considerably less data are available in the literature on the use of electrostrictive compositions for thin-film actuators. PMN:$PbTiO_3$ electrostrictive compounds show very large strain levels in bulk ceramics without the hysteretic response that is characteristic of PZT under large drive levels. If comparable properties can be achieved in thin films, such materials would be attractive for precise positioning components.

In contrast, there have been several reports on the properties of antiferroelectric–ferroelectric phase-switching materials for thin-film actuators, with the majority of the activity being centered in the United States (Gaskey *et al.*, 1995; Tani *et al.*, 1994; Yamakawa *et al.*, 1996). Square double hysteresis loops with well-defined coercive fields have been prepared from lead zirconate and doped lead zirconate compositions (especially La- and Sn-doped materials). Of particular note is the fact that strain levels of 0.3% have been generated in films, which exceeds that available in piezoelectrically actuated materials. Such films are especially attractive in digital displacement applications where well-defined on and off states are required.

Many MEMS devices require larger surface displacements than can be generated in thin films. In such applications, thicker films are required. Preparation of thick films entails considerable care in the processing in order to prevent film cracking or delamination. Several groups have demonstrated thick piezoelectric films, largely prepared by wet-chemical methods (i.e., sol-gel or MOD). In particular, PZT films of 12 μm in thickness have been prepared on Pt-coated Si (Chen *et al.*, 1996), and up to 10 μm in thickness on ZrO_2 substrates (Brooks *et al.*, 1996).

6. CONCLUSIONS

Over the past few years, it has been clearly demonstrated that ferroelectric thin films have tremendous potential for integration with silicon-based electronics. Significant strides in appropriate materials selection, film deposition and characterization, and IC-compatible processing have been made. In particular, prototype devices have been demonstrated using ferroic films in DRAMs, FRAMs, decoupling capacitors, pyroelectric sensors, and piezoelectric or phase change transducers. Both low-density FRAMs and pyroelectric sensors are now being produced commercially.

It is clear, though, that much additional work is required in order to realize fully the benefits of ferroelectric thin films in integrated applications. For the high-density memory applications, where there are tremendous potential advantages to ferroic film incorporation, significant work still needs to be done to optimize the film properties to promote both short-term and long-term device reliability, facilitate low-temperature deposition, and improve compatibility of both the electrode and the capacitor with silicon electronics processing. In the areas of pyroelectric and piezoelectric devices, only modest efforts have been expended to date in the development of film composition and film integration. Vendors capable of supplying a range of thin-film compositions for prototyping would also be an important boost in terms of demonstrating the viability of the technology.

GLOSSARY

Aging: The continuous change of properties in a ferroelectric as a function of time under zero external stimulus and constant temperature.

Curie Temperature: The temperature that is the boundary between ferroelectric and paraelectric phases in a ferroelectric crystal.

Curie–Weiss Temperature: If the dielectric stiffness in the paraelectric phase is of the form $x = x_0(T - \theta)$, i.e. following a Curie–Weiss law, it is the Curie–Weiss temperature θ where the extrapolated stiffness would go to zero.

Fatigue: The loss of switchable polarization as a function of the number of switching cycles between "saturated" polarization states.

Imprint: Development of a favored remanent polar state under asymmetric pulsed switching conditions.

Morphotropic Phase Boundary (MPB): A phase boundary in the phase diagram of a ferroelectric solid solution system that is nearly vertical from the composition axis; i.e., a composition close to the boundary will remain close over a wide temperature interval.

INTRODUCTION

Tides and wind-driven waves in the ocean are major repositories of renewable energy at global scales. Astronomically forced tides acquire their energy from gravitational attraction forces produced by the moon and sun. Tides are simply a particular class of ocean waves. The remainder of the ocean waves are dominated energetically by wind-generated types. The energy source for these waves is heat from the sun, which drives the variations in the distributions of pressure within the Earth's atmosphere that result in winds. Tides and, to a lesser extent, other ocean waves are responsible for currents that are locally very important in the transport of water masses, suspended and dissolved material distribution, and the erosion and accretion of shorelines and the seafloor near the ocean boundaries. Currents driven by winds and by density differences such as those caused by varying water temperatures and salinities are principally responsible for the mixing and transport phenomena within ocean basins. However, very near the shoreline, the movements caused by tides and waves are often the dominant mechanisms.

Energy in any system of gravity waves, tides included, is divided between potential and kinetic forms. Linear wave theory provides that there is equipartion between kinetic and potential energy in surface gravity waves of low steepness in deep water. The assumption of equipartition has been extended, in practice, to all waves in all depths of water. Wind waves are inherently random in amplitude and with a broad spread of directions such that estimates of their energy density are averaged both spatially and temporally to provide useful engineering values. Tides, conversely, are very predictable and change sufficiently slowly that meaningful information is contained in the discrete elevation history.

Attempts have been made to estimate the global level of energy in tides and wind waves (Isaacs and Seymour, 1973; Isaacs and Schmitt, 1980) with assumed values on the order of 3 TW for each resource. Power has been extracted from both sources in a limited number of applications representing only a minuscule drain on the overall resources. Tidal power, perhaps because of its predictability and accessibility in sheltered locations, was the first to be utilized in pre-

digital Encyclopedia of Applied Physics

vious centuries through waterwheel-driven mills. In the last half of this century, a few sites have been exploited to produce electricity from tides (Warnock and Clark, 1992), and a significant effort has been undertaken internationally to develop a similar capability from wave power (McCormick, 1981; Carmichael and Falnes, 1992).

Tides have been observed and predicted by mariners for many centuries, and their correlation with the moon phases has been understood (Darwin, 1911). The earliest records of continuous observations date from the thirteenth century at London Bridge on the Thames. Newton in the Principia explained the astronomical tide-generating force in 1687 and provided a basis for the number of tidal cycles per day. Lord Kelvin, in about 1870, was the first to develop the concept of the tides as a sum of harmonic components. This led directly to the modern methodology for tide prediction. The frequencies of the components are developed from the detailed knowledge of the motions of the sun and the moon relative to the Earth. Measurements are made at a specific site, typically hourly for 18.6 years to encompass the longest astronomical period, and the phases and amplitudes of the tidal responses are determined for the designated frequencies. The coefficients can then be applied to future values of the astronomical forcing functions and summed to make predictions of the tides at that location. Tides at locations between observation points are estimated with lesser accuracy by interpolation and, in some cases, by measurement over shorter periods of time.

Laplace (Lamb, 1932) developed a dynamical theory of tides through a set of shallow-water wave equations for a fluid layer on a spherical Earth, derived from the conservation of mass and momentum. These form the basis for modern tide theory, later enhanced by a number of theoreticians to include consideration of density stratification, Coriolis forces, varying depth, and the effects of solid-Earth tides. Realistic solutions to the modified Laplace equations have been obtained numerically for global tides. A comprehensive review of the development of modern theory is found in Hendershott (1981).

The understanding that winds act on the surface of oceans and lakes to produce waves has been available for centuries. However, theoretical work on these interactions between wind and waves has been relatively recent, occurring entirely within the twentieth century. The initial efforts were directed at attempts to understand the influence of the ocean on the boundary layer of the atmosphere. Charnock (1955) first proposed that the roughness length over the sea surface should vary as the wind speed. Drag coefficients have been determined empirically by a number of investigators (Large and Pond, 1981; Wu, 1982). Although weakly dependent upon wind speed, drag coefficients were found to vary significantly. Attempts followed to factor in wave characteristics to explain the variation in the drag coefficient (Janssen, 1989). None of this work, however, provided any significant insights into the mechanisms whereby the wind stress transmitted energy and momentum to the waves.

During World War II, an effort was begun to develop empirical models for estimating the wave-generation process from knowledge of the wind fields over the ocean. Bretschneider (1952) extended the wartime work of Sverdrup and Munk (1947) in developing semiempirical models relating the wind speed, duration, and fetch—the distance over which the wind acts—with the height and characteristic period of the waves. Pierson *et al.* (1953) provided a method for predicting a spectrum of wave energy, an improvement over the two-parameter height-period characterization. More recently the JONSWAP group (Hasselmann *et al.*, 1973) developed a refined spectrum from an extensive wave-generation observation program in the North Sea.

Waves that are still increasing in size as a result of the wind are referred to as *sea;* those that travel beyond the generation area are called *swell.* Snodgrass *et al.* (1966) showed that swell could propagate from Antarctica to the western coast of North America without significant loss of energy. Because swell obeys a dispersion relationship such that energy in deep water propagates at a speed inversely proportional to frequency, the swell is dispersed over a greater area over time and the height diminishes as the energy is spread. In many locations, swell dominates the local wave climate. In the Pacific and the South Atlantic, very energetic swell with characteristic heights of more than 3 m is not uncommon.

Significant research programs have been undertaken internationally, particularly in the 1970s, to develop methodologies for extracting energy from waves. Although extensive laboratory testing and some field deployments have been accomplished, only a limited number of installations have reached the commercial stage. Although environmentally benign and a truly renewable resource, wave energy is inherently of low quality as a power source because of its extreme variability, and the mechanisms are subject to extreme loads, stress corrosion, and fatigue.

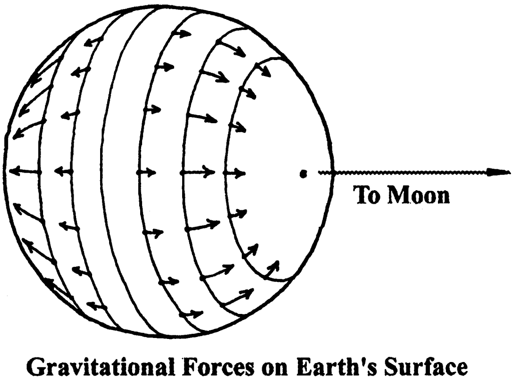

FIG. 1. Tangential components at the Earth's surface resulting from the gravitational attraction of the moon. Similar, but smaller, forces are produced by the sun.

1. TIDAL ENERGY

1.1 Physical Principles of Tides

The astronomical forcing of tides results from the gravitational attraction of the moon and the sun. The rotation of the Earth and the perturbations of the orbits of the Earth about the sun and of the moon about the Earth result in time-varying forces when viewed from any spot on the Earth's surface. The direct attraction of the moon is the principal component, that of the sun second, both with periods on the order of half a day. The variations produce attraction components of lesser degree with periods ranging from about a day to more than a decade. Typically, as many as 30 periodic components are employed to represent the complete astronomical attraction force. At a particular spot on the Earth's surface, each periodic component produces a small horizontal oscillatory force with a unique amplitude and phase. The distribution of these forces for a single component is illustrated in Fig. 1.

Lord Kelvin (Lamb, 1932) showed a solution for the Laplace shallow-water wave equations on a rotating sphere that produces a trapped wave at the shoreline. For waves traveling around an ocean basin in an counterclockwise direction in the Northern hemisphere, these Kelvin waves have maximum amplitude at the shoreline, decaying exponentially with offshore distance. For waves of infinitesimal height, the wave velocities are everywhere zero normal to the shoreline. On a sloping shore with real waves, a small normal component is required to conserve mass, such that the orbits of Kelvin waves are highly flattened ellipses, as shown in Fig. 2, with the long axis parallel to the shoreline. The Kelvin wave provides a capability to form resonant wave systems in ocean basins where an integer number of waves can fit into a rotary pattern with a wave crest passing a point about every 12 or 24 h. The resonant pattern corresponding to the principal lunar forcing component for a portion of the North Atlantic is shown in Fig. 3. The apparent center of rotation of the system, which is

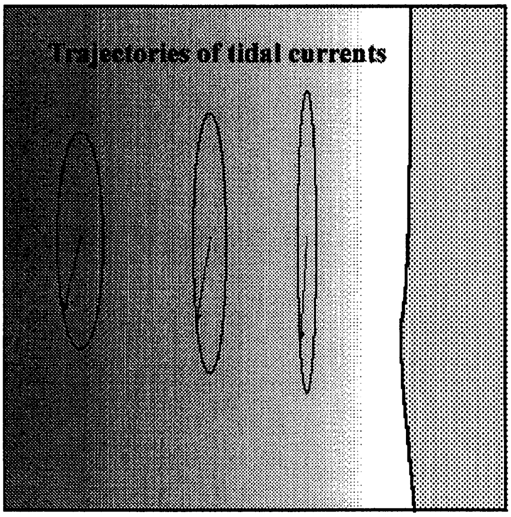

FIG. 2. The velocities produced by Kelvin waves on the continental shelf follow orbits that are flattened ellipses, particularly in shallow water. The dominant tidal currents along relatively straight coastlines are therefore largely parallel to the shoreline.

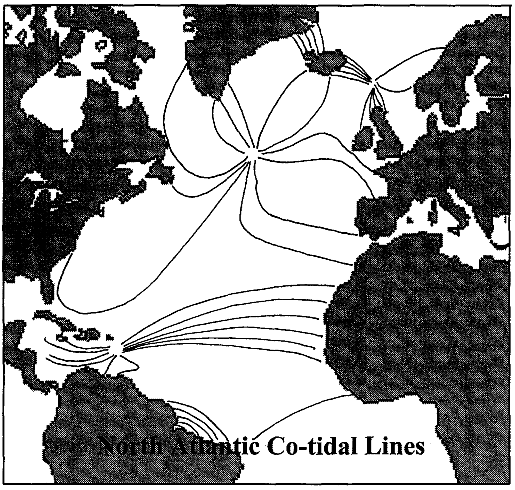

FIG. 3. The co-tidal lines, or regions with the same tidal phase, for a single component of the tide in the North Atlantic. Thus, the lines can be interpreted as the location of the crests of the Kelvin waves at one instant in time. The rotary system, which moves counterclockwise in the Northern Hemisphere, is clearly apparent.

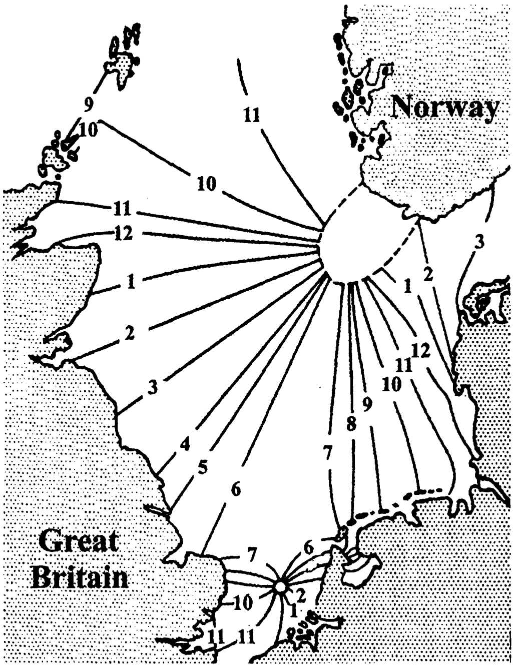

FIG. 4. An illustration of the interaction between systems of rotary tidal waves in the North Sea, with relative times of high tide in hours after the moon passes over Greenwich. Only a single tide component is shown. The smaller system in the channel propagates slowly because of the reduced water depth and is therefore able to remain in phase with the larger North Sea system.

a point of disappearingly small tidal excursion, is called an amphidromic point. The propagation speed of these trapped coastal waves is determined by the water depth, as given by

$$c = \sqrt{gh}, \tag{1}$$

where c = celerity of the tidal wave, g = gravitational constant, and h = water depth.

Because slower waves in shallow water basins have proportionately shorter wavelengths, the overall size of these shallow systems is smaller than those in deep ocean basins. This allows neighboring systems of rotary resonances to mesh constructively. An example of these interactions in the vicinity of the British Isles is shown in Fig. 4.

In many locations, long narrow embayments, such as the Adriatic, the Bay of Fundy, and the Gulf of California, open to large seas or ocean basins. A Kelvin wave beginning at the open end of such a marginal sea and traversing the right-hand shoreline will reflect from the end and continue down the opposite shore. The effect of the interactions between the incoming and outgoing wave is to form what appears to be a rotary system of waves with one or more amphidromic points near the center of the bay. In the three examples mentioned, the amplification that occurs from shoaling and narrowing in the shallower water at the head of the sea results in tidal heights that are many times the magnitude that occurs at the open end where tide characteristics must match those of the ocean basin. For example, the Adriatic Sea has very substantial tides at its northern end, in the vicinity of Trieste, but matches the nearly tideless Mediterranean at its southern opening.

The result is that any water body of the right shape, size, and depth to support a resonant wave system with a period close to 12 or 24 h will exhibit a recognizable tide, provided that the resonant system can exist in synchrony with the resonant tidal waves in neighboring and connected bodies of water. If these conditions are not met, the tides in that basin or region will be negligible as, for example, in the Baltic Sea.

Tides, as gravity waves, are variations about mean sea level. If worldwide sea level changes by tens of meters, as it has over geological time scales, the pattern of tides will change radically as well. This is caused by the detuning effect of changing both the water depth (which changes the speed of propagation of the tidal waves) and the size and shape of the water body substantially, affecting the ability to establish resonant wave systems at the appropriate periods. Temporary changes in sea level can result from wind stress. Hurricanes and typhoons can raise sea level by several meters along local sections of wide and shallow continental shelves. Global changes in climate, such as the El Niño–Southern Oscillation event that alters wind patterns over the Pacific, can result in changes of tens of centimeters along the boundaries of whole ocean basins for intervals on the order of a year. Astronomical tides persist as variations about these temporarily modified sea levels, although, in general, the depth and geometry changes are either too local or too small in amplitude to result in significant changes to astronomical tides.

In shallow basins such as the Patagonian shelf and the Bering Sea, the friction of tidal currents can reach significant levels (Hendershott, 1981). Energy is conserved within the sun-moon-earth system by a gradual slowing of the Earth's rotational speed, resulting in a relative increase in the length of the Earth day. Angular momentum is conserved by an appropriate increase in the distance between the moon and the Earth. Hendershott (1981) provides a comprehensive review of the evolution of the physical oceanography of tides.

1.2 Global Distribution of Tidal Energy

Rotary systems of Kelvin waves account for most of the tidal energy in the large ocean basins of the world, as shown in Fig. 5. Although difficult to convey with a single diagram, the tides are the sum of many rotary wave systems that are largely linearly independent. With a few exceptions, the tidal ranges are limited to about 2 m or less, resulting in energy densities too small to be of economic interest. Along the Patagonian coast and the French coast of the English Channel, for example, tidal waves do achieve substantial ranges (4 to 6 m). For the most part, however, such large tidal ranges are limited to a few scattered locales around the world where marginal seas, embayments,

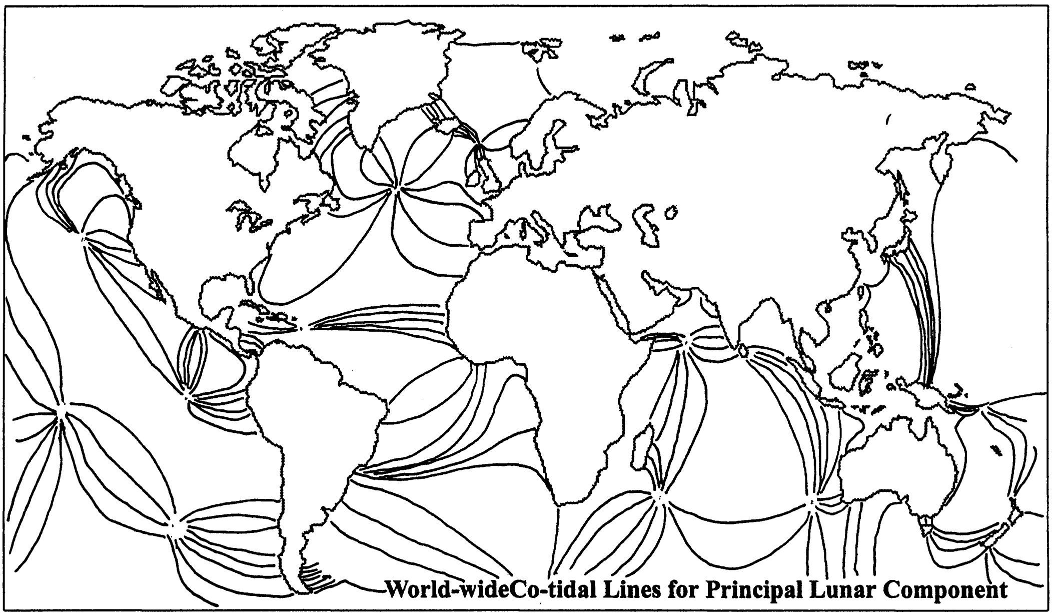

FIG. 5. One component of the world tidal system is shown to illustrate the interactions between ocean basins. The world tide is seen to be dominated by rotary systems of Kelvin waves.

and estuaries provide sites for amplification. Rivers at the heads of these locations may feature substantial reversing bores that can convey tidal energy up to tens of kilometers inland. Ippen and Harlemann (1966) review the tidal dynamics in estuaries. Figure 6 indicates where tidal ranges reach what might be economically attractive size.

1.3 Utilization of the Tidal Resource

Tidal power has been employed for mechanical energy in small, local applications for centuries, analogous to the use of windmills, to power machinery of various types. Early in the twentieth century there was strong interest in generating electrical power in regions without access to conventional hydropower. Studies of electrical power plants in the Bay of Fundy go back at least as far as the 1920s. For the reasons discussed in the following sections, the number of actual installations has remained small and is not expected to grow substantially.

1.3.1 Types of Power-Extraction Systems Existing and planned tidal-power installations follow a similar plan. A relatively small basin adjacent to a larger body of water with a substantial tidal range is selected for modification. A dam (also referred to regionally as a dyke or a barrage) is constructed to close off the basin. Openings are provided in the dam wall so that controlled flows can occur between the basin and the outer body. This system can be arranged for single-effect or double-effect power extraction. In a single-effect system, the water is allowed to flow relatively unimpeded through sluice gates into the basin on the rising tide. As the tide outside the basin begins to fall, these gates are closed, and when the head between the basin and the falling level outside reaches about half of its maximum potential, the outflow is allowed to pass through one or more low-head turbines, which drive generators and produce electricity. In a double-effect system, the turbines are capable of operating with flows in either direction, similar to reversing the propellers on an aircraft, and so generate on both rising and falling tide stages. The generators can be operated as motors, allowing the turbines to be used as pumps so that the system can provide for pumped storage to assist in load matching when the tide cycles are fav-

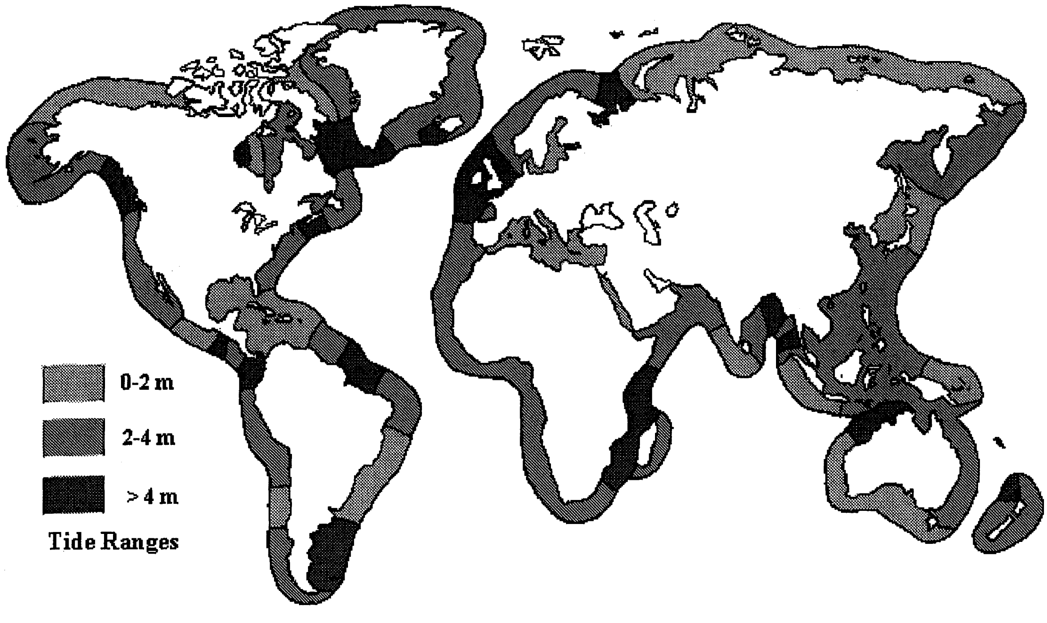

FIG. 6. Tidal ranges vary significantly globally. The figure indicates broad categories of ranges. The areas with darkest shading are macrotidal ranges (>4 m), the intermediate shading defines the mesotidal ranges (2–4 m), and the lighter shading defines the microtidal ranges (0–2 m).

orable. In double-effect systems, the turbine blades can be fully feathered to assist the sluice gates in allowing flow into the basin. These turbines operate at very low heads (4–15 m), contrasted with the hundreds of meters available in many hydroelectric systems, and are therefore expensive and inefficient by comparison. The development of bulb-type submerged generators, coaxial with the turbines as shown in Fig. 7, has made the modern tidal-power installations feasible. A recent development has allowed even more efficient flow configurations by mounting the generator in a ring outside of the turbine blades, such that the flow is entirely inside of the generator rotor. A review of the state of the art is found in Warnock and Clark (1992).

1.3.2 Tidal-Power Installations The four existing major tidal-power installations in the world were all constructed in the last half of the twentieth century. The largest is at La Rance on the Brittany coast of France. It contains 24 generators rated at 10 MW each and operates with a 8.5-m tidal range. The turbines are double effect, and the units can be used for pumped storage. The second largest is at Annapolis, Nova Scotia, Canada. Although many sites have been studied on the Bay of Fundy, this is the only plant yet constructed. It took advantage of an existing causeway to provide a basin. The single generator is of the concentric type, rated at 20 MW, and the turbine runner is 7.6 m in diameter. It is considered a prototype for modern tidal-power installations. The third largest is at Jiangxia, Zhejiang Province, China. Again, an existing dam intended to reclaim marshland was employed. Five bulb-type and one concentric generators were installed for a total capacity of 3.9 MW. The mean tidal range is 5 m. The bulb units are double effect. The remaining unit is at Kislaya Guba on the Barents Sea coast of Russia. It is a modest unit with a single (400-kW) bulb turbine but was intended to be the prototype of a 10 000-MW installation at Tugur Bay on the Sea of Okhotsk and a 15 000-MW installation at Mezen Bay on the White Sea. Neither of these larger units was ever constructed.

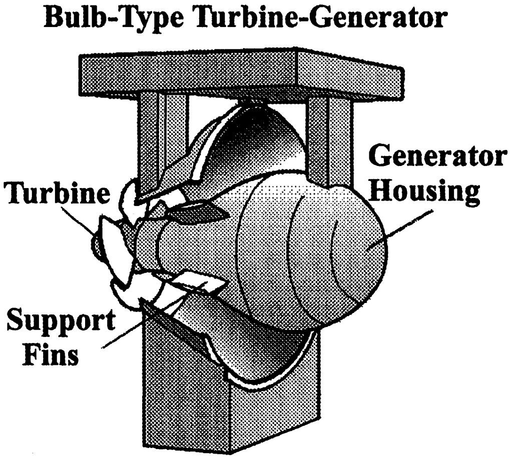

FIG. 7. The general configuration of a bulb-type, low-head turbine generator used in modern tidal-energy installations. The generator is mounted in the bulbous housing and is directly coupled to the turbine blades.

During the last two decades of the twentieth century, a number of major sites have been investigated. These are shown in Table 1. Of these, only the two in the United Kingdom, the Severn, and the Mersey Estuaries showed sufficient economic potential to proceed into detailed engineering design. Both of these sites are considered as candidates, but no construction decisions have been made.

1.3.3 Environmental Effects Concern for adverse environmental impacts appears to have been as important as weak economic justification in delaying or canceling proposed tidal-power projects. Two of the existing major plants involved minor changes to barrages constructed years earlier before the international environmental movement coalesced. In this manner, they avoided being assessed by both the major cost of the barrage and the responsibility for disturbances

Table 1. Proposed sites for major tidal-power installations.

Site	Proposed capacity (MW)
Cook Inlet, Alaska, U.S.A.	1440
Garolim Bay, Korea	400
Gulf of Kachchh, India	600
Site B9, Bay of Fundy, Canada	5338
Severn Estuary, United Kingdom	8640
Mersey Estuary, United Kingdom	700

to wetlands. Salinity and sedimentation patterns can be substantially altered by the modifications to the flow characteristics, which results in stress to the unique assemblages of plants and animals that colonize the large intertidal regimes. The impediments to migratory fish stocks and the fish mortality associated with passage through the turbines have resulted in substantial objections by commercial and sports fishermen to proposed installations. Numerical modeling of the potential effects of large Bay of Fundy projects has resulted in predictions of measurable modification of the ocean tides along the northern coast of the United States (Greenberg, 1984). Although these predicted changes are small, they could, in principle, result in more frequent closing of Logan Airport in Boston Harbor because of water on the runway. The liability from such an occurrence is one of the factors cited in reducing the economic attractiveness of Bay of Fundy power installations. Tidal-power generating stations have a beneficial environmental effect in minimizing the production of greenhouse gases. Because of the difficulty in predicting the influence of the installation on the natural production of carbon dioxide, it is not possible to state that this power source results in no atmospheric pollution. Daborn (1976) reviews the overall environmental impacts in the Bay of Fundy.

1.3.4 Economics The barrages and the generating equipment in tidal plants have exceptionally long working lives, which tends in part to offset the very high installed cost. Further, the load factor is relatively low so that the capital cost per unit of power generated is further increased. With relatively low maintenance and no fuel costs, the amortization of the capital cost and interest on the investment constitute 85–90% of the total energy cost for tidal-power schemes (Shaw, 1992). The value of the energy produced depends to a large degree on the local market. Even with pumped-storage potential, it is never possible to match the plant output with typical demand cycles because the dominant tidal period is slightly greater than 12 h. This degrades the value of the energy when compared with sources that can provide true load-matching capabilities. The recent history of economic analyses suggests that only in those cases where the cost of the barrage can be partially or fully borne by some other application, such as a bridge connecting otherwise remote shorelines, can tidal power be competitive with thermal power plants. A review of the factors influencing tidal-power economics is found in Shaw (1992).

2. WAVE ENERGY

2.1 Physical Principles of Wind-Generated Ocean Waves

The transfer of energy and momentum from wind to waves has been studied extensively over most of this century, but no general theory has yet been agreed upon. Jeffreys (1925) proposed that waves were generated by wind stress acting normal to the sea surface. Sverdrup and Munk (1947) added the energy transfer due to the tangential component of stress. A series of basically empirical models, beginning during World War II, has resulted in a useful ability to predict wave growth from a knowledge of the wind field. However, the precise physical mechanisms involved have yet to be explained. Presently, considerable effort is centered upon considering the state of development of the waves (Donelan *et al.*, 1993). In all of this work, wind stress on the surface has been treated as a scalar aligned with the mean wind direction. Recently, Rieder *et al.* (1994) have shown that the direction of the wind stress is strongly influenced by the direction of pre-existing swell waves that are not aligned with the wind.

The models for wave generation are based upon the general equation

$$\frac{\partial E}{\partial t} + v_j \frac{\partial E}{\partial x_j} = S_i + S_n + S_d, \tag{2}$$

where E = wave energy, v_j = group velocity along coordinate x_j, S_i = atmospheric input source term, S_n = nonlinear wave–wave interaction source term, and S_d = dissipation term. The effort by investigators, utilizing field observations and theoretical considerations, has been to develop relationships for the three source terms in equation (2).

2.1.1 Global Distribution of Wave Energy Three global-scale features dominate the distribution of wave energy on a climatic basis. The first is the existence of the trade-wind bands in the tropics on either side of the equator. Most of the year, the wind is comparatively strong, steady, and unidirectional (trade winds, blowing toward the west) at these latitudes resulting in one of the most consistent wave climates anywhere on the globe, particularly in the Pacific where the wind can act on the waves for a very long distance. Because, under these circumstances, the waves develop toward a spectrum with energy peaked at a frequency that reaches a propagation speed equal to the wind speed, the rate of input of additional energy decreases sharply. Further, slowly occurring nonlinear interactions among wave frequencies result in the creation of waves of lower frequency, which run ahead of the waves in the generation area. This results in a very constant appearance of low to moderate swell in the tropical Pacific. Although not as energetic as some of the waves produced by higher-latitude winds, the constancy of the resource is attractive for certain energy-extraction scenarios. The second important global-scale effect is the very energetic storm sequences that are found in higher latitudes (generally toward the east) during the winter season for either hemisphere. This results in a seasonality to the wave climate that introduces problems in energy extraction, even though the resource is large averaged over the year. The third feature is the particular geometry of the continental land masses in the southern hemisphere. The band of ocean surrounding Antarctica is the only place on Earth where there is a continuous fetch. That is, most of the energy in the waves generated by the strong winds blowing out of the west is never dissipated by striking a shoreline, but it is continuously maintained at the highest possible energy density as it travels endlessly around the world. The result is the highest waves and the highest average wave-energy densities of any place on Earth. No serious plan has been made to use this resource both because of its extreme nature and because of the relatively lower power demands in the Southern Hemisphere. A generalized representation of the global average wave-energy densities is shown in Fig. 8. These represent deep-water values. There is a marked reduction in energy density as the waves approach shore. The power associated with

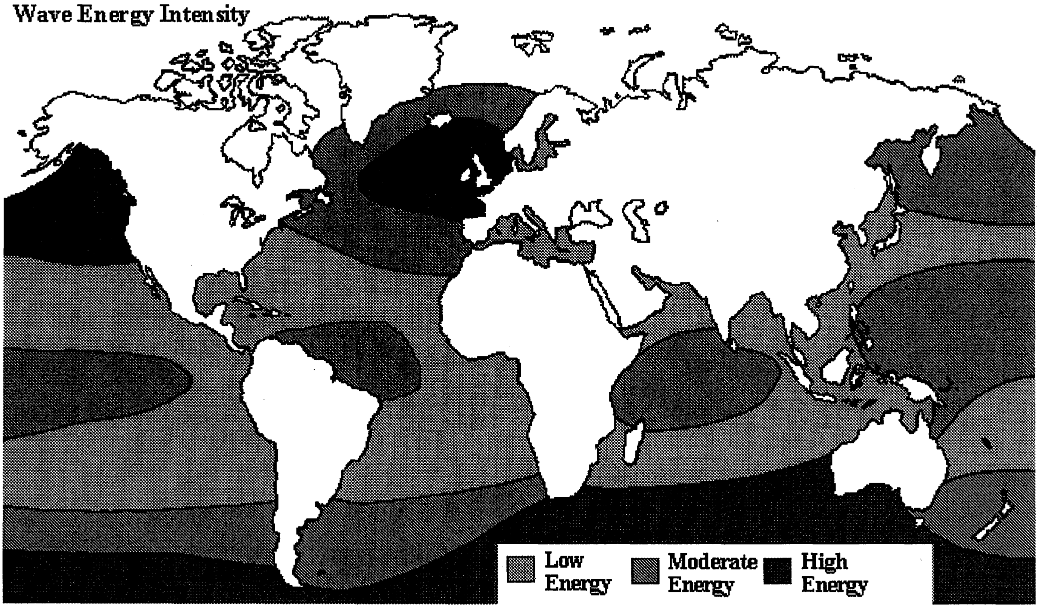

FIG. 8. A generalized view of the global distribution of relative average wave energy. Darker shading indicates a more energetic wave climate. The North Sea, the area in which the greatest research and development activities have been undertaken, is a high-energy region.

ocean waves can be calculated through the equation

$$P = (\rho g^2/64\pi)H_s^2T_m, \tag{3}$$

where P = wave power per unit of wave front in deep water, ρ = density of seawater, g = acceleration of gravity, H_s = significant wave height, given by four standard deviations of the surface elevation variation, and T_m = period associated with the maximum energy in the wave spectrum.

2.1.2 Spectral and Directional Distribution of Wave Energy Wind imparts energy to waves in all directions with the energy distributed roughly proportional to $\cos^n(\Theta/2)$, where Θ is measured relative to the mean wind direction. The exponent n increases with decreasing frequency so that higher-frequency waves are more broadly spread in direction. The generation mechanism results in wave energy being broadly spread in frequency as well. The spectrum of wave energy at the point of generation is shown generically in Fig. 9. The energy is sharply peaked, falling off nearly vertically at lower frequencies and approximately proportional to f^{-5} at frequencies f higher than the peak. As previously discussed, when the waves propagate away from the generation area, or if the wind diminishes, the spectrum narrows in frequency because of dispersion. Further, the directional spreading narrows as well as the wave field diverges. As a result, incident wave energy varies from the fully spread sea within the generating area to swell that is essentially unidirectional and very sharply peaked in frequency. This imposes design restrictions on wave-power systems, which must be capable of effective operation in a wide range of conditions.

2.2 Utilization of the Wave Resource

2.2.1 Types of Power-Extraction Systems There have been a very large number of systems proposed for harnessing the energy in waves. Internationally, the patents granted in this area number in the hundreds. However, it is possible to classify almost all of the systems into three broad types. The first, the tapered-channel system, in which energy is converted into hydrodynamic head behind a low dam, has many of the characteristics of the tidal-power installations. This system is shown schematically in Fig. 10. The second broad category is the caisson type in which a bottom-resting chamber with

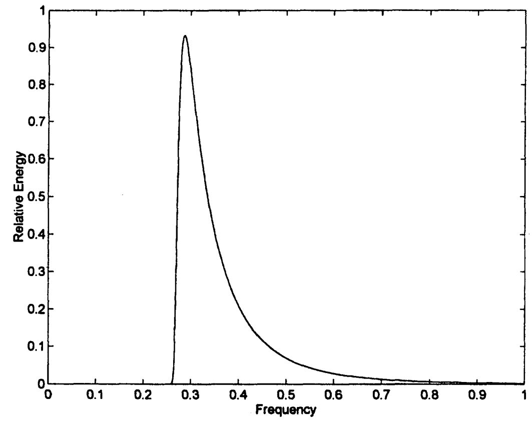

FIG. 9. A generalized spectrum of wind wave energy in a fully developed sea, i.e., one where the waves are in equilibrium with the wind. Coordinate units are arbitrary. The wave components at the peak of the spectrum are moving at a phase speed approximately equal to the wind speed. The energy falls off rapidly at either side of the peak.

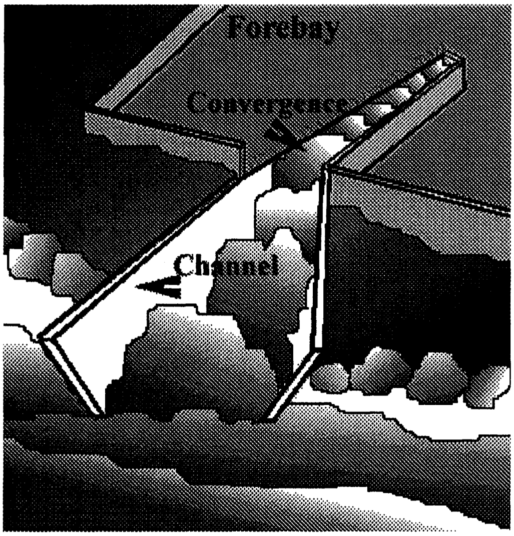

FIG. 10. A schematic representation of the tapered-channel wave-energy extraction system. The waves build rapidly in height as they traverse a converging channel and then spill over a collector system into a forebay that maintains the level above the local sea level. Energy is extracted through low-head turbines similar to those employed in tidal-power plants.

one or more openings below the surface captures the wave energy through the pressure oscillations in an air column above the water or by mechanically driving a float or flap. A typical pneumatic caisson type is shown in Fig. 11. The third type encompasses the floating systems in which the heaving or swaying motion of the hull is converted into mechanical energy. Carmichael and Falnes (1992) and Hagerman (1992) provide details of the various mechanisms.

Waves approaching shallow water tend to increase in crest height until they become unstable at a depth of the same order as their height and break, resulting in the conversion of most or all of the energy into small-scale turbulence and heat. If the shoaling is very rapid, a wave may not have time to break and will uprush onto the shoreline to substantially above its crest height. If a wave enters a channel with converging walls, the energy in the wave is trapped between the narrowing channel boundaries and increases in magnitude until it becomes unstable and breaks. The first type of extraction device, the tapered channel, utilizes both of these effects and also borrows technology from tidal plants. A natural basin is selected facing a shoreline with water of sufficient depth so that typical waves do not break before reaching it. The basin is sealed off with a low dam, similar to that employed in tidal basins. An artificial channel, or an artificially enhanced natural channel, is constructed that rapidly decreases in depth and narrows in width approaching the dam. The resulting uprush of the moderate to large waves is sufficient to carry a substantial quantity of water over the top of the dam, trapping it in the basin. Power is extracted by a low-head turbine exhausting to a sheltered area not subject to wave impact (Menlum, 1991). The height differential between the basin and mean sea level can be maintained at about the 3-m range along a coast with a robust wave climate. Although this is a smaller head than is typically found to be economically attractive for tide-energy extraction, the power generation is continuous so long as the wave intensity persists. Wave persistence is typically very much longer than the fraction of a tide cycle where tidal power can be extracted. Further, the head is constant over this period so that turbines can be optimized for a fixed flow rate.

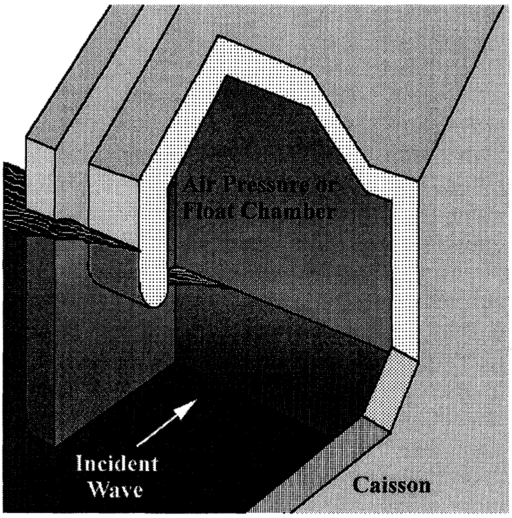

FIG. 11. A cross section through a generic pneumatic-caisson type of wave-energy system. The rising and falling water level inside the caisson chamber produces oscillating air pressure, or may be used to lift a float or other mechanical device.

The caisson-type devices have been the subject of significant theoretical and laboratory research (Mei, 1976; Falnes, 1980). In the most common configuration, a capture chamber is constructed so that the incident wave energy enters the front of the chamber but is trapped by side and rear walls. This results in a significant amplification as the wave is reflected. The chamber shape and the entrance configuration have been tested in a number of configurations in an attempt to achieve broad-band resonance with the incident waves. If the top of the chamber is closed, air trapped above the rising wave will be strongly compressed, while a decompression will occur on the falling portion of the cycle. Typically, an air turbine is arranged above the chamber and is driven by the flow of air out of and into the chamber in response to the water elevation changes. Valves have been used to rectify the air flow (Masuda, 1987) and self-rectifying turbines developed that turn in a single direction regardless of the direction of flow (Gato and Falcao, 1988). Direct mechanical conversion has been attempted in a modification to the basic caisson approach that utilizes oscillating flaps driven directly by the water motions. The pneumatic caisson provides a distinct advantage in that no moving parts are in direct contact with seawater. Because severe storm waves typically are an order of magnitude more energetic than the commonly occurring waves, material fatigue, stress corrosion, and outright structural failure are constant threats to machinery directly impacted by waves. In the case of the Kvaener pneumatic caisson discussed below, the caisson was constructed into a nearly vertical rock face, and the entire system was lost because of fracturing of the rock foundation during a severe storm.

In general, the first two types are shore-based or are constructed in relatively shallow water close to shore. The third type of system, of which there are almost unlimited variations, can be employed offshore in moderately deep water. In these applications, the hull of the device floats at the surface, tethered such that it remains in location, and responds to the wave forcing by some combination of heaving (vertical motion), swaying (horizontal motion), or pitching (tilting). The motion of the hull is constrained by attachment to an anchoring system, by inertia, or by making the hull large compared to the dimensions of the waves, thus summing the various forces along the wave to produce a nearly stationary platform. One of the simpler forms (Fig. 12) uses the vertical excursions of the hull to activate a pump. The pumps have included conventional piston types as well as flexible hoses that contract when put in tension and decrease in internal volume. The hose provides the anchoring cable in this instance. Researchers in the United Kingdom, Denmark, and Sweden have been particularly active in research on this general class of energy-extraction devices. A survey of these developments is contained in Ross (1995). Although these devices can, in principle, be shown to be more efficient in trapping incident wave energy than the previous two classes, they suffer from inherently high installation and maintenance costs because of having moving parts in contact with seawater and being subject to millions of fatigue cycles per year. The reliability of a submarine power cable subjected to repeated flexure cycling has never been established over the anticipated service lifetimes. Any of the wave-power systems can be vulnerable to total destruction by waves exceeding those that it was designed to resist. However, the nearshore systems can be somewhat less sensitive to this catastrophic failure mode if sited in areas where shallow water offshore limits the height of the wave that can impact it.

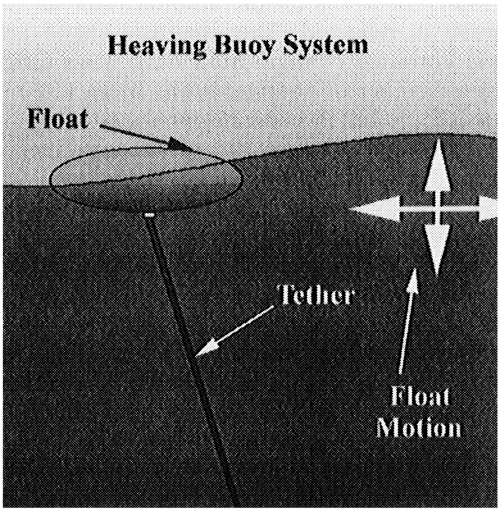

FIG. 12. A schematic arrangement of a heaving-buoy system, in which the vertical motions of a moored float are utilized to extract power from waves. The motion of the mooring line can drive a pump or other mechanical system.

2.2.2 Wave-Power Installations Only a few installations intended to supply energy from waves for public use have ever been attempted, in spite of the large research and development programs undertaken by several nations. Two of these were constructed along the Atlantic coast of Norway during the late 1980s. The tapered-channel system at Toftestallen, with a capacity of 0.35 MW, remains the only commercial wave-power system in operation in the world at this time. The Kvaerner pneumatic caisson, whose failure was discussed previously, was constructed nearby with a capacity of 0.5 MW, although its capacity factor was only 15%. This compares to 25% for the Toftestallen tapered-channel installation (Hagerman, 1992). Japan has led in the total number of installations, including a floating-caisson type system in a shiplike hull (Carmichael and Falnes, 1992), but all of them have been developmental in nature and none has survived. A 150-kW pilot plant of the caisson type has been installed and operated off the southwest coast of India. The British attempted a large installation of a caisson system with 2-MW capacity, called the OSPREY. It sank while being towed to its installation site in 1995.

2.2.3 Environmental Effects All of the installations to this time have been at such a small scale that they have had no discernible effect on the environment. If large-scale facilities were to be constructed in the future, and these power plants blocked a substantial fraction of the incident wave energy, some significant modification of the local environment is possible. For example, if, in an extreme case, the wave-energy extraction systems were sited close to shore and were to function as a breakwater and provide relatively calm water in its lee, then the transport of sediment along the shoreline would be reduced. As is the case with conventional offshore breakwaters, sand could be deposited in the lee forming a spit. In the process, this sand would be denied to downcoast beaches and substantial erosion could occur. If the wave-power station were sufficiently far away from the shoreline, diffraction would tend to eliminate the wave shadow. At an offshore distance several times the shore-parallel length of the wave-power system, the shadowing effect would be significantly reduced by diffraction. Because considerable freedom may exist in the selection of the location for an installation within a broad area of suitable resource, it could be feasible to avoid environmentally significant bottom resources such as reefs or rock outcrops that support unique biotic assemblages. It is generally assumed that wave-energy systems will be among the most environmentally benign power sources.

2.2.4 Economics Hagerman (1992), in an optimistic assessment of the economics of wave-energy utilization, comes to the conclusion that wave power is more economical than any other form of ocean energy, except the largest tidal plants, such as those presently under study in the United Kingdom. This finding includes systems employing the temperature difference between warm surface water and cold deep water (Johnson, 1992), as well as tidal energy. He also finds that tapered-channel type wave-power systems are less costly than conventional coal-fired plants when the plant size is less than 30 MW. Unless a significant economic penalty is assessed in the future for atmospheric pollution from fossil fuel plants, it would appear that wave power will be relegated to small, niche markets, such as isolated islands, where fossil fuel is relatively more expensive to obtain. This study, which uses a standardized cost estimation methodology in an attempt to obtain a fair comparison of a wide variety of systems, also concludes that the tapered-channel systems will produce energy at roughly one-third to one-half the cost of the caisson or floating types. Because of the extreme variability in the resource, wave power will necessarily have a lower economic value than power that can be generated to match demand. Some improvement in this condition can be made through power-storage devices, such as conventional pumped storage and the storage of compressed air. The latter mechanism has particular attraction in the ocean where air can be stored in simple open-bottom containers, using hydrostatic pressure of the surrounding water to maintain the necessary pressure. Other solutions to the variable resource include the manufacture of storable products, such as hydrogen (Isaacs and Seymour, 1973) and the direct desalinization of seawater by reverse osmosis (Hagerman, 1992). The reverse-osmosis application is well adapted to heaving systems that directly drive pumps.

GLOSSARY

Amphidromic Point: In a system of rotary tidal waves, the apparent axis of rotation, usually with negligible tide elevations.

Capacity Factor: Similar to **Load Factor** as defined below. It is usually applied to wave-power systems, which must be designed with the capacity to withstand an occasional very large wave. It refers to the fraction of the power rate associated with this ultimate capacity that is achieved on average.

Characteristic Period: In a wave field with a broad frequency spectrum, a single period (reciprocal of frequency) chosen to represent the central or significant frequency, such as the period at which the energy in the spectrum is at a maximum.

Dispersion Relationship: Surface gravity waves in water travel at a speed inversely proportional to frequency such that broad-band wave fields tend to disperse into narrow-band fields given enough time and distance.

Fetch: The distance over water, measured in the direction of the wind, that waves are subject to energy input from a wind field.

Load Factor: In a power-generation plant, the fraction of the maximum power output rate achieved on average.

Marginal Sea: A large body of water, usually semienclosed, with free communication to an ocean basin.

INTRODUCTION

The measurement of time and frequency is the most precise measurement we can make at present. The accuracy and stability of standard frequency generators and clocks have been improved by many orders of magnitude since the operation of the first cesium-beam frequency standard in the mid-1950s. Rapid progress has been made in the measurement technologies as well. The frequency range as well as the precision of the measurement are still growing, a result mainly of the progress in optics including nonlinear optics materials, tunable semiconductor lasers, stable solid-state lasers, high-quality mirrors, laser cooling of atoms, and so on. Such progress has expanded the applications of precise time and frequency measurement. One example is the standard of length, which is now derived from the standard of time. The standard voltage is also defined in terms of frequency, the inverse of time.

Time is a continuous dimension in which events occur. We can allot a set of real numbers to it in various ways, but in due order. There is no absolute rule for the allotment. Periodic phenomena such as the rotation of the Earth, the orbital motion of the Earth, oscillation of a pendulum, vibrational oscillation of a quartz crystal, or oscillation of radiation from an atom have been used to define the unit of duration. By fixing the unit

of duration as well as the epoch of origin (zero), the allotment is automatically done. Thus, each event has a corresponding real number, which is the reading of time at the epoch of the event. The difference between two numbers is the reading of time interval between the corresponding two events. The frequency of a periodic phenomenon is defined to be the inverse of the time interval at which events repeat.

Graduation of time based on the periodicity of a physical event has been confronted with difficulties, because general relativity predicts that the period of the same physical event is invariant only in local inertial frames, but can change from place to place, and because the amount of variation may be large enough to be recognized by accurate clocks. The proper time (and the proper frequency) associated with a clock can maintain the periodicity, but it serves only along the world line of the clock. The definition of time scales and that of clock synchronizations must be revised within the framework of relativity.

Remote comparisons of time play an important role in the international coordination of time scales. The Global Positioning System (GPS) has been conveniently used for this purpose. Intercontinental clocks are compared every day with an accuracy of 10 ns, which requires relativistic effects to be taken into account in the data processing. In this way, the realization of international time scales as well as the international comparisons of clocks are performed usually on the basis of general relativity. On the other hand, general relativity has been tested by accurate clocks and precise comparisons.

1. TIME SCALES

When any event is described by its position and its time, three dimensional space coordinates and one dimensional time coordinate are used as a reference system of coordinates. The time coordinate differs from the other space ones by its unidirectional nature: time is passing from past to future irreversibly.

To establish a system of time coordinate, one must define two quantities: the unit of duration and the epoch, or the origin of the time. An example of a naively defined one is the time used in Japan in the Edo era, in which the unit of duration in day time was the period from sunrise to sunset and the one in night time was the period from sunset to the next sunrise. Each period was equally divided into six parts to give a unit time interval. This time scale was not uniform because the interval between sunrise and sunset changes in a period of year and as a function of latitude of the location. The origin of time was also different from place to place because the times of sunrise and sunset depend on the location. However, such nonuniformity and differences of time did not matter at that era, since human activities were limited to a small area and the speed of transportation was slow enough to neglect the time difference.

The Industrial Revolution changed the situation. Human activities were expanded to worldwide scales by the technological developments such as railroads and telecommunications. The different time systems of different countries caused much trouble and confusion. The unification of longitudes and times was desired not only for scientific purposes but also for the purposes of navigation, commerce, and international communications.

1.1 Universal Time

The International Meridian Conference held at Washington, D.C., U.S.A., in 1884 decided on the adoption of the unique determination of longitude based on the Greenwich prime meridian. The adoption of Universal Time (UT) was also decided, which is the mean solar time of Greenwich (Greenwich Mean Time, GMT). Following the decision, many countries adopted the standard longitude to determine the standard time, which differs from UT by a (usually) integral number of hours. In UT and the standard times, the unit of duration is the mean solar day, which is the rotational period of the Earth with respect to the "fictitious mean Sun," a fiducial point on the celestial equator. Variations in the rotation of the Earth were discovered more than 50 years ago through comparisons with quartz-crystal clocks. UT is no longer a uniform time scale, but it still remains the basis of public time in the form of Coordinated Universal Time

(UTC). (Note: initialisms such as UTC are based on the French forms of the names.)

1.2 Atomic Time

Atomic time scales are integrated time scales that are produced by accumulating standard time intervals. The unit of duration is the International System (SI) second that is defined as follows: "The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom."

1.2.1 International Atomic Time International Atomic Time (TAI) is a coordinated time maintained by the International Bureau of Weights and Measures (BIPM) according to international conventions. TAI is realized in two steps. First, data from all available high-precision atomic clocks, of which are now more than two hundred distributed worldwide, are combined using an algorithm to form a free-running data-controlled time scale. It is compared in duration with primary frequency standards, the accuracy of each of which is carefully evaluated. Corrections are applied to maintain the unit of duration for TAI as close as possible to the definition of the SI second.

The increasing accuracy of clocks and advances in precise time comparisons require us to treat TAI as one of the four-dimensional space-time coordinates consistently with the framework of relativity. Apart from its error, each atomic clock gives an ideal atomic time at the location of the clock, which is called a proper time in terms of relativity. Different (ideal) atomic clocks located at different places show different time readings in general. For example, an atomic clock located on the top of a mountain (1000 m above sea level) has a clock rate higher by amount of 10^{-13} than other atomic clocks at rest at sea level. In order to establish TAI with an accuracy better than 10^{-15}, it is needed to know the location of each high-precision atomic clock with an error of height less than 10 m. The precise locations of clocks are also needed for precise clock comparisons using electromagnetic signals. Comparisons with a precision of 10 ns require the estimation of the travel path length of signals with an error less than 3 m.

In the refined definition of TAI, the unit of duration is one SI second realized as a proper time interval of an ideal atomic clock fixed on the geoid (the equipotential surface of the Earth's gravity potential that most nearly coincides with mean sea level), and TAI is a time coordinate of the geocentric coordinate system by which proper times of any fixed or mobile clocks near the geoid are related to TAI within the accuracy of TAI itself. Propagation of any electromagnetic signals in the vicinity of the Earth is also described in terms of TAI and the space coordinates of the system (see Sec. 5.1.2).

1.2.2 Coordinated Universal Time UTC is a time scale that is approximate to UT but is generated from TAI. UTC differs from TAI only by an integer number of seconds. Therefore the duration of time is the same as that of TAI. UTC is maintained within 0.90 s of UT by introducing a 1-s step (leap second) when necessary, usually at the end of June or December. Standard Time and broadcast time of most countries are now based on the UTC.

1.3 Dynamical Time Scales

Every physical time scale is a dynamical time scale in some sense. It is usually based on the periodicity of a dynamical process. For example, UT is related to the rotational motion of the Earth, which has a period determined by the dynamics concerned. However, because of many dissipative processes that are not well modeled yet, changes of UT are not predicted by any dynamical model to the required accuracy. UT is not categorized into dynamical time scales for this reason.

The orbital motion of the Earth in the solar system is described to good accuracy by dynamical theories such as Newtonian mechanics and Einstein's theory of general relativity. When the variations in rotational motion of the Earth became significant, the orbital motion of the Earth was adopted in determining the unit of time. The observable configuration of the solar system is given as a function of the time argument in the ephemeris as a solution of the equations of motion in Newtonian mechanics. The observed configuration at some instant gives the corresponding time argument in the ephemeris, Ephemeris Time (ET), which is a dynamical time scale. The second was defined as the fraction 1/31 556 925.9747 of the tropical year for 0 January 1900 (i.e., 31 December 1899) at 12 h Ephemeris Time. This definition was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960 and was replaced in 1967, after only 7 years, by the new one based on the quantum transition of Cs-133 atoms.

The concept of dynamical time scales has an increasing importance, because of the increasing accuracy in atomic time scales. As mentioned in Sec. 1.2, the description of any physical event in four-dimensional space-time is required to correspond to the accuracy of the measurements. A dynamical time scale in the framework of general relativity is considered as a realization of coordinate time, which is one of the coordinates in space-time. Dynamical time scales used in astronomy and their relations to TAI have been very important in the field of astronomy and metrology (Guinot, 1989; Seidelmann and Fukushima, 1992).

2. FREQUENCY GENERATORS AND CLOCKS

2.1 Quartz-Crystal Oscillators

A quartz crystal, a single crystal of SiO_2, is one of the best macroscopic resonators for stable frequency generators. It has very low internal friction losses and low temperature coefficients of elasticity and expansion. The piezoelectric effect of this material is used to excite mechanical vibration by putting an oscillating electric field on the crystal. An electric circuit coupled to the mechanical resonator forms a positive-feedback amplifier and generates an oscillating signal. Quartz-crystal oscillators are used as stable frequency generators in various fields of application such as satellite communications, digital telecommunications, wrist watches, TV and radio receivers, local oscillators used in atomic clocks, and so on. Recent progress in understanding and design of resonators as well as in understanding the influence of electric circuits has led to significant improvement in their operation. Reduced aging, better short-term stability, low thermal transients, and small environmental dependence have been obtained and have led to advantages in design of atomic frequency standards (Bessen, 1989).

A precise frequency control of the oscillator, commonly required in many applications, is attained by a voltage-controlled crystal oscillator (VCXO), in which a capacitance in the equivalent circuit of the oscillator is changed by an external voltage control.

2.2 Atomic Frequency Standards

Atomic frequency standards are based on the principles of quantum mechanics. The frequency of the electromagnetic radiation emitted or absorbed by an atom or molecule during a change of its quantum state between two discrete energy levels is related only to the energy difference between the two levels. The energy levels for unperturbed atoms or molecules are regarded as constants, and thus the frequency of the radiation has a unique value.

Atomic frequency standards are categorized by their mode of operation into two types, namely, active and passive. Figure 1 shows the principles of atomic frequency standards in each type. The active mode of operation uses maser or laser action with the stimulated emission of radiation. In the passive mode of operation, an ensemble of particles undergoing the desired quantum transition interacts with synthesized radiation. The transition occurs at maximum probability if the frequency of the radiation exactly coincides with the proper frequency of the transition. A VCXO is ordinarily used as a slave oscillator, and its frequency is controlled in a feedback system to maintain the coincidence.

2.2.1 Cesium-Beam Frequency Standards Cesium-beam frequency standards typically operate in a passive mode. Figure 2 shows the operation principle of the cesium-beam frequency standard. Since the current definition of the second is based on the hyperfine transition of the cesium atom, as mentioned before, cesium-beam frequency standards play an important role in generating atomic time scales as well as in realizing the unit of time, the second. Commercially available frequency standards are distributed worldwide and contribute significantly to TAI. Laboratory-made primary frequency standards are working in several time-keep-

maser standard. Hydrogen masers are very stable for averaging times from 1 to above 10^4 s. They are used as local oscillators for very long-baseline interferometry, as well as clocks and reference frequency generators.

Rubidium clocks are relatively low-cost clocks and have better stability than quartz-crystal oscillators for measurement times >100 s. They are usually subject to greater frequency drift than hydrogen masers or cesium clocks.

Several new-type atomic frequency generators such as Mg-beam standards, trapped Hg ion standards, and Cs fountain standards have been proposed and are under development. Among them, a first prototype of a cesium-atom fountain has been realized and has worked as a frequency standard to indicate a stability of the order of 2×10^{-15} for durations of a few days (Clairon *et al.*, 1995).

A superconducting cavity can be used as a frequency discriminator in stabilizing a generator. Such a generator is called a superconducting-cavity–stabilized oscillator (SCSO) and has one of the best stabilities for averaging times below several thousand seconds; however, it has no absolute frequency reference.

2.3 Frequency Stability of Generators

Frequency standards and clocks are subject to random as well as systematic variations of their frequency or rate. A nearly sinusoidal signal voltage generated by a frequency standard is written as

$$V(t) = [V_0 + e(t)]\sin[2\pi f_0 t + \phi(t)]. \tag{1}$$

Here V_0 is the nominal value of the amplitude and $e(t)$ is the amplitude fluctuation, which we assume negligible in most cases. f_0 is the nominal value of the frequency, and $\phi(t)$ is the phase fluctuation. The instantaneous frequency of the signal is given by

$$\begin{aligned} f(t) &= f_0 + \frac{1}{2\pi}\frac{d\phi}{dt} \\ &= f_0\{1 + dx(t)/dt\} = f_0\{1 + y(t)\}, \end{aligned} \tag{2}$$

where two useful quantities are introduced: $x(t)$ is the instantaneous "phase-time" error and $y(t)$ is the instantaneous normalized frequency error (Kartaschoff, 1978). The instantaneous frequency and thus $y(t)$ cannot be measured, but the average normalized frequency error is measured instead; it is given by

$$\langle y\rangle(t,\tau) = \frac{x(t+\tau) - x(t)}{\tau} = \frac{1}{\tau}\int_t^{t+\tau} y(t)dt. \tag{3}$$

As a statistical measure of the frequency stability, popularly and conveniently used is the Allan variance, which is defined by

$$\sigma^2(\tau) = \frac{1}{2N}\sum_{k=1}^{N}(y_k - y_{k-1})^2,$$

where y_k and y_{k-1} represent successive samples of $\langle y\rangle$. Figure 4 shows the frequency stabilities of typical frequency standards and clocks in terms of the Allan variance as a function of the averaging time interval τ (Allan, 1989).

2.4 Laser: Optical and Near-Infrared Frequency Generators

A variety of lasers have been developed since the first operation of a ruby laser in 1960. The frequency of laser emission is predominantly governed by the resonant frequency of its optical cavity combined with the active medium inside the cavity in which the laser action occurs. Careful design of the cavity may reduce the frequency noise. An

example is a monolithic isolated single-mode end-pumping ring laser (MISER), which has a spectral linewidth less than 10 kHz under free-running conditions, because the cavity is monolithically integrated with the laser crystal. A laser frequency can be further stabilized to a high-finesse Fabry–Pérot cavity, and a linewidth of less than 1 Hz has been attained (Day *et al.*, 1992; Uehara and Ueda, 1993). Very stable Nd:YAG lasers of this type have been studied as powerful coherent light sources for a very long-baseline laser interferometer for the detection of gravitational waves (Giazotto, 1989; Fujimoto, 1992). Because the resonant frequency of a cavity is geometrically determined, the absolute frequency is not well determined. An accurate laser frequency is obtained by its stabilization to a certain spectral line of an atom or molecule. An example is a CH_4-stabilized He-Ne laser, where the inverted Lamb dip in the saturated absorption of CH_4 at 3.39 μm is used as the frequency reference because of its Doppler-free nature. Hyperfine-structure components in the absorption line of I_2 at 633 nm are also widely used to stabilize a He-Ne laser in the visible region. These stabilized He-Ne lasers are of importance in the realization of the meter (see Secs. 3.3 and 5.3.1).

3. MEASUREMENT OF FREQUENCY AND TIME

3.1 Measurements by Means of Electronic Counters

Electronic counters are widely used for frequency, period, and time-interval measurements. The basic block diagram of such an instrument is shown in Fig. 5. The input circuits process the wave form of input signals so as to make the events unambiguously countable. The gate starts the counting operation when an "open gate" signal is received from the control unit, and stops on arrival of a "close gate" signal. All timing operations are controlled by the time base. A stable quartz-crystal oscillator is usually used as a frequency source for the time base, from which the timing signals with a required time interval are generated by frequency dividers.

In frequency measurements, the number of events is counted in a time interval τ and is divided by τ to give the mean frequency averaged over the time interval τ.

In period measurements, event signals and timing signals interchange their roles: an event signal opens the gate to start counting the timing signals, and the succeeding event signal closes the gate to stop the counting (Fig. 6).

Time-interval measurements differ from period measurements only in the gate signals: the "open gate" and "close gate" signals are produced separately by the two different input signals (Fig. 7).

FIG. 7. Time-interval measurement.

The leading error in the measurements comes from the ±1 count ambiguity, which is usually larger than the other errors such as the trigger errors in the gate operation and the time-base accuracy. This ambiguity corresponds to a normalized resolution of $1/f\tau$ in a direct frequency measurement with averaging time τ. In a period measurement with averaging time τ, the normalized resolution amounts to $1/f_0\tau$, where $1/f_0$ is one period of the time base corresponding to the ambiguity. If the measured frequency is higher than the frequency of the time base, the frequency measurement gives better resolution than the period measurement, but in the case of a lower-frequency measurement, the period measurement is better than the frequency measurement. In order to increase the resolution of frequency measurement with limited averaging time, a beat frequency produced by mixing the measured signal with a reference signal is measured by its period. By this heterodyne method, the resolution is improved by a ratio of the signal frequency to the beat frequency.

3.2 Phase Measurements

If the signal frequency is almost equal to the reference one in the heterodyne method, the beat frequency is almost zero and is difficult to measure in a limited time. This is the case when two very stable oscillators such as atomic frequency standards are compared in frequency and time. Phase measurement is useful in this case. Phase measurement is in principle a time-interval measurement between the zero crossings of two signals. Figure 8 shows a block diagram of the so-called dual-mixer time-difference (DMTD) measurement, as an example of phase measurements. Two mixers and a transfer oscillator produce two beat signals from the two oscillators to be compared. The time difference between positive zero crossings of the two beat signals is measured by a time-interval counter. Resolution of the measurement is enhanced by the ratio of the signal frequency to the beat frequency in the same way as in the heterodyne method. By this method, very high time resolution, better than 1 ps, is obtained (Allan, 1975).

3.3 Frequency Chains

Even the best electronic counter can measure frequency only up to about 100 GHz, which is three or four orders of magnitude lower than optical frequencies. The precise measurement of near-infrared or optical frequencies has been carried out by using a skillful method, a frequency chain. Figure 9 shows a historical example of the chain in

frequency measurement that produced the first measurement of a visible frequency (Baird *et al.*, 1979) and of a CH_4-stabilized He-Ne laser in the near-infrared region (Evenson *et al.*, 1973). The frequency ratio between the visible radiation at 520 THz and a klystron at 10.6 GHz is about 5×10^4. This huge gap was bridged by introducing several intermediate-frequency generators including a HCN laser, a H_2O laser, six CO_2 lasers, three He–Ne lasers, a Xe laser, and a CO laser. Each frequency difference between the neighboring generators up to the 1.52-μm He-Ne laser was measured by heterodyne method, in which a point-contact W-Ni diode played an important role by generating harmonics of each signal and by mixing them to produce a beat frequency within the measurable frequency range. The product of the CH_4 frequency by the interferometric measurement of the wavelength gave the absolute value of the light velocity, which was afterward adopted as a defining constant in the definition of the meter (see Sec. 5.3.1). The direct frequency measurement of the iodine-stabilized He-Ne laser at 473 THz (633 nm) was the basis for redefinition of the meter because its wavelength could be calculated very accurately from its frequency. Then it could be used to realize the meter with a significant increase in accuracy over the krypton method (Jennings *et al.*, 1983). Frequency chains consist of a series of oscillators at intermediate frequencies between optical and microwave regions of the electromagnetic spectrum. The intermediate frequency generators must have good frequency stability and sufficient power for harmonic generation. They can be phase-locked to each other in the chain by feedback using a number of harmonic mixers and interpolation oscillators. Consequently, each frequency chain has been designed and constructed for exclusive use at a particular frequency, and its operation has required elaborate work. A recent measurement of the Ca intercombination line, by use of a phase-coherent optical-frequency chain from the Cs atomic clock to the visible, gives the optical frequency of the line with an uncertainty less than 10^{-12} in normalized frequency. The chain is composed of ten laser oscillators, eight microwave oscillators, and a quartz oscillator (Schnatz *et al.*, 1996).

3.4 Optical-Frequency Synthesis

The optical or near-infrared frequencies that are connected to the microwave-frequency standards by chains are so coarsely distributed in frequency that any one of them is not always close enough to the frequency to be measured. There remains a large frequency difference that cannot be measured by means of electronic counters. Several approaches to measure large optical-frequency differences have been proposed. One method is a coherent bisection of optical-frequency intervals by using a nonlinear phase-locking scheme (Telle *et al.*, 1990; Wynands *et al.*, 1992). As shown in Fig. 10, the second-harmonic frequency of the third laser, $2f_3$, is compared with the sum frequency of the two lasers, $f_1 + f_2$, generated in a nonlinear crystal, and the frequency of the third laser is controlled by an optical phase-locked loop such that $2f_3 = f_1 + f_2$, or $f_3 = (f_1 + f_2)/2$. Then we obtain $f_3 - f_1 = (f_2 - f_1)/2$. Cascading of n bisection stages generates a difference frequency $f_n - f_1 = (f_2 - f_1)/2n$. After 14–16 stages, an optical-frequency difference is reduced to one in the microwave region. Optical-frequency division using an optical parametric oscillator (OPO) has also been proposed (Wong, 1990). Figure 11 shows how an OPO acts as a frequency divider. The input pump frequency f_p is divided into two output frequencies, a signal f_1 and an idler f_2. The output difference frequency $\delta = f_1 - f_2$ is phase-locked to a microwave reference frequency.

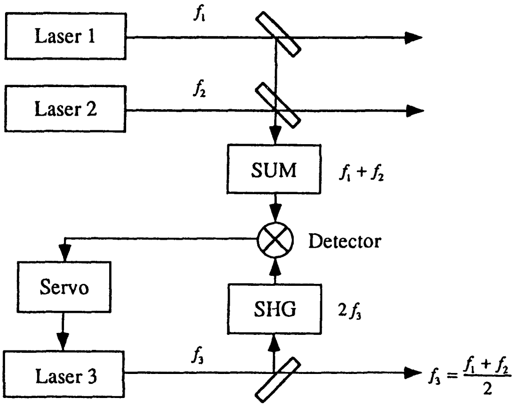

FIG. 10. Optical difference-frequency divider based on the nonlinear phase-locking scheme.

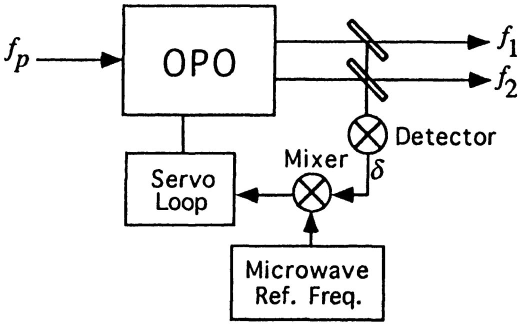

FIG. 11. Optical-frequency divider using an optical parametric oscillator.

Then we obtain $f_1 = (f_p + \delta)/2$ and $f_2 = (f_p - \delta)/2$. As shown in Fig. 12, the optical-frequency differences can be measured in the microwave-frequency region if we use the OPO dividers in series for frequency down-conversion and if we use a pair of the *n*th-stage OPO dividers for frequency comparison.

A different method of optical-frequency synthesis is to use an electro-optic modulator in an optical cavity to generate higher-order sidebands spanning the difference frequency of more than a few THz at the frequency interval of a few GHz (Kourogi *et al.*, 1992). The comb of frequencies can be used as a ruler that has graduations limited by wavelength dispersion in the cavity. The frequency difference between the nearest modulation sideband and the optical frequency to be measured is obtained by measuring the heterodyne frequency.

4. REMOTE COMPARISONS

International coordination of time-scale determination requires precise time and frequency comparisons among clocks or frequency standards in remote locations. The remote comparisons also provide a means of disseminating the time and the second to many sites around the world. Any remote comparison consists at least of two direct comparisons. As pointed out by Einstein (1905) in his discussion on simultaneity of physical events, clocks can be compared only at the same place and at the same instant. Therefore only a direct comparison has a sense. In order to make an indirect comparison between two distant places, an intermediate clock is required to move from one site to another and to be compared directly with each clock in each site. Not only a real operating clock but also time signals are used as the intermediary in remote comparisons. As shown in Fig. 13, an essential part of re-

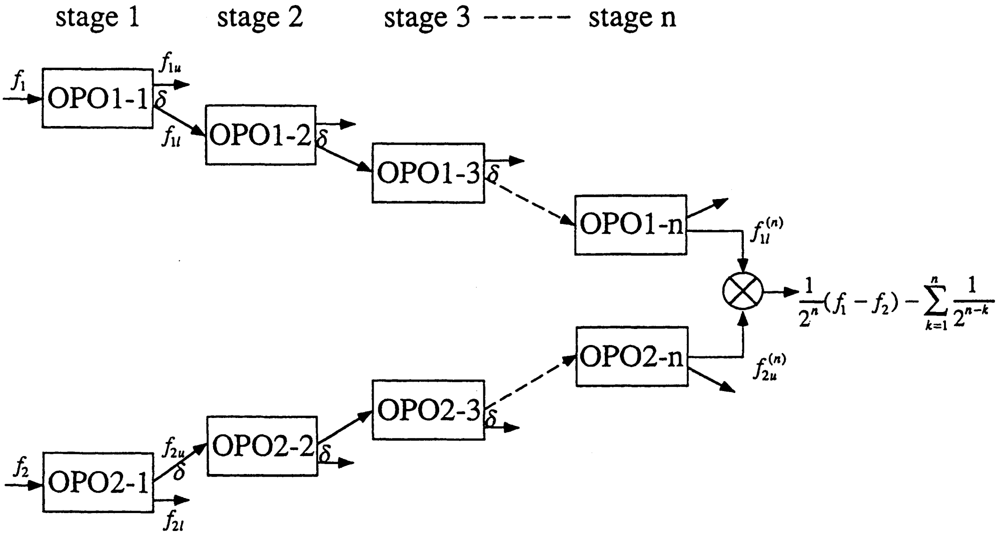

FIG. 12. Serial configuration of *n* OPOs for frequency division (only upper or lower of the two chains), and parallel configuration of *n* stages of two OPOs for frequency comparison.

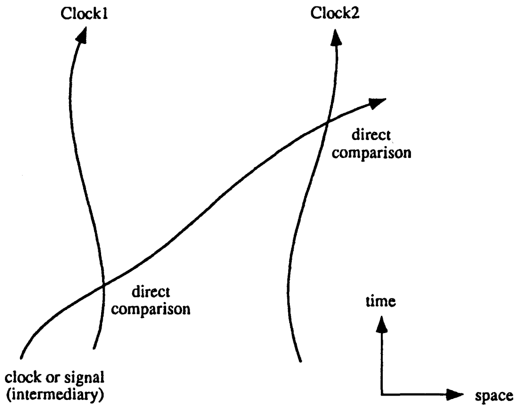

FIG. 13. World-line scheme describing remote comparison of clocks.

mote comparisons is described in terms of relativity by three world lines, intersections of which express the events of direct comparison.

4.1 Portable Clocks

A naive remote comparison of clocks is made by use of a portable clock. A portable clock keeps in operation during a trip. The clock is adjusted and kept as close to the frequency of the reference clock at one site as possible and then carried to another site and compared there. Usually a round trip is made to compare the clock again with the reference clock. By this procedure, the clock error accumulated during the trip is evaluated, which serves as a measure of confidence about the errors in this comparison. For accurate comparisons, relativistic effects must be taken into account (Hafele and Keating, 1972): the effect of gravitational field on the clock rate difference (about 1 part in 10^{13} per kilometer change in altitude), the effect of transportation velocity of the clock relative to ground-based clocks, and so on. The clock rate changes by about 1 part in 10^{13} when it is transported by airplane with speed of 700 km/h. Time comparisons by portable atomic clocks were the most reliable and accurate method of international and domestic clock comparisons before the common-view method of GPS time comparison was widely adopted in about 1985.

4.2 Radio Time Signals

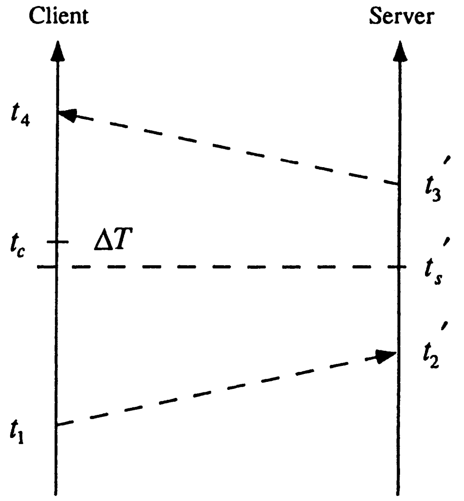
Time comparisons by the use of time signals require the knowledge of the propagation delay. The accuracy of the comparison is often limited by the uncertainties in the propagation delay. Two-way methods, in which the time signals are exchanged simultaneously back and forth along the same path, can eliminate the common delay in the data processing. These methods, using artificial satellites, can give the accuracy of time comparisons at the nanosecond level. However, in the two-way methods complex equipment is required in order to transmit and receive the time signals. One-way methods are more popularly used. Time signals superimposed on transmitted radio waves are widely used as simple and cost-effective means of distributing time. Many countries have standard frequency transmissions with a time code. These high-frequency time signals are subject to delay variations caused by ionospheric disturbances and can provide an accuracy of only 1 ms. One mode of operation is to receive the same signal at two or more sites. By exchanging the data, the difference of readings of the clocks is obtained if the differential delay of propagation is known. The signals of TV, LORAN-C, GPS, and quasars [measured with very long-baseline interferometry (VLBI)] are used for accurate time comparisons by this method. Among them, the GPS has popularized rapidly and has a sufficient accuracy for most users. Therefore only the GPS time comparison is further described in the next section.

4.3 GPS

Global Positioning System is a satellite positioning system developed by the Department of Defense of the United States, which includes 24 satellites on 12-sidereal-hour orbits. The positioning is based on range measurements. Each satellite emits a pseudorandom noise-coded signal, the timing of which is controlled by the onboard atomic clock, the satellite clock. The received signal is correlated with the same code generated by a GPS receiver, the timing of which is controlled by the local clock. The tracking of the satellite signal gives the time difference between the time of the signal reception, registered by the local clock, and the time of emission counted by the satellite clock. This difference contains the actual propagation time interval from the satellite to the receiver antenna, the time offset between the satellite and the local clocks, and the receiver delay including instrumental and cable delays. The positioning requires at least four range measurements for different satellites. Four unknown parameters, three space coordinates of the antenna position and one time offset of the local clock, can be solved for from the four relations given by the four measurements. The other parameters including the relations are position coordinates of each satellite, propagation delays due to the refraction, and time difference between each satellite clock and a common time reference in the system called GPS time. All these are computed from the ephemeris, model parameters for the refraction, and extrapolated values of time offset for each satellite clock, which are all transmitted by the satellites. If the position of the antenna is already determined with good precision, a single measurement of a satellite gives the time offset between the local clock and GPS time. Precise time comparisons between two remote clocks are made by exchanging the value of the offset (local clock minus GPS time) with each other and by eliminating GPS time. When the tracking of the same satellite is carried out simultaneously at both sites, the error in estimating GPS time from the satellite clock cancels completely, and the error in the satellite position also cancels to some extent. This common-view method of GPS time comparison is widely used for the international coordination of time scales (Allan *et al.*, 1985). Accuracy in time comparison by this method reaches about 10 ns on daily averages. Apart from the precise time comparisons, GPS receivers have been popularized very quickly mainly for the application of automobile and small-boat navigation. Inexpensive and downsized receivers are commercially available today, and some of them generate a second pulse synchronized to the UTC that is useful to obtain the time as accurate as a few microseconds at any location.

4.4 Computer Clock Synchronizations by Network Time Protocol

The network time protocol (NTP) is a method to synchronize clocks of UNIX-based computers via computer networks (Mills, 1992). NTP servers that supply the time information at the request of a client are ranked into many strata. The server in stratum 1 has a clock that is synchronized to UTC by means of direct connection with an atomic clock or reception of the GPS time signals. When packets are exchanged between the server and the client, each packet is time-marked by the transmitting computer clock, and its reception time is registered by the receiving computer clock. If the propagation delays in the network are equal in the two directions, the clock difference between the server and the client and the propagation delay between them are estimated from the four readings of the clocks (Fig. 14). The accuracy of the clock synchronization by NTP is less than 1 ms, mainly limited by the fluctuations in propagation delay, but is attainable accurate to the tens of microseconds level.



$$\Delta T = t_c - t_s' = \frac{t_1 + t_4}{2} - \frac{t_2' + t_3'}{2}$$

FIG. 14. Schematic diagram of signals used in clock synchronization by network time protocol.

5. APPLICATIONS OF PRECISE TIME AND FREQUENCY MEASUREMENTS

5.1 Experimental Relativity

5.1.1 Test of Local Position Invariance

Local position invariance (LPI) is a part of Einstein's principle of equivalence, which plays an essential role in constructing the relativistic theory of gravitation. It asserts that the outcomes of experiments made in local free-falling frames do not vary with time and position. Gravitational redshift experiments test the existence of spatial dependence. If LPI is valid, a gravitational redshift is universal, independent of the nature of the clocks being measured, and is given for weak gravitational fields by $df/f = dU/c^2$, where f is the nominal clock frequency, U is the Newtonian gravitational potential, and c is the speed of light (Will, 1981). A hydrogen maser, with frequency stability better than 10^{-14} over 100-s averaging time, was flown on a rocket to an altitude of about 10 000 km, and its frequency was compared to a similar clock on the ground (Vessot and Levine, 1979). In this experiment, the gravitational redshift on the clock was verified with 0.02% uncertainty. It is the most precise experimental result on this effect until now. A null gravitational redshift experiment that compares two different types of clocks in the same laboratory has been performed (Turneaure *et al.*, 1983). The rates of two H maser clocks were compared with those of three superconducting-cavity–stabilized oscillator clocks over a 10-d period. During this period the solar gravitational potential at the laboratory changed sinusoidally with a 24-h period by 3×10^{-13} because of the Earth rotation, and also changed approximately linearly at 3×10^{-12}/d because of the Earth's orbital motion. An upper limit on the relative frequency variation of 1.7% of the external potential was set. It was a direct test of LPI. If every type of clock varied with position in the same manner, there would be no operational way to detect the violation of LPI, since clock rates are always measured relative to a chosen standard clock.

Temporal dependence of the outcomes of local experiments is the other key test of LPI. The constancy of the fundamental nongravitational constants over cosmological time scales was studied in a wide range of observations such as comparisons of spectral emission lines in distant galaxies and quasars (Wolfe *et al.*, 1976; Pagel, 1977), measurements of isotopic abundances of elements in the solar system (Shlyakhter, 1976), laboratory comparisons of atomic clocks (Turneaure and Stein, 1976), and so on.

It is not an obvious fact that the time argument appearing in the dynamical equations of motion coincides with the one used in quantum mechanics. The question remains to be verified by all possible experiments whether an atomic time scale, which is an accumulation of the SI second defined by a quantum mechanical transition, is exactly equal to a proper time that is a concept of space-time physics, such as special and general relativity. As discussed in Sect. 1.2, TAI is a realization of a coordinate time in a geocentric system of coordinates, which is established on the assumption that Einstein's principle of equivalence is valid. Long-term observations of dynamical behavior in the solar system or in extraterrestrial stellar systems such as a spinning neutron star (pulsar) system, by using TAI as a time reference and by comparing with the theoretically expected configurations, can provide an opportunity to check the validity of the assumption.

5.1.2 Clock Synchronizations

In relativity, the notion of simultaneity is not given *a priori* so that a conventional choice of a definition has to be made. A widely used definition is that of coordinate simultaneity and corresponding coordinate synchronization (Allan and Ashby, 1986; Klioner, 1992). Two events are said to be coordinate simultaneous when they have the same value of time coordinate in some specified reference system of coordinates, whatever their space coordinates are. The synchronization of two clocks by this definition is entirely dependent on the chosen reference system.

Taking the GPS as an example, it adopts four-dimensional space-time coordinates to describe the motion of the satellites, behavior of the satellite clocks, and propagation of the radio signals. The time coordinate is GPS time, and the space coordinates are those of the World Geodetic System (WGS), which is a geocentric coordinate system with uniform rotation. Ideal atomic clocks operating on satellites run at different rates with respect to GPS time, because they move with different relative velocities and are submitted to different gravitational fields. The mean rate difference between the ideal clock on the satellite and that on the rotating geoid is 4.43×10^{-10}. Taking this into account, the real atomic clocks carried by the satellites are all tuned to a frequency shifted lower by 4.45×10^{-10}, before being launched. This makes the satellite clocks easy to be synchronized with GPS time. Each satellite moves in a nearly circular orbit with an eccentricity less than 0.01. But because of the small eccentricity, the reading of the satellite clock differs from GPS time. The difference varies sinusoidally with a 12-sidereal-hour period and with an amplitude of 25 ns at most. Propagation delay of signals from the satellite to the antenna of the receiving site is calculated from the space coordinates of satellite and those of the antenna. The calculation includes an effect on light propagation in a rotating reference system, the Sagnac effect, which depends on the configuration of the satellite and the antenna and amounts to more than 100 ns in some cases. Since the accuracy of GPS time comparisons is less than 10 ns, all these relativistic effects are taken into account every day in the international time comparisons (Allan *et al.*, 1985).

Synchronizations of much better clocks with much more precise comparison methods, which are expected in the near future, can be made by taking all the relativistic terms up to 10^{-18} into account (Wolf and Petit, 1995).

5.2 Pulsar Timing Observations

Pulsars are rapidly rotating neutron stars emitting beams of electromagnetic radiation. Their observed periods range from 1 ms to a few seconds and have been found to be very stable except for occasional irregularities. If we regard a pulsar as a stable clock that emits pulses regularly, then timing observations of the pulsar, yielding a series of measurement of the pulse arrival time by the observer's clock, is a kind of the remote clock comparison, which may be called an interstellar clock comparison. In this comparison, the propagation delay involves the following: the geometrical change of distance between the pulsar and the observation site originating from a relative acceleration due to the differential rotation of our Galaxy (Damour and Taylor, 1991), orbital motion of the pulsar if it forms a binary system, and the orbital and rotational motion of the Earth; change in propagation speed of the electromagnetic wave originating from the fluctuation of dispersion measures in the circumstellar, interstellar, and interplanetary plasmas; and Shapiro delays (Shapiro, 1964) in the gravitational fields of a possible companion star, possible gravitational lensing bodies, and the solar system bodies, as well as the effect of gravitational waves possibly crossing the propagation path, and change of relativistic time difference between the terrestrial time scale and the time scale referred to the solar-system barycenter. Timing observations of the binary pulsar PSR 1913+16 provide a successful test for the existence of gravitational radiation through the precise determination of the orbital motion of the pulsar (Taylor *et al.*, 1979). The pulsar PSR 1937+21 having a period of 1.6 ms shows very small irregularities in the period. Because of the intrinsic increase of the period, which is about 10 times larger than the deceleration of the Earth's rotation, the pulsar alone cannot give a good measure of time. However, the pulsar has probably smaller random instabilities than the best atomic time scales for averaging times longer than one year, and use of the pulsar may improve the long-term stability of atomic time scales (Davis *et al.*, 1985). The timing observation of this pulsar has also set an upper limit on the energy density of stochastic gravitational waves that may have been generated, in the early stage of our Universe, by vibrations of cosmic strings, collisions of cosmic bubbles or giant black holes, or other unknown processes.

5.3 Metrological Standards

5.3.1 Standard of Length The speed of light, $c = 299\,792\,458$ m/s, consists of a number, 299 792 458, a unit of length, 1 m, and a unit of time, 1 s. The speed of light was determined by measuring the wavelength and the frequency of electromagnetic radiation. The relation $c = f\lambda$ gives the value of the speed of light. Limitations on accuracy of the measurement due to the definition of the length forced us to face the problem of the definition of the unit of length. The uncertainty in the measured number for the speed of light was always limited by the uncertainty of wavelength, which comes from the uncertainty of the unit of length.

This problem was solved by introducing a revolutionary new redefinition of the scale of length. The new definition of the meter, adopted by the 17th General Conference on Weights and Measures (CGPM) in 1983, is as follows: "The meter is the length of the path travelled by light in vacuum during a time interval of 1/299 792 458 of a second." In this way, the meter is defined in terms of the second because frequency can be measured much more accurately than wavelength. The numerical value of the speed of light, 299 792 458, is exactly fixed in this new definition.

Since relativity requires that the speed of light is an invariant physical quantity and that time multiplied by the light velocity is a metrical component of four-dimensional space-time along with the space components, it seems quite natural from the relativistic point of view to define a single metrical unit, such as the second.

The meter is realized practically by interferometric techniques using optical or infrared radiation. In order to meet the definition, it is necessary to compare the frequency of radiations in the optical and infrared region with one in microwave region with sufficiently high accuracy. The development of frequency measurement in the optical or near-infrared region is still a necessary spectroscopic activity to provide frequency and wavelength standards in all parts of the electromagnetic spectrum (see Secs. 3.3 and 3.4).

5.3.2 Voltage Standard In the ac Josephson effect, the frequency of oscillations generated by a voltage bias V applied to a weak link of superconductor is given by $f = (2e/h)V$. This relation is used to define the volt in terms of frequency with the defining constant, $2e/h$ = 483 597.9 GHz/V (Taylor and Witt, 1989; see also CONSTANTS, FUNDAMENTAL). 1- and 10-V Josephson voltage standards are now commercially available, and 1-V standards in the national metrological laboratories have been compared by means of a transportable apparatus with uncertainty below 3×10^{-10} in each case.

INTRODUCTION

Positron-emission tomography (PET) is the noninvasive external detection of positron-emitting radionuclides distributed according to physiological and biochemical function in a living subject. The goal of PET is to obtain knowledge about normal and pathological states in humans and to apply this knowledge to the research, diagnosis, prognosis, treatment, and monitoring of disease. In its most general use, PET refers to the process of producing an image of the distribution of radionuclide in a slice

digital Encyclopedia of Applied Physics

through a living subject. The steps involved in the PET process are

1. acquisition of radionuclide distribution data,
2. reconstruction of quantitative images of the radionuclide distribution,
3. extraction of quantitative measurements of the radiopharmaceutical distribution, and
4. interpretation of results related to functional or parametric information.

The most attractive advantage of PET is that common isotopes within biologically active molecules can be labeled with positron-emitting isotopes with little mass differences (i.e., ^{11}C for ^{12}C and ^{18}F for ^{1}H). The biochemical behavior of these radiolabeled molecules or traceable compounds is known, and they can be introduced into the body in small amounts without affecting the body's normal processes. PET thus provides quantitative measurements of the distribution of labeled biologic and synthetic compounds or drugs.

In Sec. 1, a review of the basic principles of positron decay provides an understanding of the advantages of positron-emitting radionuclides for detection and localization in the living human body. The incorporation of these physical advantages, through annihilation-photon coincidence detection, into commercially available positron scanners is described in Sec. 2. In addition, the limitations of quantification in PET are discussed both in the context of acquisition devices and in regard to their effect on the interpretation of PET results.

Inherently, the interpretation of PET images requires an understanding of the sources of errors, the accuracy of correction methods, and knowledge of the applied image-processing methods producing the resultant images. In Sec. 3, methods of image reconstruction from projections and techniques for correcting the factors affecting the accuracy of PET images are given. Sections 5 and 6 describe quantitative accuracy, image quality, and diagnostic accuracy. A basic understanding of digital image processing as it applies to PET is given in Sec. 7.

Section 8 discusses clinical PET applications and provides some example studies. A list of Further Reading is provided for the interested reader.

1. BASIC PRINCIPLES

1.1 Radioactive Decay and Ionizing Radiation

Radioactive decay is a nuclear transformation process involving the emission of particles and/or photons and the release of nuclear energy. The emissions can interact with atoms, nuclei, and electrons of surrounding matter, whereby energy is imparted or transferred to the surrounding material, causing *ionization* and *excitation.* When referring to emissions from radioactive decay, the term *ionizing radiation* is often used, since ionization is the primary event.

1.2 Positron Decay

Nuclei containing excess protons undergo spontaneous nuclear transformations leading to a more stable condition. To reach greater stability, these nuclei reduce proton content by either *electron capture* or *positron emission.* Electron capture occurs when an inner orbital electron combines with a nuclear proton to form a neutron and a small massless, chargeless particle called a *neutrino.* The overall result is a decrease of the atomic number by one and the emission of characteristic x rays as a consequence of the rearrangement of orbital electrons. Positron emission results when a nuclear proton is transformed into a nuclear neutron, resulting in the ejection of a positively charged electron or *positron* and a massless neutrino from the nucleus. The positron travels a short distance, depending on its kinetic energy and the nature of the material in which it is contained, and combines with an electron in an annihilation event. Because of the laws of conservation of energy and momentum, two 511-keV photons are emitted simultaneously from the site of annihilation at approximately 180° ± 0.25° to each other (see Fig. 1). The noncollinearty of the annihilation photons results because the positron or electron may not be completely at rest upon annihilation.

Since positron emission decreases the atomic number by one, the number of orbital electrons must also decrease by one as soon as the positron is ejected from the nucleus. The atomic mass of the daughter nuclide must be two electron masses smaller

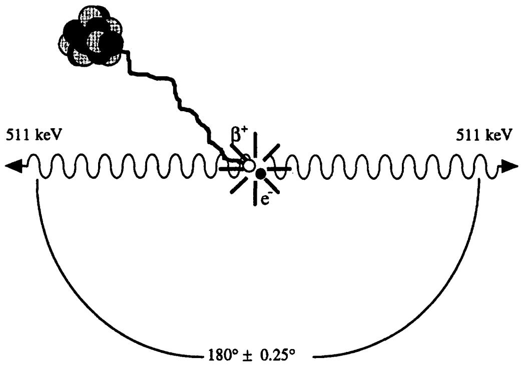

FIG. 1. Diagram of positron emission and annihilation event.

than the parent radionuclide. Since this mass difference eventually manifests itself as energy, a minimum of 1.02 MeV is required for positron emission. Since there is no energy requirement for electron capture, proton-rich nuclei reach stability by these different but competing modes, each having its own characteristic emissions. As the energy difference between parent and daughter nuclei approaches the 1.02-MeV requirement, the probability of positron emission decreases, while the probability of electron capture increases. Positron emission occurs frequently in lighter elements, while electron capture is favored in heavier elements. The transformation of a single unstable atom to a more stable atom is irreversible and is called a *disintegration* or *decay event.*

All unstable nuclei in a sample decay randomly. The number of unstable nuclei, N, and therefore of disintegrations, decreases continuously with time. The rate of decay or the disintegrations per unit time is called the *radioactivity, A*, of a sample.

$$A = -\frac{dN}{dt}. \tag{1}$$

Radioactivity is proportional to the number of unstable nuclei present in a given sample and is given by

$$A = \lambda N, \tag{2}$$

where λ is the *decay constant* representing the constant fraction of activity or number of nuclei disintegrating per unit time interval. The mathematical expression for N at time t_1, $N(t_1)$, is given as

$$N(t_1) = N(t_0)e^{-\lambda(t_1-t_0)}, \tag{3}$$

and since A is proportional to N,

$$A(t_1) = A(t_0)e^{-\lambda(t_1-t_0)}. \tag{4}$$

Thus, for given values of λ and $\Delta t = t_1 - t_0$, the quantity $e^{-\lambda\Delta t}$ is called the *decay factor.* The reciprocal of the decay factor, $e^{\lambda\Delta t}$, can be applied to $A(t_1)$ to obtain $A(t_0)$, the activity *decay corrected* to reference time t_0.

The *half-life*, $T_{1/2}$, of a radionuclide is defined as the time required for an amount of radionuclide to decay to one-half of its original activity and is given as

$$T_{1/2} = \ln(2)/\lambda. \tag{5}$$

Each positron-emitting radionuclide has its own unchangeable characteristics as shown in Table 1.

Nuclear decay is a statistical process in which the probability of a nuclear disintegration event is independent of all other events. A single disintegration can occur at any time. With this in mind, $N(t_1)$ given in Eq. (3) must be sufficiently large to allow for statistical averaging when using the decay constant to determine the radioactivity of a sample at any other time. Because of nuclear decay, multiple measurements are often impractical, and a single measurement is made as an estimate of the true value of the radioactive sample. The probability of obtaining the true value from a single radioactivity measurement, N, follows the *Poisson* distribution and is related to the variance σ^2 of the distribution. For the Poisson distribution,

Table 1. Physical properties of positron-emitting radionuclides of medical interest.

Isotope	Half-life (min)	Maximum positron energy (MeV)	Positron emission (%)
^{11}C	20.30	0.96	99.8
^{13}N	9.97	1.19	100.0
^{15}O	2.03	1.70	100.0
^{13}F	109.80	0.64	97.0
^{68}Ga	68.30	1.90	88.0
^{82}Rb	1.27	3.35	96.0

the variance is equal to the true value, but since we cannot know the true value exactly, we use N as an approximation. One measure of the statistical reliability of N is the percent coefficient of variation, defined as

$$\%\mathrm{CV} = 100\% \cdot \frac{\sigma}{N} = 100\% \cdot \frac{\sqrt{N}}{N} = \frac{100\%}{\sqrt{N}}, \qquad (6)$$

which indicates that the uncertainty in a single measurement decreases with increasing number of counts.

1.3 Photon Interactions with Matter

When photons traverse matter, some pass through without any alteration and some lose all or part of their energy through a series of interactions with the atoms, nuclei, or electrons of the material. Photon interactions occur in several different ways that result in high-energy electrons and secondary photons of lesser energy. The two principal mechanisms by which annihilation photons interact with matter are the *photoelectric* and *Compton scattering* processes. In the photoelectric process, a photon is completely absorbed by an atom, through the transference of all its energy to an orbital electron. This photoelectron is ejected from the atom with kinetic energy E_{pe} equal to the energy absorbed minus the binding energy of the photoelectron ($E_{pe} = E_0 - E_B$). Compton scattering is modeled as an elastic collision between a photon and an orbital electron. The incident photon is deflected into a different direction through a scattering angle with reduced energy, E_{sc}. The relationship between the scattering angle θ and the energy of the incident photon, E_0, is given by

$$E_{sc} = \frac{E_0}{1 + (E_0/m_0c^2)(1 - \cos\theta)}, \qquad (7)$$

where $m_0c^2 \approx 511$ keV is the rest energy of an electron.

The kinetic energy of the ejected recoil electron, E_{re}, is equal to the energy absorbed by the atom minus energy of the scattered photon ($E_{re} = E_0 - E_{sc}$). From Eq. (7), the amount of energy transferred from the photon to the recoil electron does not depend on any property of the absorbing material; it depends only on the incident photon energy and scattering angle. The angular distribution of the scattered photon is dependent upon the incident photon energy E_0. For 511-keV photons, the scattering angle is usually small (i.e., the photon scatters in the forward direction), resulting in Compton-scattered photons near the energy of the incident photons.

The probability that a photon interaction will occur depends on the energy of the photon and the characteristics of absorbing or attenuating material. For 511-keV photons in body tissue, the most probable interaction is Compton scattering. In order to examine the quantitative aspects of photon attenuation, consider Fig. 2, in which a beam of collimated (parallel) monoenergetic photons is incident on an absorber of thickness Δx. As the beam with incident intensity I_0 passes through the absorber, some of the photons are completely absorbed, some are scattered, and some are transmitted through the absorbing material with intensity I. The probability that a photon will be transmitted through the absorber is given by

$$I/I_0 = e^{-\mu x}, \qquad (8)$$

where μ is the linear attenuation coefficient of the absorber for the energy of the incident radiation. For a positron-emitting radionuclide surrounded by photon-attenuating media (see Fig. 3), the probability that either of

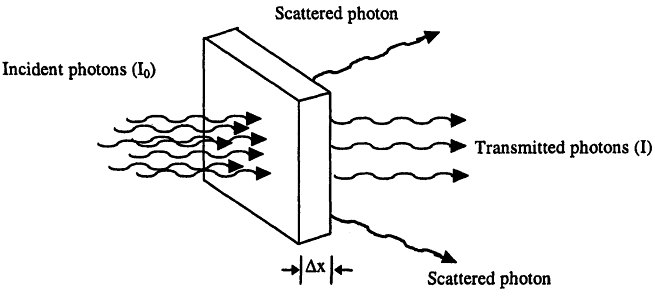

FIG. 2. Monoenergetic photon beam transmitted and scattered through an absorbing medium.

the two annihilation photons will exit the body without interaction is given by the product of each photon's probability of escape:

$$I/I_0 = e^{-\mu x_1}e^{-\mu x_2} = e^{-\mu(x_1+x_2)} = e^{-\mu l}, \qquad (9)$$

where x_1 and x_2 are the respective distance the two photons travel through the absorbing material (as shown in Fig. 3) and l is the total absorber thickness ($l = x_1 + x_2$).

The attenuation of an annihilation photon pair, thus, is dependent on the total distance l along the path traveled and on the absorbing material's linear attenuation coefficient μ, and is independent of the position of the annihilation event. This is an important fact in estimating the absolute radioactivity concentration in an object, which is confounded by photon attenuation, as discussed later.

2. ACQUISITION DEVICES

Because of their high energy, annihilation photons are not well suited for detection by conventional nuclear-medicine imaging devices. Devices for the imaging of positron emitters typically use special annihilation coincidence-detection electronics and detectors that efficiently absorb high-energy photons. However, conventional imaging devices using special collimators and dual-head coincidence detectors are becoming popular, as the use of positron-emitting radiopharmaceuticals becomes more attractive in the clinical setting. Even so, this discussion will emphasize dedicated tomographic devices.

Tomographic imaging devices differ from the majority of nuclear-medicine imaging approaches, in that the data acquisition and image reconstruction are based on rigorous mathematical algorithms. The data collected consist of directional views of the radioactivity distributed within an object, taken at many angles around the object. The value at any point of a particular view represents the contribution of all photon emissions detected along lines extending through the object projecting onto that point. These acquired projections are the raw input data for the computed methods of tomographic reconstruction of images of the radioactivity distribution.

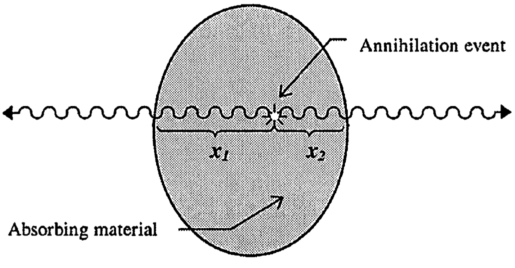

FIG. 3. Annihilation photons travel respective distances of x_1 and x_2 through an absorbing material.

2.1 Imaging Systems

Imaging systems consist primarily of an acquisition device and its electronics, a computer, and a workstation. The workstation is the interface between the operator and the computer, and it controls the acquisition device and performs post-acquisition data processing such as tomographic reconstruction. The major difference among most imaging systems is in the acquisition device and its electronics, reflecting the specific application involved and thus the type of processing required.

2.1.1 Anger Camera Anger cameras use heavy-metal absorbers as collimators, placed in front of position-sensitive detectors, to discriminate against photons traveling along undesirable directions toward the detector. Because of the attractiveness of positron-emitting radiopharmaceuticals, Anger cameras have been fitted with high-energy (511 keV) collimators. Since most of the potentially useful photons are removed by the absorptive collimation, and because the detectors employed are usually designed for much lower-energy (100–200 keV) single-photon–emitting radionuclides, the performance of these systems is poor in comparison with true PET imaging systems.

Planar images obtained from the Anger camera are projection images. The radioactivity in the organ of interest can be obscured by activity either in front of or behind the organ, and the photons originating from the organ are attenuated by the surrounding tissue. These problems are overcome by rotating the camera to acquire multiple projections and correcting the attenuation in a tomographic reconstruction (described later). This method of radionuclide imaging is called single-photon–emission computed tomography or SPECT.

2.1.2 Multihead Camera Systems As with the Anger camera, the attractiveness and availability of positron-emitting radiopharmaceuticals have spawned a great interest in development of relatively inexpensive imaging devices for clinical and research use. These systems, like the more complex dedicated tomographic systems, employ "electronic collimation" of position-sensitive detectors through coincidence circuitry. However, because of their simple design, they do not have the ability of simultaneous detection of photon emissions at all angles about the object, as do ring systems. In order to obtain tomographic information, these detector systems must undergo some kind of motion (i.e., rotation and/or translation) and are useful for measuring radionuclide distributions that do not change rapidly in time. When kept stationary, these systems are utilized for determining rapid rates of uptake or elimination in studies that do not require tomographic reconstruction for radionuclide localization and quantitation.

2.1.3 Ring Systems The majority of PET scanners in use today utilize a multiple-ring design; these represent dedicated tomographic devices. Typically classified by ring diameter into head or whole-body scanners, almost all commercial ring PET scanners operate on the same basic principle of a circumferential array of block detectors (described later) that provide both high detection efficiency and rapid data acquisition. Recent advances in technology have provided three-dimensional (3D) imaging in addition to the more common two-dimensional (2D) or transverse-slice imaging.

The physical configuration of most commercially available PET systems consists of one or more circular rings of detectors. The field of view (FOV) is determined by scanner and detector geometry and the electronic configuration of detector pairs. If the detector size is constant, then the number of rings determines the axial FOV. The transaxial FOV is dependent upon the ring diameter and the selection of coincidence detector pairs. Conventional transverse-slice (2D) imaging devices are designed to maximize the detection of annihilation photons within a transaxial plane or transverse slice while minimizing the detection of out-of-plane activity. The former is achieved by the fact that each detector in a ring can be in coincidence with any other detector in the ring. The latter is accomplished by separating rings by thin heavy-metal shielding called *septa.*

Modern PET scanners have retractable septa, allowing scanners to be operated in a fully 3D mode. By eliminating septa from the FOV and electronically allowing each detector to be in coincidence with all other detectors in the scanner, maximum detection of annihilation photons is achieved.

2.2 Annihilation-Photon Detection and Localization

Radiation detection is based on the interaction of photons with matter. A photon is detected through the ionization effects of the secondary electrons produced by its deposition of energy within a detector. As previously stated, the probability of photon–detector interactions is dependent on both photon energy and the physical properties of the detector. Since the annihilation-photon energy is high, the stopping power of the detector must also be sufficiently high.

The localization of a positron emitter in an object is based on the fact that annihilation photons are emitted simultaneously at approximately 180° to each other. This property allows the coincidence detection of the two annihilation photons by a pair of detectors placed on opposite sides of the object, as shown in Fig. 4. This *electronic collimation* of annihilation photons is a more efficient method than conventional *absorptive collimation* in the detection and subsequent localization of annihilation photons.

2.2.1 Scintillation Detectors Scanners in nuclear medicine are based on the use of scintillation detectors. Scintillation detectors are crystalline material containing small amounts of impurity. When ionizing radiation deposits energy within a detector, a free secondary electron is produced in the crystal lattice. This electron moves through the lattice until it encounters an impurity and becomes trapped. The trapping atom is in an excited state and will relieve this excitation by rapidly dissipating energy through the emission of visible or ultraviolet light. Any

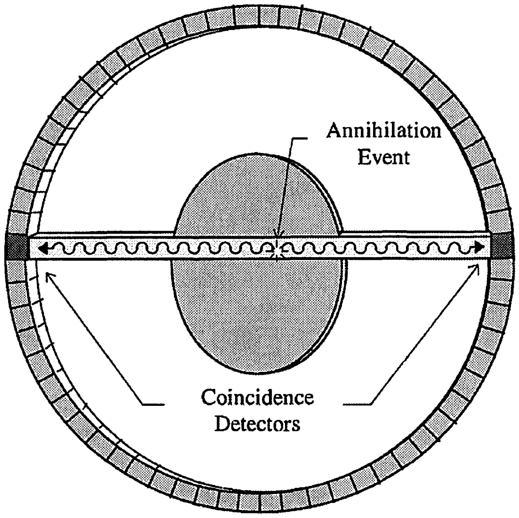

FIG. 4. The coincidence detection of annihilation photons arriving in opposing detectors.

energy not emitted as light will be dissipated eventually as heat. Since the energy levels of the excited impurity are different from those of the main substance, there is a high probability that visible light will escape the crystal. Each photon of visible light represents a free electron produced by the breaking of a valence bond by a definite amount of energy. The total amount of visible light thus produced is proportional to the total energy deposited in the detector crystal.

Important characteristics of scintillators are photon yield or the average number of light photons per keV of ionizing radiation absorbed (the higher the better), density and atomic number (stopping power; the higher the better), the decay of the burst of visible light (decay time; the shorter the better), emission of light in the visible energy range (matched to the characteristics of the photocathode of the photomultiplier tube), little or no self-absorption of visible light, and low cost. Many different scintillators have been used in nuclear medicine, but thallium-activated sodium iodide, NaI(Tl), has been the most common. Although NaI(Tl) is an efficient scintillator, it is fragile and hygroscopic, requiring special handling, temperature, and sealing to prevent fractures and discoloration, which impair visible light transmission through the crystal. The first commercial PET scanners used NaI(Tl), but most modern PET scanners use a block concept of bismuth germanate ($Bi_3Ge_4O_{12}$) or BGO block detectors (described in the next section). BGO has become the scintillator of choice because of its high density and atomic number, which indicates that high stopping power is the most important detector characteristic (see Table 2). However, because it has lower light output when compared with NaI(Tl), BGO has poorer energy resolution and timing characteristics. Lutetium orthosilicate [$Lu_2SiO_5(Ce)$] or LSO is a new scintillator material that, like BGO, has high stopping power but also has significantly better light output and shorter decay time.

Although scintillators are efficient photon detectors, they are inefficient energy converters. Through the use of a photomultiplier tube, PMT, optically coupled to the scintillation detectors, weak light signals striking the PMT photocathode are converted to a pulse of electrical current that is proportional to the intensity of the light signals. The amount of electrical current produced at the PMT anode is, thus, also proportional to the amount of energy deposited in the crystal. The electrical pulse of the PMT is used by electronic components that determine the location of photon–detector interaction, the amount of energy deposited in the detector, and the time when the interaction took place.

2.2.2 Coincidence Electronics As mentioned above, most commercial PET scanners are designed with BGO block detectors in coincidence. A block detector is one in which an array of small detector crystals (scintillators) are interfaced to a small num-

Table 2. Comparison of NaI(Tl) and BGO scintillator properties.

	NaI(Tl)	BGO	LSO
Density (g/cm^3)	3.67	7.13	7.4
Effective atomic number	50	74	172
Decay time (ns)	230	300	40
Photon yield (per keV)	40	4.8	30
Energy resolution (FWHM %)	7	15	11
Hygroscopic	Yes	No	No
Emission wavelength (nm)	415	480	420

ber of PMTs to generate the location of the detector–photon interaction. The encoding or addressing scheme used to identify the crystal in which an annihilation photon was absorbed, commonly referred to as Anger logic, is obtained by comparing the relative output from individual PMTs within a block (see Fig. 5). The total output of all PMT pulses in a block is used to determine the amount of energy deposited and the time when the photon was detected in the block. Once produced, the block pulse is compared to preset upper and lower thresholds. If the pulse amplitude falls between the upper and lower voltages established, the energy requirements for the event are fulfilled and the timing and positioning information are retained.

The coincidence logic circuit receives the timing and position information and with the timing information checks for the occurrence of the simultaneous detection of another event in an opposing detector. A coincidence event is recorded only if pairs of events in opposing detectors occur within a narrow interval of time determined by the resolving time of the detectors and the electronics used for energy discrimination and position determination. After a coincidence event is detected it is stored in computer memory at a location corresponding to the particular line of response (LOR) between the coincidence-detector pair. In some systems, events not found in coincidence, called *singles,* are also stored in computer memory according to detector position.

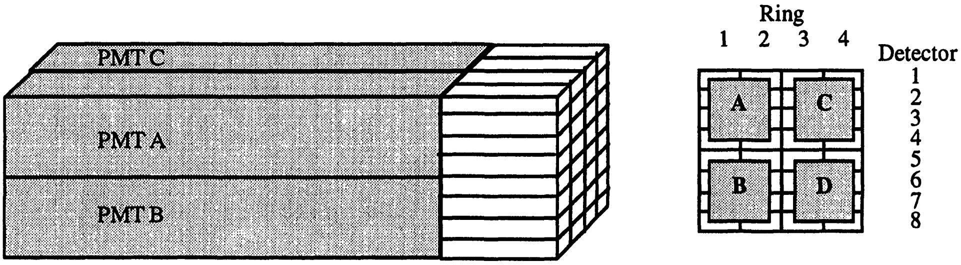
Timing resolution is thought of as the capability of the PET system to determine the time of photon–detector interaction as in time-of-flight acquisition, where temporal information is used to improve the accuracy of image reconstruction. In order to use time-of-flight information, very fast detectors (i.e., short decay time) and electronics must be used. BGO is not sufficiently fast, and most current scanners do not use this additional time-of-flight information.

2.3 Resolution

Resolution is the process of separating or clarifying the parts or components of an object. In PET, resolution is a measure of a scanner's ability to localize the positron emitter both in time and in space.

2.3.1 Spatial Resolution The spatial resolution of a PET scanner determines its visual and quantitative capabilities. Typical measurements of spatial resolution include *transverse* and *axial* resolution. Spatial resolution is limited physically by the kinetic energy of the positron and the distance it travels from the nucleus prior to its annihilation, the deviation from exact collinearity of the annihilation photons, the dimensions of the detectors, and the distance between opposing detector pairs.

2.3.1.1 Transverse Resolution. Transverse or in-plane resolution is characterized by the response of the detector system to a



$$\text{Ring} = \frac{(A+B)-(C+D)}{A+B+C+D}$$

$$\text{Detector} = \frac{(A+C)-(B+D)}{A+B+C+D}$$

FIG. 5. Block-detector array and Anger logic for crystal identification.

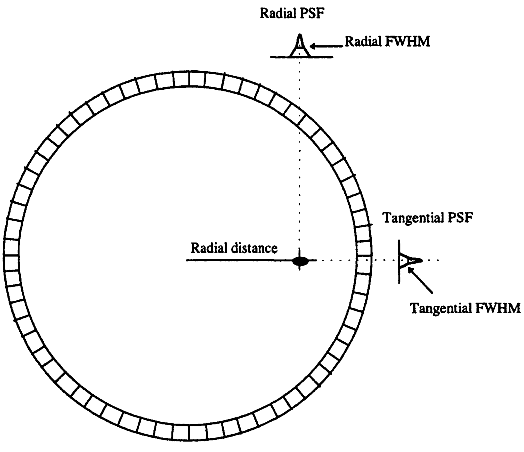


FIG. 6. Transverse resolution determined at a radial distance from the PET scanner FOV center in both the radial and tangential point-spread functions (PSFs).

point source or impulse of radioactivity. From an image of a point source, a count profile through the center of the source, called a point-spread function (PSF) or impulse response function, is obtained along lines through the point in both radial and tangential (perpendicular to the radial) directions, as shown in Fig. 6. The most common measures of transverse spatial resolution are the full width at half maximum (FWHM) and the full width at tenth maximum (FWTM) of the radial and tangential PSFs at various radial distances from the transverse FOV center.

Spatial resolution is the distance that two point sources must be apart from each other in order to be distinguished as separate objects. Shown in Fig. 7 are the contributions of two individual point-source profiles at various distances of separation to the resultant line profile through both point sources.

If a radioactivity distribution can be conceptualized as a linear combination of point sources, then the image of the radioactive object is the linear combination of scaled point-spread functions superimposed on one another. The object's profile thus becomes a blurred version of the actual profile, and the image is an inaccurate reproduction of the actual object radioactivity distribution, as shown in Fig. 8. In essence, the image is the convolution of the object with the scanner's PSF.

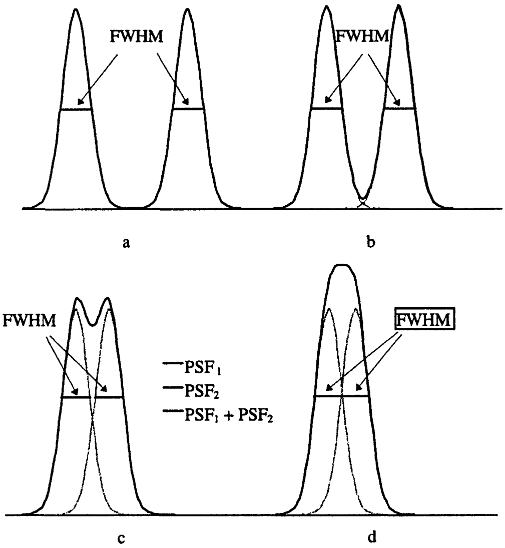

FIG. 7. The effects of imperfect spatial resolution on the discrimination of two impulse response functions. (a)–(c) As the distance between two sources approaches the FWHM, the ability to distinguish one point source from the other becomes more difficult until (d) they no longer appear as two separate objects.

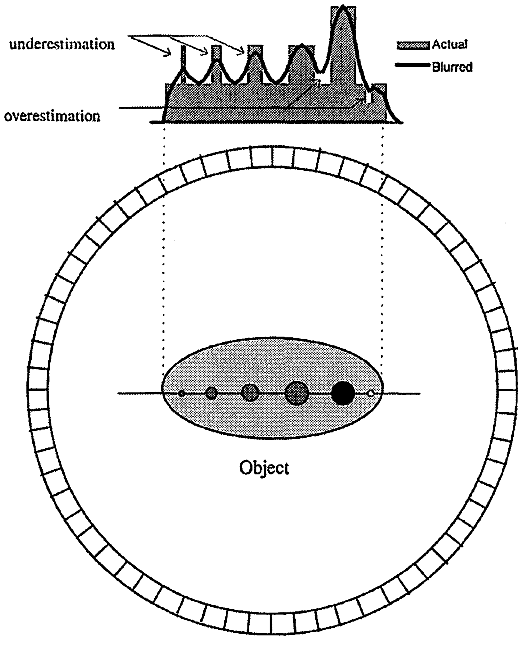

FIG. 8. The profile of an actual object (shaded) and blurred (line) by a PSF.

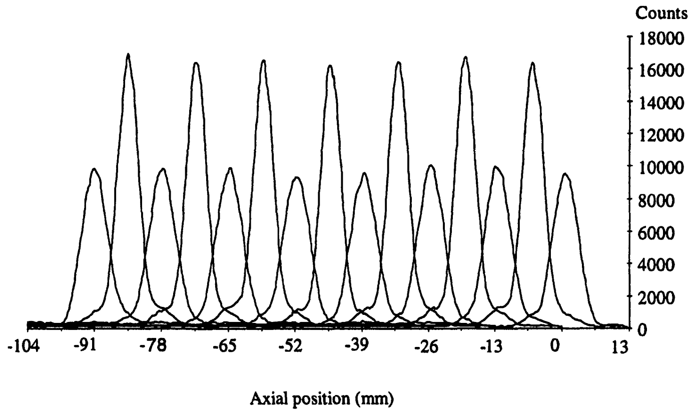

FIG. 9. Axial response function obtained at the center of the FOV in a 15-slice PET scanner by moving a point source in 0.5-mm steps in the axial direction.

Because of the limited spatial resolution of the PET system, as objects become smaller the detected object radionuclide concentration is reduced. As shown in Fig. 8, all objects in the image can become "contaminated" with radioactivity from surrounding objects, making the delineation of the radionuclide concentrations between different objects difficult.

2.3.1.2 Axial Resolution. Axial resolution is analogous to transverse resolution in that an impulse response along the axial direction is obtained from a stationary point source. This parameter is only appropriate if the axial sampling (determined by the axial dimension of the detectors) is sufficient, as discussed below. What is often indicated as axial resolution is more appropriately termed the *axial response function.* The axial response function is obtained, for each scanner plane, from the coincidence counts of a point source of radioactivity as it passes in the axial direction through the scanner FOV in small increments at various radial positions, as shown in Fig. 9. Parameters used to describe the axial response function are the FWHM, FWTM, and the center-to-center slice separation for a specific radial distance from the center of the FOV.

The axial response functions indicate that a source has its greatest contribution to the PET scanner response (highest count recovery) at the axial center of each plane and that interplane (cross) slices have higher sensitivity than do in-plane (direct) slices (see Fig. 10). Transverse and axial resolution define the smallest volume that can be resolved by the PET scanner. The total amount of radioactivity detected from this volume determines the volume's observed radionuclide concentration. For example, the amount of radioactivity from a single small object partially occupying this volume, in the absence of any other source of radioactivity in the volume, can only be resolved as originating over the entire volume; thus the object's measured radionuclide concentration is less than its true radionuclide concentration. In addition, the presence of other sources in the volume (i.e., from adjacent objects) also contribute or spill over radioactivity into the object. These *partial-volume* and *spillover* effects reduce both qualitative and quantitative accuracy and are most noticeable for small objects and the edges of all objects. Partial-volume effects become less significant as ob-

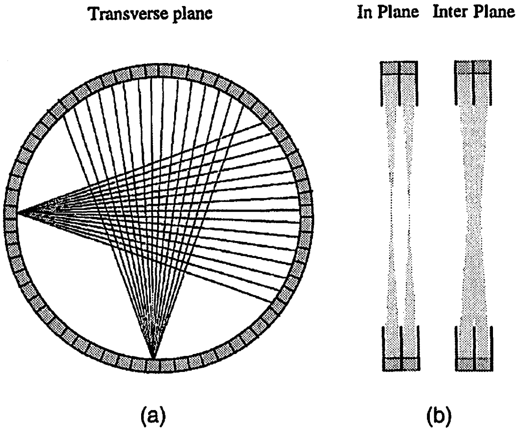

FIG. 10. Sampling patterns of detectors in a multiple circumferential array (ring) configuration.

ject size increases relative to the spatial resolution in all directions, but spillover effects (and blurring) remain along edges defining the boundaries between structures.

2.3.2 Temporal Resolution Temporal resolution is the ability of the PET scanner to depict the changing distribution of coincidence events in time. For this purpose, PET scanners may be operated in either histogram or list mode. In histogram mode (by far the most common method of acquisition), all coincidence events detected along a particular LOR over a specified interval of time are accumulated at a corresponding location in computer memory. For each new acquisition frame, the information accumulated must be transferred, stored, and cleared. The temporal sampling rate is thus dependent upon the amount of memory required and limited by the detection electronics described in the previous sections. In general, the longer the accumulation time interval or frame, the higher the number of events collected, which in turn provides a statistically better (less noisy) estimate of the radionuclide concentration. Alternatively, the PET scanner can be operated in list mode, where coincidence events are stored sequentially as they are detected with their position and timing information. This information can be used for retrospective reconstruction of variable-duration image frames. The ability to reflect accurately the temporal changes in radionuclide concentration is important for the determination of pharmacological rate constants obtained by tracer kinetic modeling of image-derived measurements of physiological processes. Generally, image acquisition protocols consist of a number of short scans followed by scans increasing in duration. The short scans are required to measure the initial rapid change in tissue tracer concentration. Although noisy, more initial short measurements are often more desirable than fewer, less noisy or longer measurements in characterizing the radionuclide concentration as a function of time.

2.4 Sampling

With arrays of discrete detectors, conventional PET scanners measure radionuclide distributions at discrete points. These points are thus separated by distances equal to the detector's dimensions. As discussed above, one of the limitations imposed on the spatial resolution of a PET system is detector size. In earlier PET systems, with large detectors, the activity distribution was grossly undersampled, and as a result, images suffered from poor resolution and artifacts. One common method to increase sampling was to employ some sort of gantry motion (i.e., wobble or translation). With the use of small high-density detectors, the detector spacing or the linear sampling interval is smaller, reducing the need for additional gantry movement to improve spatial resolution. Since PET scanners using circumferential arrays of block detectors are operated in coincidence with multiple detectors on the opposing side of the array and in coincidence with detectors in other rings (Fig. 10), the continuous radioactivity distribution is sampled or viewed from many discrete angles around an object (*angular sampling*) simultaneously. This configuration, however, does not provide uniform sampling, but is sufficient (not optimal) to provide quantitatively accurate images of the radionuclide distribution.

Expressed differently, information is lost in the sampling process, and the solution becomes one of establishing sampling conditions that allow the radioactivity distribution to be recovered accurately. The Fourier transform and the convolution theorem provide the tools for an in-depth study, as is addressed below. For now, it suffices to recognize that complete recovery of the continuous radioactivity distribution from discrete samples requires a linear sampling interval whose spacing across each projection, d, satisfies

$$d = 1/2\nu_{\max}, \tag{10}$$

where $\nu_{\max}$, known as the Nyquist frequency, is the maximum spatial-frequency component of the continuous radioactivity distribution. If the continuous radioactivity distribution sampled at interval d happens to be limited to frequencies less than $\nu_{\max}$, then the distribution is completely determined by its discrete samples. If Eq. (10) is not satisfied, then the frequency (information) content of the radionuclide distribution above $\nu_{\max}$ is erroneously contained in frequencies below $\nu_{\max}$. This effect, referred to as *aliasing*, prevents the radionuclide distribution from being recovered fully and leads to reduced contrast and image artifacts. In practice, the sampling interval is limited by finite detector width, and the frequency spectrum is examined to determine whether aliasing effects are minimized (i.e., the Fourier transform approaches zero as the frequency approaches $\nu_{\max}$). With circular arrays of coincidence detectors, the number of view angles, w, is equal to the number of detectors over an arc of 180° around the object:

$$w = \frac{n}{2} = \frac{2\pi r}{2d} = \frac{\pi D_{\text{ring}}}{2d}, \tag{11}$$

where n is the total number of detectors in the ring, r is the gantry radius equal to $\frac{1}{2}$ of the ring diameter D_{ring}, and d, again, is the linear sampling distance. The angular sampling interval should be equal to the linear sampling about the periphery of an object located within the FOV diameter, D_{FOV}, having the same requirements of the linear sampling interval. These sampling requirements are both met when D_{FOV} is equal to $D_{\text{ring}}/2$.

The size of the detectors and the scanner geometry thus determine the sampling of the radioactivity distribution. The effects of insufficient transverse sampling in PET systems are a suppression of high-frequency information (reduction of spatial resolution) and aliasing. Another major problem with stationary PET systems employing a circular array of detectors is the fact that transverse sampling is irregular, producing spatially variant resolution. This is the reason why spatial resolution is usually measured both tangentially and radially, and at different radial positions, as described above.

The axial sampling or interplane spacing between rings is also important for multiple-ring systems. Since two rings sample the interplane space, the sensitivity is better; however, the interplane axial response function varies to a greater degree in comparison with in-plane resolution (see Fig. 10).

2.5 Sensitivity

Because of the multiple sampling paths for each detector, the sensitivity of a PET system is greatly increased in comparison with single sampling path systems like SPECT (single-photon emission computed tomography, which is based on the Anger camera; see above). Sensitivity is the counting rate (c/s) produced per unit radioactivity concentration ($\mu\text{Ci}\cdot\text{mL}^{-1}$) for a given distribution. Sensitivity is expressed as the counting rate of a ring or plane for an activity concentration of a pure positron emitter uniformly distributed in a 20-cm-diameter phantom. The sensitivity of a ring PET system is dependent on the *geometric* efficiency of the system and the *intrinsic* efficiency of the detector crystals.

The total geometric efficiency for a circumferential array is the sum of individual detector geometric efficiencies g given by

$$g = S/4\pi r^2, \tag{12}$$

where S is the surface area of the detector face and r is the ring diameter. Since g decreases according to $1/r^2$ and the total number of detectors increases in proportion to r, the total geometric efficiency and therefore the total coincidence counting rate decrease in proportion to $1/r$ for a source located at the ring's center.

Geometric efficiency is thus defined as the fraction of photons emitted by a source that actually strike detectors. The *intrinsic efficiency* of the detectors, primarily determined by the detector material and size, is defined as the fraction of photons striking the detector that deposit energy above the threshold of acceptance for the detectors.

2.6 Coincidence Events

When a photon deposits its energy in a detector, an electronic pulse is produced whose amplitude is proportional to the energy deposited. Most PET scanners employ two discriminators for energy verification. The first is the timing discriminator, which prevents noise pulses and very low-energy events from triggering timing event pulses. Once the pulse amplitude exceeds a low-energy threshold, a timing event is generated corresponding to the instant the detector was hit by a photon. The timing pulse is delayed pending verification of the initial pulse by a second energy discriminator set for the lowest and highest acceptable photon energies. This timing pulse has a finite width τ, called the *coincidence resolving time.* Timing pulses from opposing detectors that overlap within ± τ of each other are considered in coincidence. A *coincidence event* is thus defined as two photons depositing sufficient energy in opposing detectors within the *coincidence timing window* of 2τ (i.e., $\pm\tau$).

The width of the timing pulse is chosen such that most of the signal from photons emitted from the same annihilation event fall within the timing window of the coincidence circuitry for maximum sensitivity. Because of this finite pulse width τ, there is a chance that photons from unrelated annihilation events will accidentally or randomly be detected in coincidence. In addition, energy discriminators form a window that the photon energy deposited in the detector must fall within. The lower setting is used to discriminate against the detection of scattered photons; however, for 511-keV photons, scatter is in the forward direction, imparting little energy to recoil electrons, resulting in photon energies at or near 511 keV. The upper setting is used to discriminate against additional energy deposited by multiple photons striking the detector at the same time (*multiple coincidences*). Thus, for a detector pair the total coincidence counting rate, R_{total}, is given by

$$R_{\text{total}} = R_{\text{true}} + R_{\text{scatter}} + R_{\text{random}}, \qquad (13)$$

where R_{true}, R_{scatter}, and R_{random} are the true, scatter, and random counting rates, respectively. Figure 11 graphically depicts the events producing these counting rates in a coincidence-detector pair.

2.6.1 True Coincidence Events True coincidence events occur when two unscattered photons from the same annihilation event are detected in coincidence in opposing detectors. The true coincidence counting rate R_{true} is given by

$$R_{\text{true}} = E\epsilon_1\epsilon_2 g e^{-\mu l}, \qquad (14)$$

where E is the annihilation-photon pair emission rate, ϵ_1 and ϵ_2 are the intrinsic efficiencies of each detector in the coincidence pair, g is the geometric efficiency, μ is the linear attenuation coefficient of the absorbing medium, and l is the length or distance traversed by the annihilation photon pair through the absorbing medium [see Eq. (9)].

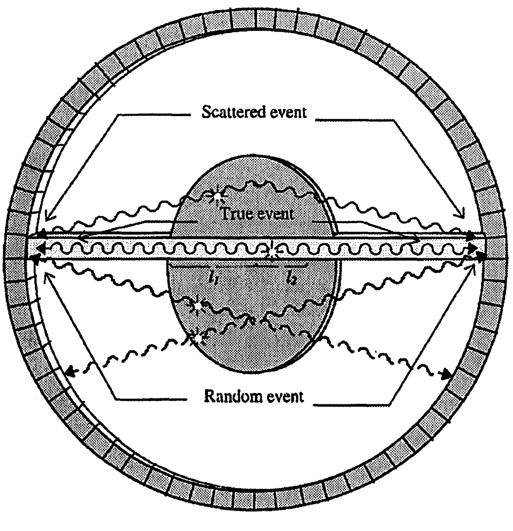

FIG. 11. Coincidence detection of annihilation events. True events occur within the volume defined by the detector pair and electronic collimation. Scatter coincidences involve events occurring outside the sensitive volume in which one or both annihilation photons arrive simultaneously at opposing detectors. Random events occur by chance detection of photons resulting from unrelated annihilation events.

The attenuation of photons reduces the total number of true coincidence events detected.

2.6.2 Random Coincidence Events The random or accidental counting rate R_{random} is given by

$$R_{\text{random}} = 2\tau R_{\text{singles1}} R_{\text{singles2}}, \qquad (15)$$

where R_{singles1} and R_{singles2} are the singles counting rates from detector 1 and detector 2 of the coincidence pair, respectively, and τ is the width of the pulse. The singles counting rate R_{singles} for a source located midway between two coincidence detector pairs is given by

$$R_{\text{singles}} = 2E\epsilon g e^{-\mu l/2}, \qquad (16)$$

where $l/2$ appears in the equation to account for the distance traveled by a single photon in the absorbing material and the factor 2 accounts for each photon produced by each emission in E. Since g enters into Eq. (15) twice, R_{random} decreases as $1/r^4$ for a detector pair. However, the total geometric efficiency decreases as $1/r$ for a circumferential array of detectors, and thus the total random counting rate decreases as $1/r^2$.

2.6.3 Scatter Coincidence Events Compton scattering is the most probable interaction for annihilation photons in human tissue. Scattered coincidence events that occur when one or both photons originating from the same annihilation event scatter and are detected in coincidence result in erroneous positioning of annihilation events. Scatter also results in undetected events for photons scattered out of the sensitive volume between two detectors, thereby reducing (attenuating) the true coincidence counting rate. In addition to scatter in the object, in high-resolution PET employing narrow detectors, photons scatter from one detector into another, resulting in loss of spatial resolution by broadening of the radial PSF as it moves from the center of the FOV outward (Fig. 6) and in the tangential PSF mainly below the FWTM (Fig. 12). Because scatter depends on both the detector and the object geometry, it is impossible to represent scatter by a definite expression. However, the contribution of scatter to total coincidence counting rate for a source located midway between two coincidence detector pairs can be expressed as

$$R_{\text{scatter}} = KE\epsilon^2 g^2, \tag{17}$$

where K is a constant that accounts for the scatter absorption and angular distribution, detector and object geometry, and all other aspects of scatter.

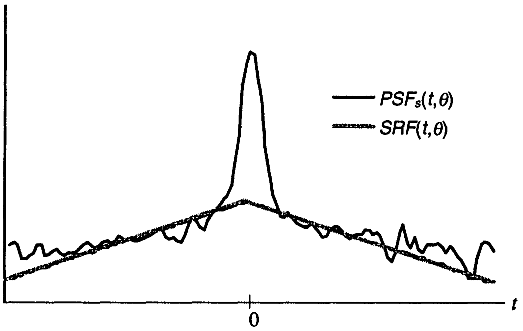

FIG. 12. Point-spread function in a scattering medium.

2.7 Dead Time

Dead time is the time during which the scanner cannot detect a new event because it is processing previous events. Electronic pulses produced by radiation detectors have a finite time duration or width as previously described. If an event occurs during the dead time of a preceding event, two pulses overlap. When this overlap occurs in the detector, the energy-sensitive information of the output pulse is distorted, and the second pulse introduces its own additional dead time. Shifted or overlapped detector pulse amplitudes may fall outside the energy discriminator window, resulting in the loss of both events and extending the dead time to subsequent events (*paralyzable* dead time). Dead time in some components of the electronic circuitry may result in the loss of only the second event by limiting the counting rate to one event per dead-time interval (*nonparalyzable* dead time). In PET, each detector is assigned to coincidence circuitries with many other detectors. The coincidence detection of three or more single events results in the rejection of all events (multiple-coincidence rejection circuitry) even though two of the events may have produced a true coincidence event. Because of dead-time losses, the observed counting rate is less than the true counting rate. Dead-time losses can be minimized by lowering the amount of radioactivity in the FOV or shortening the dead time through a reduction of pulse duration and integration times.

Dead time depends on the distribution of radioactivity in the scanner FOV, the difference between arrival times of the two annihilation photons at opposing detectors, the detector recovery time, the light integration time, the position discriminator circuitry, the energy discriminator circuitry, the coincidence-circuitry resolving time, and the time required to transfer data from the electronic circuitry to the computer.

2.8 Uniformity

A PET scanner consists of a large number of separate detectors with both electronic and other manufactured components. Inherently, the electronic pulses produced by each PMT in a detector block are different, as is the efficiency of each individual detector crystal. The efficiencies of detector pairs are also nonuniform on account of the geometry of the system. In ring-type PET systems, coincidence detector pairs toward the edge of the FOV have significantly smaller *solid angle* of detection (the angle between the axis of the detector and the line defined by the two detectors) than that at the FOV center. Not only does the effective width of the detector become narrower, but the probability of photon penetration into a neighboring detector becomes greater as a result of the reduced effective depth of the detector crystal. The reduction in surface area reduces the geometric efficiency [Eq. (12)], while the increased photon penetration in adjacent detectors results in asymmetry and broadening of the detector PSF. These effects become greater with increasing detector displacement from both the transverse and the axial FOV center. However, for a particular FOV, the magnitude of the nonuniformity decreases with increasing ring diameter. While proper system design and component optimization are effective in reducing nonuniformities, it is still necessary to balance the individual detector efficiency and the overall efficiency of the entire system to avoid serious artifacts and provide the best statistical quality in the images produced.

3. TOMOGRAPHIC RECONSTRUCTION

A tomogram is an image of a cross-sectional slice of an object. The formation, processing, and interpretation of PET images is similar to that found in other scientific disciplines (i.e., radio-astronomy or electron microscopy) and other medical applications [i.e., x-ray computed tomography (CT)]. In these applications, some property of the object is obtained by indirect measurements of radiations reflected from, transmitted through, or emitted by the object. For devices such as PET, these measurements are estimates of line integrals of the radionuclide distribution or the projection of the object's radionuclide distribution onto a particular angular view. These projections are related to the process under study but are often not readily suitable for interpretation. Tomographic image reconstruction of the acquired projection data facilitates the interpretation of the process or property under investigation through the formation of images representing the distribution of radionuclide concentration.

3.1 Radon Transform

The problem described as image reconstruction from projections, defined in this section, will be in the context of a function $f(x,y)$ on a cross-sectional plane through a three-dimensional object. The elements or members of a projection are the summation of all events along a line of response (LOR) between detector pairs called a Radon transform, given by the line integral

$$R(t,\theta) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y) \times \delta(x\cos\theta + y\sin\theta - t)\,dx\,dy, \qquad (18)$$

where δ is the Dirac delta function.

As shown in Fig. 13, a parallel projection is formed by combining a set of line integrals for a constant θ. Similarly, a fan beam projection can be formed from all line integrals meeting at point t.

Thus, the inversion of all Radon transforms will produce an image of $f(x,y)$ (the object distribution).

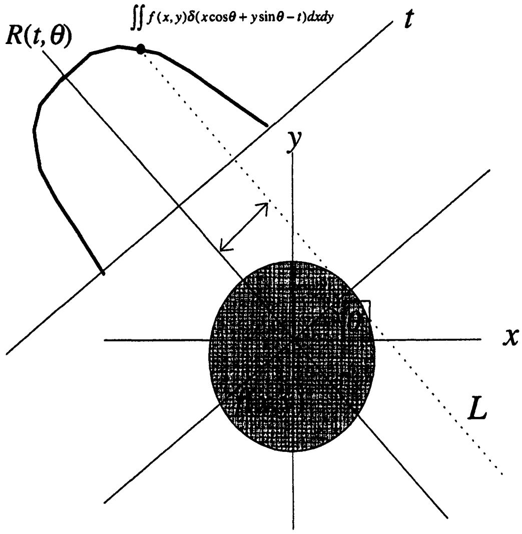

FIG. 13. Parallel projection obtained for object $f(x,y)$ at angle θ is the collection of all line integrals parallel to line $L(t,\theta)$ (i.e., lines having the same θ).

3.2 Fourier Reconstruction

The inversion of the Radon transform can be achieved in many ways. One such method is based on the *projection, Fourier,* or *central slice* theorem, which states that the coefficients of the two-dimensional (2D) Fourier transform of the object along a line through the origin at angle θ are the coefficients of the one-dimensional (1D) Fourier transform of the Radon transform (projection) obtained at angle θ. Mathematically, the theorem is described as follows.

The 2D Fourier transform $F(u,v)$ of the object distribution $f(x,y)$ is

$$F(u,v) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y)e^{-i2\pi(ux+vy)}dxdy, \qquad (19)$$

and the inverse Fourier Transform is given by

$$f(x,y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(u,v)e^{i2\pi(ux+vy)}dudv, \qquad (20)$$

where u and v are dimensions of spatial frequency. If we introduce the polar coordinates

$$x = t\cos\theta,\quad y = t\sin\theta,\quad u = \omega\cos\theta,$$
$$v = \omega\sin\theta, \qquad (21)$$

Eq. (19) becomes

$$\begin{aligned} F(\omega\cos\theta,\omega\sin\theta) &= \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y) \right.\\ &\quad \times \delta(x\cos\theta + y\sin\theta - t)\\ &\quad \left.\times e^{-i2\pi t\omega}dxdy\right]dt\\ &= \int_{-\infty}^{\infty} R(t,\theta)e^{-i2\pi t\omega}dt. \qquad (22)\end{aligned}$$

Thus, by obtaining the 1D Fourier transforms of the Radon transforms, forming parallel projections, interpolating them to appropriate locations to provide a 2D array of Fourier coefficients, and applying the inverse 2D Fourier transform to this coefficient array, an image of the object can be obtained. This method is called *Fourier reconstruction.*

3.3 Filtered Backprojection

Another, more common reconstruction method, called filtered backprojection, is derived from Eq. (20) where polar coordinates are again used, as follows:

$$\begin{aligned} f(x,y) &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(u,v)e^{i2\pi(ux+vy)}dudv,\\ &= \int_{0}^{\pi}\int_{0}^{\infty} |\omega|F(u,v)e^{i2\pi\omega(x\cos\theta+y\sin\theta)}d\omega d\theta,\\ &= \int_{0}^{\pi}\int_{0}^{\infty} |\omega|\left[\int_{-\infty}^{\infty} R(t,\theta)e^{-i2\pi t\omega}dt\right]\\ &\quad \times e^{i2\pi\omega(x\cos\theta+y\sin\theta)}d\omega d\theta, \qquad (23)\end{aligned}$$

where the integration can be thought of as a filtering followed by a backprojection of filtered projections, $R_f(t,\theta)$. Filtering is performed for each projection and is given by

$$R_f(t,\theta) = \int_{0}^{\infty} |\omega|\left[\int_{-\infty}^{\infty} R(\tau,\theta)e^{-i2\pi t\tau}d\tau\right]e^{i2\pi\omega t}d\omega \qquad (24)$$

and is described as the inverse 1D Fourier transform of the Fourier product, $|\omega|$ (known as the ramp filter because it increases 1 to 1 with increasing frequency), and the 1D Fourier transform of the Radon transform at angle θ. The backprojection is also performed at each angle and is given as

$$\begin{aligned} f(x,y) &= \int_{0}^{\pi} R_f(t,\theta)d\theta,\\ &= \int_{0}^{\pi} R_f(x\cos\theta + y\sin\theta,\theta)d\theta,\\ &= \int_{0}^{\pi}\int_{-\infty}^{\infty} R_f(t,\theta)\delta(x\cos\theta + y\sin\theta - t)\\ &\quad \times dtd\theta. \qquad (25)\end{aligned}$$

It is worth noting that the filtering portion of filtered backprojection can be performed equivalently in the spatial domain and that filtering after backprojection is also possible. These two latter techniques, however, are seldom used in practice.

The accuracy of Fourier and filtered backprojection reconstruction methods is affected by bandwidth limiting and interpolation. Bandwidth limiting is imposed because of the discrete sampling of the projections at finite intervals equal to the width of the detectors as discussed above. The main effect of bandwidth limiting is to limit spatial resolution. For PET scanners employing a circumferential array of detectors, interpolation of projections is required for the digital filtering prior to backprojection reconstruction. For Fourier reconstruction, interpolation is required to form the two-dimensional array of Fourier coefficients prior to applying the inverse 2D Fourier transform to obtain an image. It must also be emphasized that for computer implementation of these techniques, integration is replaced by discrete summation in the equations above. The degree of accuracy, with the exception of the loss in high-frequency information imposed by sampling and interpolation, is not further degraded by the use of discrete summation.

There are several problems with the Radon inversion approach. First, the assumptions that the data are noise free and that the detector response is spatially invariant are, obviously, untrue. Second, the resultant images contain negative numbers that, although are mathematically feasible, are not physically possible.

Since PET measurements are based on Poisson counting statistics, a reasonable approach to image reconstruction is to apply a more complete statistical model. Several reconstruction algorithms have been based on this approach. From a historical perspective (of PET), an iterative expectation-maximization (EM) approach is the oldest of these algorithms. Because each iteration requires computation time roughly equal to that of filtered backprojection and hundreds of iterations are often required, EM algorithms have not been widely accepted for routine clinical use. However, practical computation times are now being achieved by accelerating EM algorithms through the introduction of Bayesian "priors" (penalty functions) and noise-reduction techniques to reduce the convergence of the EM algorithm to the maximum-likelihood reconstruction.

3.4 Corrections

One of the main advantages of PET is its ability to provide a quantitative image of the radionuclide distribution in an object or subject. Often these images, in turn, are used for functional parameter estimation. The techniques used to estimate functional parameters are critically dependent upon the quantitative accuracy of the raw data. PET reconstruction techniques assume that each datum point $R(t,\theta)$ is a line integral that represents all activity between two coincidence detectors. Inherent in this assumption is that the spaces between detectors and their respective responses and efficiencies are the same. However, detector sensitivity and resolution are not uniform, and events are lost on account of attenuation and dead time. Random and scatter coincidence events are assigned to erroneous lines of response. All these factors reduce accuracy in PET. Many of these aspects have been addressed through improved system designs, materials, and electronics, but inevitably design tradeoffs lead to compromises in order to reduce costs and maximize detection efficiency and accuracy. Because of these hardware compromises, software correction schemes, incorporated in all PET scanners, are essential for quantitative PET.

3.4.1 Normalization The efficiencies of the many detector pairs in a PET system are nonuniform because of differences in the materials and electronics and the geometry of the system. While it is mechanically possible to adjust or tune the electronic components so that the PMT signals are optimized before they enter the energy discrimination, timing, and positioning circuitry, the individual detector efficiencies remain nonuniform. Normalization is the application of small correction factors to data obtained from individual detector pairs to produce consistent counting rates per unit activity in all detector combinations. These correction factors are produced from a data set obtained with an activity source that has minimum scattering material, low activity to avoid counting-rate effects (i.e., random coincidence events and dead-time losses), and a uniform distribution. The majority of circular PET scanners employ a small-diameter rotating-rod source that over time facilitates the detection of many events in all coincidence-detector pairs. Correction factors that normalize individual detector efficiencies relative to other detectors in the system are calculated and stored. Thereafter, the normalization correction factors are applied to acquired data prior to reconstruction.

Failure to correct for differences and changes in detector performance can result in serious artifacts and reduced statistical quality of images. For these reasons normalization should be performed at least monthly or as needed depending upon the stability of the particular system.

3.4.2 Random-Event Correction If left uncorrected, random or accidental coincidence events produce a diffuse background of activity leading to reduced image contrast. Randoms can be effectively reduced by decreasing the coincidence timing window [Eq. (15)]; however, if the timing window is too short, true coincidence events may be lost. In addition, larger system diameters have higher true-to-random event ratios on the basis of efficiency relationships derived above. Usually, random events are measured indirectly and subtracted from the total acquired coincidence events prior to reconstruction. Random events can be measured by delaying signals produced in one detector of a coincidence pair by several times the coincidence timing window and passing these with the nondelayed signals of the other detector through a second coincidence circuit. The delay introduced cannot produce any true coincidence events, and so the resulting coincidences in this second circuit can only be due to unrelated random events. Random events determined in this manner can easily be subtracted on line. A second method is to measure the singles counting rate of individual detectors, determine the random events using Eq. (15), and subtract them from the true coincidence events off line.

3.4.3 Scatter-Event Correction Scattered coincidence events, like random coincidences, are indistinguishable from true coincidences and result in misplaced events, adding a slowly spatially varying (low spatial frequency) background to an image. Photon scattering occurs within the object, in material surrounding the PET system, and in the detector itself. Unlike random coincidences, there is no technique for measuring scatter events electronically, and system design becomes very important in reducing photon scattering. In PET, scatter is reduced by the use of septa between rings to shield them from scattered photons originating within the object but outside a given ring. Septa are also placed at the ends of the scanner to remove scattered photons originating outside the scanner (e.g., body or walls). For 3D imaging techniques, the septa between rings are retracted, producing an increased detection of scattered coincidences. Within a given ring, photon scattering in detectors at the edge of the FOV (because of the large solid angle) reduces spatial resolution by broadening the FWTM of the PSF and results in a loss of image contrast. Reducing the solid angle, however, reduces the detection of true coincidence events, resulting in poorer sensitivity. Scattered events are also reduced by raising the low-energy discriminator since scattered photons have lower energy than unscattered photons. However, most scattered photons have energy near that of unscattered photons. Since the energy resolution of BGO detectors, employed in most PET scanners, is 50 to 100 keV, raising the energy threshold is inadequate to remove the majority of scattered events. The scatter fraction, the ratio of scattered events to total coincidences, is reduced with increased ring diameter. The degradation of image contrast, resolution, and quantitative accuracy due to scattered photons depends on the distribution of radioactivity, the PET system design and operation, and the scattering media. Since there is no exact method for the correction of scattered events in software, the approach to minimize the effects of scattered photons is initially through system design and then by careful study design and image analysis.

There are several methods for estimating and removing scattered events (Bergstrom *et al.*, 1983; Logan and Bernstein, 1983; Bendiriem *et al.*, 1987; Bentourkia *et al.*, 1995). The majority of these do not fully correct for the spatial dependences of scattered photons (subtle, high-frequency errors) but are effective in reducing the majority of large (gross, low-frequency) errors. Based on Eq. (13), the observed projection data $P(t,\theta)$ is the sum of true, scattered, and random events. After random events are removed, $P(t,\theta)$ is described as

$$P(t,\theta) = E(t,\theta) + S(t,\theta), \tag{26}$$

where $E(t,\theta)$ and $S(t,\theta)$ are respectively the contributions of true and scattered events. Scattered events, $S(t,\theta)$, are most often modeled as a convolution of $E(t,\theta)$ with a scatter response function $\mathrm{SRF}(t,\theta)$:

$$S(t,\theta) = E(t,\theta)^{*}\mathrm{SRF}(t,\theta), \tag{27}$$

where the asterisk denotes convolution. Substituting Eq. (27) into Eq. (26) gives

$$\begin{aligned} P(t,\theta) &= E(t,\theta) + E(t,\theta)*\mathrm{SRF}(t,\theta), \\ &= E(t,\theta)*[\delta(t,\theta) + \mathrm{SRF}(t,\theta)], \end{aligned} \tag{28}$$

where $\delta(t,\theta)$ is the Dirac delta function. Substituting Eq. (28) into Eq. (27) and rearranging; we obtain

$$E(t,\theta) = P(t,\theta) - E(t,\theta)*\mathrm{SRF}(t,\theta). \tag{29}$$

This convolution-subtraction approach requires knowledge of $E(t,\theta)$, which obviously is that which we desire to know. It has been demonstrated (Bergstrom *et al.*, 1983) that Eq. (29) can be written as

$$E(t,\theta) = P(t,\theta) - P(t,\theta)*\mathrm{SRF}'(t,\theta), \tag{30}$$

where $\mathrm{SRF}'(t,\theta)$ is determined experimentally for a specific object producing $P(t,\theta)$. The standard approach is to estimate the $\mathrm{SRF}'(t,\theta)$ of the system from a line or point source placed at different locations in a scattering medium, typically a 20-cm cylindrical phantom. Since $E(t,\theta)$ for complex objects is considered to be the superpositioning of scaled system-response or point-spread functions $\mathrm{PSF}(t,\theta)$, a projection obtained for a point source in a scattering medium, $\mathrm{PSF}_s(t,\theta)$, can be used to estimate $\mathrm{SRF}'(t,\theta)$ by fitting $\mathrm{SRF}'(t,\theta)$ expressed as two monoexponential functions to data on both sides of the $\mathrm{PSF}_s(t,\theta)$ peak extrapolated to intersect inside the peak at the peak position, as shown in Fig. 12.

The standard approach is to apply Eq. (30) to determine $E(t,\theta)$. Another, less common, approach to correct $P(t,\theta)$ is by the repositioning or deconvolution of scattered events. On replacing $\delta(t,\theta)$ with the system $\mathrm{PSF}(t,\theta)$ obtained in air (without scatter), Eq. (28) becomes

$$P(t,\theta) = E(t,\theta)*\mathrm{PSF}_s(t,\theta), \tag{31}$$

where $\mathrm{PSF}_s(t,\theta)$ is the point-spread function obtained in a scattering medium. Using Fourier transforms (FTs) and the convolution theorem, and solving for $E(t,\theta)$, we have

$$E(t,\theta) = \mathrm{FT}^{-1}\left[\frac{\mathrm{FT}[P(t,\theta)]}{\mathrm{FT}[\mathrm{PSF}_s(t,\theta)]}\right]. \tag{32}$$

The accuracy of scatter correction methods are measured by scanning a 20-cm-diameter cylindrical phantom containing a uniform water distribution of radioactivity, *hot,* in which a second cylinder containing only water, *cold,* is offset from the center. Measurements of radioactivity are obtained for the hot and cold regions of an image reconstructed with all corrections. The percent scatter fraction (%SF) determined as

$$\%\mathrm{SF} = 100 \times \frac{\mathrm{cold}}{\mathrm{hot}} \tag{33}$$

should be 0% for scatter correction to be considered to have removed the majority of scattered events. Other measurements such as the FWHM, FWTM, and the full width at hundredth maximum of the $\mathrm{PSF}_s(t,\theta)$ and measurements of other more complex phantoms can help determine the effectiveness of the scatter correction with respect to the spatial variation of scatter. Scatter correction is usually performed after normalization and random subtraction and must be performed prior to attenuation correction and image reconstruction.

3.4.4 Attenuation Correction One of the attractive features of PET is that the attenuation of annihilation photons is independent of position between coincidence detectors [Eq. (9)]. If the attenuating tissue is homogenous, the detected annihilation photon intensity for true coincidences, $E(t,\theta)$, is given as

$$E(t,\theta) = A(t,\theta)e^{-\mu l}, \tag{34}$$

where $A(t,\theta)$ is the annihilation photon activity emitted in the direction of the coincidence detectors or the line integral along $L(t,\theta)$ in the Radon domain (see Fig. 13),

$$\begin{aligned} A(t,\theta) = T\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} A(x,y) \\ \times\ \delta(x\cos\theta + y\sin\theta - t)dxdy \end{aligned} \tag{35}$$

for the spatial distribution of positron radioactivity, $A(x,y)$, sampled over time T. The attenuation correction of $E(t,\theta)$ is achieved by solving Eq. (34) for $A(t,\theta)$:

$$A(t,\theta) = E(t,\theta)e^{\mu l}. \tag{36}$$

The attenuation correction factor, $\mathrm{ACF}(t,\theta)$, is

$$\mathrm{ACF}(t,\theta) = e^{-\mu l}, \tag{37}$$

where l is the total length or distance traveled by both photons through the attenuating media having linear attenuation coefficient μ. The assumption of homogenous tissue and, therefore, constant μ is reasonably valid for areas such as the brain and lower abdomen that have relatively constant attenuation coefficients. The $\mathrm{ACF}(t,\theta)$ given in Eq. (37) can be calculated by obtaining the path length l from the intersection of $L(t,\theta)$ and the perimeter of $A(x,y)$ provided the shape of $A(x,y)$ is known. The shape of $A(x,y)$ can be determined as a geometric (ellipse) or irregular shape fitted around the cross-sectional contour of an emission image of the body.

For areas of inhomogenous tissue distributions (i.e., areas containing significant amounts of air and bone), a significant error in quantifying attenuation can occur and the $\mathrm{ACF}(t,\theta)$ must be determined from the distribution of attenuation coefficients $\mu(t,\theta)$ along $L(t,\theta)$ as

$$\mathrm{ACF}(t,\theta) = \exp\left[\int_{L(t,\theta)} \mu(t,\theta)dl\right]. \tag{38}$$

Although accurately described, the above calculation of the $\mathrm{ACF}(t,\theta)$ is difficult to perform accurately because the varying tissue shape, type, and thickness are usually crudely approximated on the basis of a single additional measurement. A more accurate attenuation correction can, however, be obtained from two additional measurements. Because of the independence of source position along $L(t,\theta)$ in PET (i.e., between two coincidence detectors), a positron source external to the body that transmits annihilation photons through the body has the same probability of attenuation as an internal source that emits annihilation photons. So, without any attenuation material in the FOV, and neglecting the absorption of photons in air, an annihilation-photon source rotated around the PET FOV that transmits an intensity $I_0(t,\theta)$ along any projection $L(t,\theta)$ produces a blank scan $B(t,\theta)$ given as

$$B(t,\theta) = I_0(t,\theta). \tag{39}$$

When an attenuating object is placed in the FOV, a transmission scan $T(t,\theta)$ of the object results with the following relationship:

$$T(t,\theta) = I_0(t,\theta)\exp\left[-\int_{L(t,\theta)} \mu(t,\theta)dl\right]. \tag{40}$$

The attenuation correction factor, $\mathrm{ACF}(t,\theta)$, is easily determined by the division of Eq. (39) by Eq. (40):

$$\begin{aligned}\mathrm{ACF}(t,\theta) &= \frac{B(t,\theta)}{T(t,\theta)} = \frac{I_0(t,\theta)}{I_0(t,\theta)\exp\left[-\int_{L(t,\theta)} \mu(t,\theta)dl\right]}\\ &= \exp\left[\int_{L(t,\theta)} \mu(t,\theta)dl\right]\end{aligned} \tag{41}$$

on the assumption that both blank and transmission scans were obtained for the same duration, using the same positron source intensity $I_0(t,\theta)$.

Attenuation correction factors in PET can thus be obtained by either direct measurement, calculated approximations, or a combination of calculated and measured methods. As described by Eq. (36), the attenuation correction is performed prior to reconstruction in the projection space or Radon domain.

3.4.5 Dead-Time Correction In PET, contributions to system dead time vary with counting rate and source distribution. In PET systems employing block detectors, individual detector dead-time losses due to pulse pileup, detector recovery time, energy discrimination, and position encoding are affected by the singles counting rate of the entire block. In addition to the singles dead time, there are losses due to the overlap of pulses in the coincidence circuitry. Because of the complexity of various designs, the spatially varying radionuclide distributions of different objects, and the different types of studies (i.e., blank, transmission, and emission), each PET scanner configuration requires its own individual dead-time correction scheme.

Average dead-time loss as a function of counting rate for a particular configuration can be determined by obtaining a series of measurements of the particular radionuclide distribution. Using the physical half-life of the radionuclide, the true higher counting rates can be calculated from low-counting-rate measurements that fall with the half-life. The difference between the calculated and the measured counting rates is an estimate of the dead-time losses.

The accuracy of the dead-time correction is often determined by obtaining a series of measurements for a particular radionuclide distribution as a function of time. Typically a cylindrical phantom, uniformly filled with a known concentration of a short-lived radioisotope, is scanned repeatedly over several half-lives until dead time is negligible. To determine the range for which the dead-time correction can be considered adequate, dead-time corrected measurements are compared with expected measurements obtained by using the known radionuclide concentration and the physical half-life of the radioisotope. The highest dead-time corrected measurement of radionuclide concentration that is within ±5% of the true radionuclide concentration in a cylindrical phantom and the counting rate at which dead-time losses reach 50% are often used as a measure of PET system performance. However, the radionuclide distribution in a cylindrical phantom may not represent that found in an *in vivo* PET study, and more realistic configurations should be used to assess the accuracy of the dead-time corrections. Nevertheless, these performance parameters are useful in judging the effect of dead time on arbitrary radionuclide distributions and are important when determining the amount of radioactivity that can be administered in studies in which the activity in the scanner FOV is expected to be high.

3.4.6 Calibration In PET, local concentration of positron emitter is the quantity measured. Since only a fraction of the radiation emitted is detected, calibration of the efficiency of the PET system is required to produce measurements in standard terms of radioactivity concentration (e.g., $\text{nCi}\cdot\text{mL}^{-1}$ or $\text{Bq}\cdot\text{mL}^{-1}$). Calibration requires a PET measurement of a known concentration of positron emitter that closely matches the radionuclide distribution normally scanned. For brain studies, a 20-cm-diameter cylindrical phantom can be used. The phantom is filled uniformly with a concentration of radioactivity that is determined independently of the PET system with a calibrated radiation detector such as a well counter or dose calibrator. Since reconstructed image pixel values are based on detected coincidence counts over an interval of time, the efficiency is given in units of activity concentration [i.e., PET $\text{counts}\cdot\text{s}^{-1}\cdot\text{pixel}^{-1}\cdot(\text{nCi}\cdot\text{mL}^{-1})^{-1}$]. The calibration factors are used to scale image pixel value to units of radioactivity concentration.

4. IMAGE CHARACTERIZATION

Positron-emission tomography provides a quantitative representation of the distribution of a radiopharmaceutical in the form of a digital image. Each image element or *pixel* value is an estimate of the radionuclide concentration found in the corresponding location in the object. In PET, information can be obtained through the subjective and nonquantitative visual examination of images, as in other medical-imaging modalities, and also through the absolute quantification of region-of-interest (ROI) measurements of local radionuclide concentration. In order to characterize the capability of a PET image to depict true measures of radionuclide concentration, we must have estimates of precision and accuracy (Budinger *et al.*, 1984; Hoffman *et al.*, 1984).

For simplicity and ease of illustration, the examples following will be depicted in one dimension, while the mathematical equations will be presented in two dimensions.

4.1 Accuracy

In PET, *accuracy* is a measure of the difference between the image and the true radionuclide distribution it estimates. Since in *in vivo* experiments the truth is unknown, accuracy is difficult to measure and thus must be determined with images of test objects for which the radionuclide distribution is known independent of the PET scanner. It is important that phantoms (test objects) used to evaluate accuracy are similar to the distributions seen in *in vivo* imaging. It is well known that radionuclide concentration measurements obtained for objects whose dimension (in any direction) is less than twice the spatial resolution of the PET scanner are dependent on the object's size and position in the PET scanner.

The primary sources of inaccuracy in PET are spatial resolution and partial-volume effects. The quantitative accuracy is determined by the spatial resolution in that a system with high resolution will more accurately place events into their position of true origin, while a system with low resolution will spread events outside their point of origin. Other sources of inaccuracy include photon attenuation, random and scatter coincidence events, dead time, and system calibration. The most common measure of accuracy in PET is the recovery coefficient RC, given as

$$\mathrm{RC} = \frac{\text{Measured}}{\text{True}}, \tag{42}$$

where Measured is the image measurement (usually the maximum ROI pixel value) and True is the actual radionuclide concentration of a radioactive object (Hoffman *et al.*, 1979). RC is usually reported as a function of object diameter and FOV position for the maximum pixel obtained from an image of a radioactive (hot) spheres in a nonradioactive background and is often referred to as the hot-spot recovery coefficient, HSRC. For objects such as radioactive (hot) spheres in a background of activity, a contrast recovery coefficient CRC, defined as

$$\mathrm{CRC} = \frac{\text{Measured} - \text{Background}}{\text{True} - \text{Background}}, \tag{43}$$

is used where Measured and True are the same as given above and Background is the activity concentration surrounding the hot object (Kessler *et al.*, 1984). For nonradioactive (cold) objects in a background of activity, a cold-spot recovery coefficient CSRC, defined as

$$\mathrm{CSRC} = \frac{\text{Minimum}}{\text{Background}}, \tag{44}$$

is used, where Minimum is the smallest pixel value obtained from an image of the cold spot.

The RCs calculated above use the minimum and maximum values from a single pixel in a given region of a cold and hot object, respectively. In routine ROI analysis, the average value obtained within the ROI is used to reduce the effect of image noise on a measurement. However, because of the partial-volume effects of spatial resolution and the size of the object, too large a ROI can result in loss of recovery by reducing the measured pixel value [i.e., Measured in the numerator of Eq. (42)]. The distance by which an object is displaced from the axial center of a transverse plane also has the effect of reducing recovery.

4.2 Precision

Precision is the ability to reproduce a measurement. The precision of a PET image is affected primarily by the statistical (Poisson) variations inherent in nuclear decay and instrumentational variations in the detection of photons. These statistical variations are propagated through the image reconstruction process and can be amplified by the reconstruction filter. Ideally, the precision or random error in reconstructed images could be obtained from the variance of repeated measurements of the same test object. In practice, obtaining measurement replicas that differ only by random noise is difficult because of nuclear decay where the variation in a given measurements increases with decreasing radioactivity. Thus, precision measurements are often obtained from a single ROI (local) measurement of test object (Alpert *et al.*, 1982) as the percentage coefficient-of-variation, %CV, defined as

$$\%\mathrm{CV} = (100\%)\sigma/\mu, \tag{45}$$

where σ and μ are the standard deviation and mean radionuclide ROI concentration.

5. IMAGE QUALITY

The usefulness of PET images for diagnostic interpretation and quantitative assessment is limited primarily by finite spatial resolution and statistical noise. Improvements in instrumentation and radiopharmaceuticals have led to improvements in image quality. Image quality is difficult to define because it is highly subjective and heavily dependent on the given application. The physical factors that affect an image can serve as an objective basis for evaluating and maintaining the control of image quality.

Contrast, resolution, and *noise* describe physical aspects of an image that are not independent of one another in that improvement in one may cause serious deterioration in the other.

In PET, tomographic reconstruction preserves high object contrast within the limitations of spatial resolution governed by the detector and the reconstruction filter, photon scattering, and attenuation. Although quantitative accuracy is very important for the extraction of functional information from a PET image, much of the diagnostic information is obtained from the visual detection of physiological abnormalities. The ability to identify small changes in the patterns of radionuclide distribution reliably depends also upon the statistical noise (error) inherent in the image data.

5.1 Contrast

Contrast is the difference in image intensity between areas in the object having different radionuclide concentrations. In general, an important part of PET imaging is designing radiopharmaceuticals to have the highest uptake in a specific target structure of an object. Proper radiopharmaceutical design is crucial for maximizing object contrast and is beyond the scope of this text. Instead, we will discuss the physical and instrumentation aspects of image contrast. Image contrast C is defined as

$$C = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}, \qquad (46)$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities (radionuclide concentrations) in adjacent areas of an object. C ranges between 0 (no contrast) and 1 (maximum contrast). Image contrast is affected by the presence of background radioactivity, as shown in Fig. 14. In the presence of a constant background intensity I_b, Eq. (46) can be rewritten as

$$\begin{aligned} C &= \frac{(I_{\max} + I_b) - (I_{\min} + I_b)}{(I_{\max} + I_b) + (I_{\min} + I_b)}, \\ &= \frac{I_{\max} - I_{\min}}{(I_{\max} + I_{\min}) + 2I_b}, \end{aligned} \qquad (47)$$

where the maximum contrast (i.e., $I_{\min} = 0$) is decreased by the presence of $2I_b$ in the denominator.

In PET, scatter and random coincidences have the effect of adding an almost constant background if not corrected, substantially reducing image contrast and affecting image accuracy, as demonstrated in Fig. 14.

5.2 Resolution

Image resolution is the degree of discernible detail in an image. Image resolution, which depends on the sampling of the object (i.e., detector size and geometry), is also affected by the cutoff frequency of the reconstruction filter, the dimensions of the image pixels, and object motion. As mentioned in Sec. 2.3, the most common measure of spatial resolution is the FWHM of the PSF obtained from an image acquired with the best possible sampling and reconstructed with a

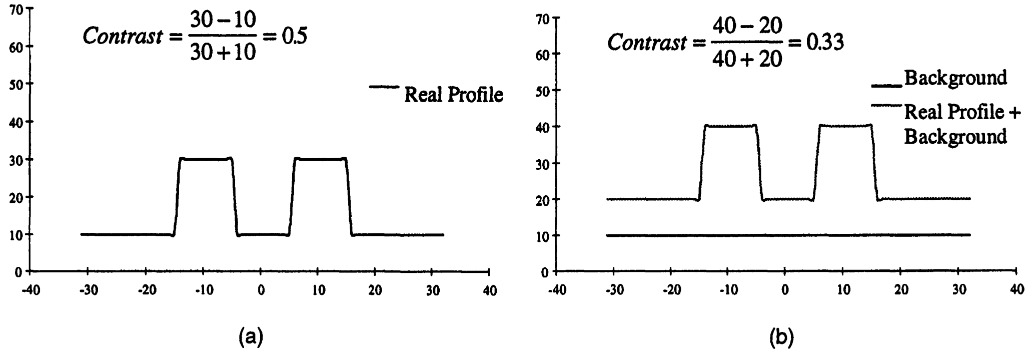

FIG. 14. The effect of adding a constant background on contrast.

filter with the highest cutoff frequency into an image display matrix having the finest element dimension.

Another, more detailed measure of resolution is the modulation transfer function (MTF), or the frequency response of the PET system. The MTF, obtained as the Fourier transform of the PSF (Fig. 15), quantitatively describes how well coarse or gradually varying changes and fine detail including small object recovery and edges of the object are reproduced in an image. An MTF value of unity indicates that a spatial frequency component of an object is accurately represented in the image.

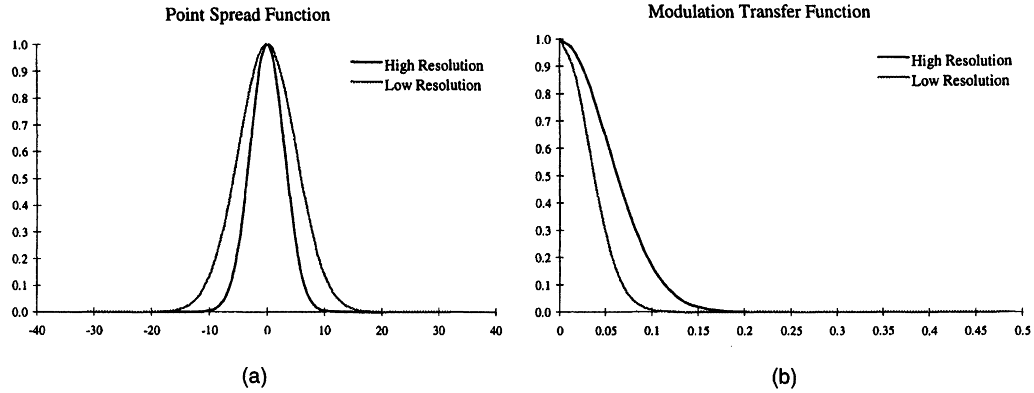
Figure 15 demonstrates that both high- and low-resolution MTFs have values near unity at low spatial frequencies and roll off to zero at higher frequencies. The higher-resolution MTF decreases to zero much more slowly, showing that fine detail is preserved to a greater extent than in a system with a lower-resolution MTF. MTF values near zero indicate that the corresponding frequency in the image is more likely to be composed of statistical variation (noise) than true signal.

Illustrated in Fig. 16 is the reduction in image contrast and edge sharpness due to the smearing of data from one region into an adjacent region in the image. This effect of finite spatial resolution on image contrast is characteristic of all PET scanners and is equivalent to a convolution of the object distribution with a smoothing function (i.e., the PSF). However, PET systems with high MTF values that extend to higher spatial frequencies produce images with higher contrast and sharper detail than systems having lower MTF values.

5.3 Statistical Noise

In PET, noise is the statistical error in an image that is related to the number of coincidence events detected. For individual pixel values in tomographic images, noise is not just a simple matter of counting statistics, as described in Sec. 5.4. For now, we recognize that the smoothness of an image is determined by the number of true coincidence events detected. In the previous sections, we demonstrated that image contrast is a function of both object contrast and spatial resolution in statistically smooth images (i.e., object contrast is reduced by the modulation transfer function and the reconstruction filter). In this section, we demonstrate that the number of detected events required to preserve object contrast is reduced with improved resolution.

The low counts in the profiles of Fig. 17 were obtained by superimposing random, count-dependent noise on the profile plots of Fig. 16, and the higher-count profiles were obtained by scaling the low-count plots of Fig. 16. The calculation of random noise is the same. The high and low levels of noise correspond to fewer and greater number of



(a) (b)

FIG. 15. (a) PSFs and their (b) corresponding MTFs. A poorer-resolution system will spread or blur acquired events to a greater degree than a high-resolution system. The FWHM of the PSF is a measure of this spread. MTF values quantitate how well a spatial frequency is reproduced in an image. Note that the highest frequency that can be preserved in a PET scan is 1/(2 × sampling distance), and the highest frequency that can be represented by an image is 1/(2 × pixel dimension) or 0.5 cycle per pixel.

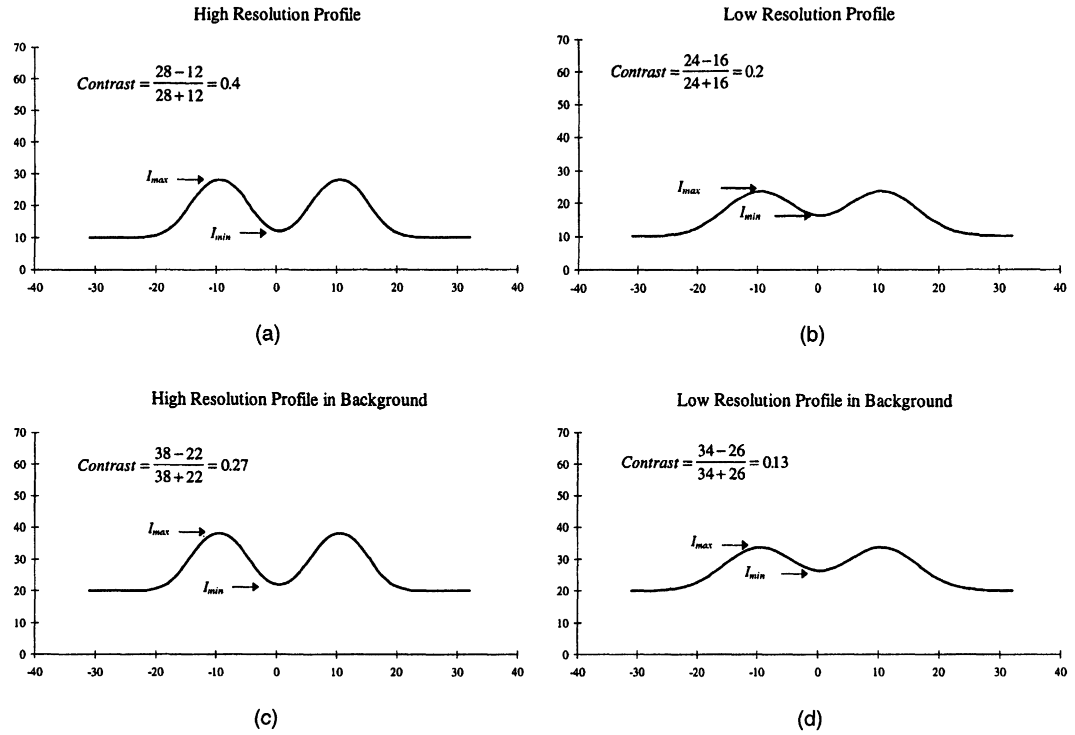


FIG. 16. Effect of reduced spatial resolution on contrast (a), (b) in an object and (c), (d) for the same object in background.

total counts, respectively. For profiles that have higher counts (lower noise) and higher spatial resolution, Figs. 17(a) and 17(b), contrast is preserved. For high counts and low spatial resolution, Figs. 17(c) and 17(d), contrast, as expected, is reduced primarily by spatial resolution. By virtue of higher spatial resolution, the activity is more correctly placed in Figs. 17(e) and 17(f), and contrast is better preserved, in comparison to Figs. 17(g) and 17(h), where contrast is virtually nonexistent because of high noise and low resolution.

Statistical noise is related to the number of coincidence events acquired, which is determined by the activity of the object, the sensitivity of the PET system, and the measurement (acquisition) time.

We have addressed the role of resolution, noise, and contrast and their effects on image quality through computer simulations in this and previous sections. We now introduce as an objective measure of image quality the root mean square error e_{rms}, which is given by

$$e_{\mathrm{rms}} = \left[\frac{1}{M}\sum_{i=0}^{M-1}[I_i - O_i]^2\right]^{1/2}, \tag{48}$$

where M is the number of image measurements (pixels), I is the observed image radionuclide distribution degraded by spatial resolution and noise, and O is the actual object radionuclide distribution. A related objective criterion is the root mean square signal-to-noise ratio ($\mathrm{S/N_{rms}}$) of the image data, which is given by

$$\mathrm{S/N_{rms}} = \left(\sum_{i=0}^{M-1} I_i^2\right)\left(\sum_{i=0}^{M-1}[I_i - O_i]^2\right)^{-1}, \tag{49}$$

where I and O are the image and object distributions, respectively. Table 3 illustrates the significance of the loss of quantitative measures of image quality due to degradation effects of resolution, statistical noise, and background. e_{rms} and $\mathrm{S/N_{rms}}$ are measures of global or overall statistical precision and accuracy, respectively, and contrast is a measure of local image quality.

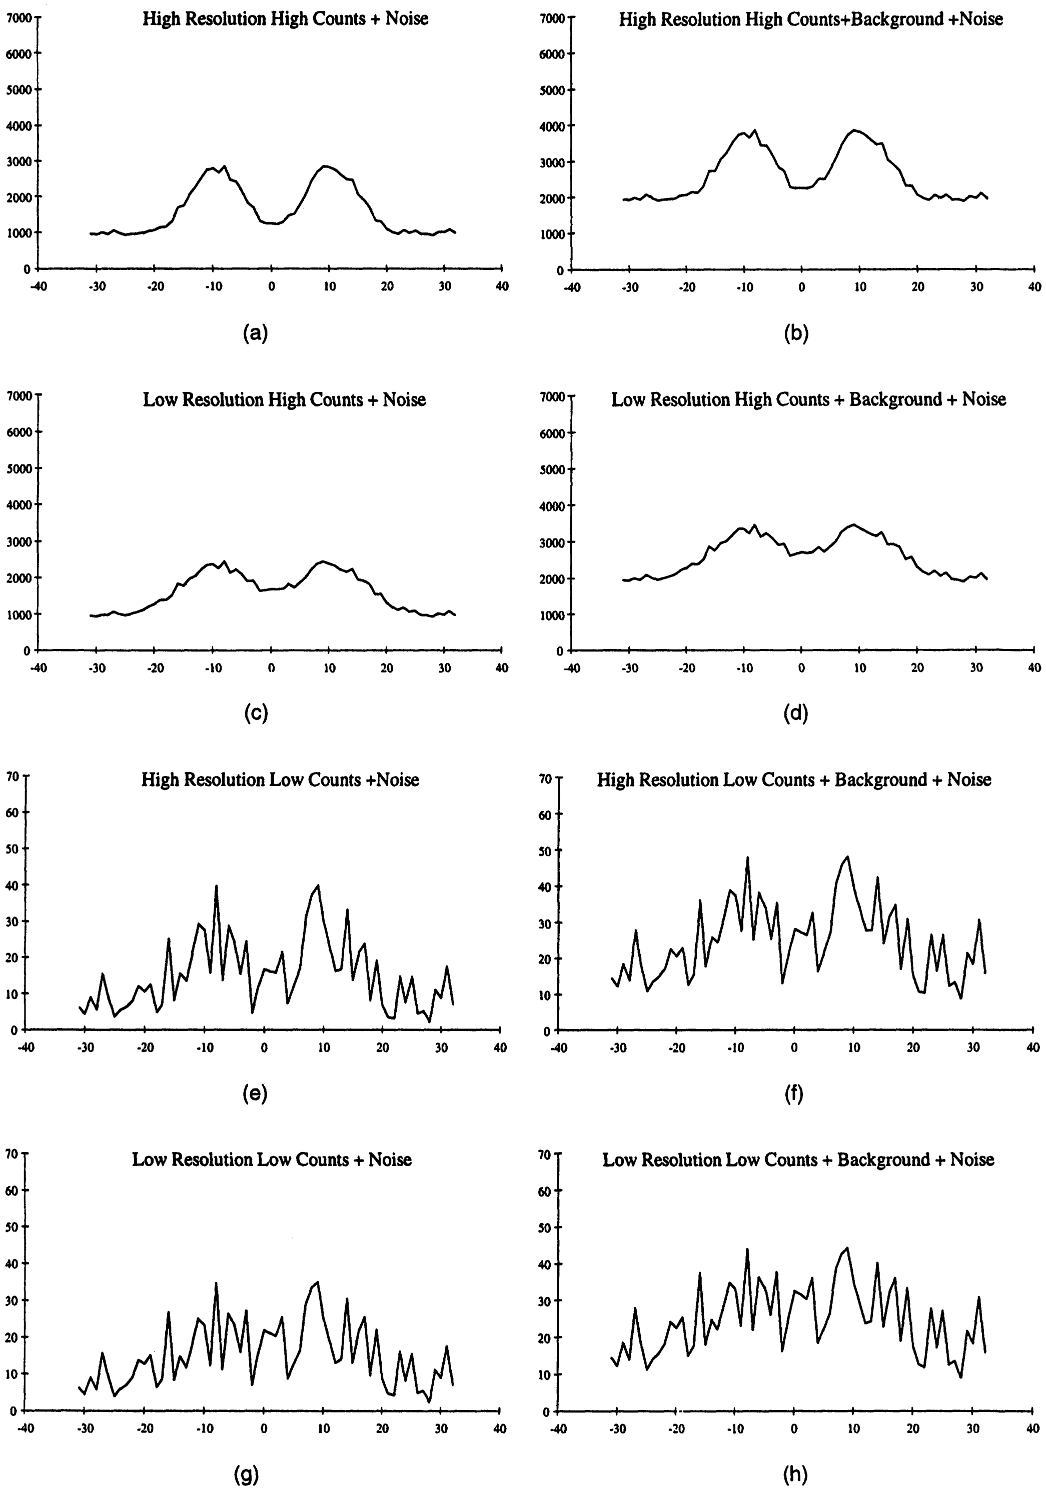

FIG. 17. The combined effects of statistical noise, background, and spatial resolution on an object profile.

Table 3. Measured parameters of objective image quality for the computer simulations given in Figs. 14, 16, and 17. Contrast measure C_0 is obtained from noise-free simulations (Figs. 14 and 16) for the given resolution and background.

5.4 Signal-to-Noise Ratio in PET

The signal, in PET, is the detected true coincidence events that form an image, and the noise is anything that deviates from the signal (i.e., random and scatter coincidences and statistical variation associated with the detection of photons arising from nuclear decay). From Eqs. (14)–(17), we know that the geometric and intrinsic efficiencies of the detectors determine the number of true coincidence events and the contribution to total coincidences by random and scatter coincidence events. On the basis of these equations, the improvements in total geometric efficiency can be achieved by reducing the system diameter and increasing the number of lines of response (2D vs 3D) by removing septa. However, either of these considerations has the effect of increasing randoms and scatter to a greater extent than trues; thus, the ratio of trues to random plus scatter is increased. To this extent the noise-equivalent counting rate,

$$\mathrm{NEC} = \frac{R_{\mathrm{true}}}{1 + R_{\mathrm{scatter}}/R_{\mathrm{true}} + R_{\mathrm{random}}/R_{\mathrm{true}}}, \tag{50}$$

which defines the effective true coincidence counting rate by taking into account random and scatter coincidences, can be used to assess the image quality. This measurement is not sensitive to local image variations and is only considered a global measurement, which is usually obtained for a uniform cylinder at different levels of activity.

When employing a uniform cylinder to study the signal-to-noise ratio, S/N can be expressed as

$$\mathrm{S/N} = N^{1/2}/1.2n^{3/4}, \tag{51}$$

where N is the number of counts in the image and n is the number of resolution cells (pixels) in the image containing activity (Budinger *et al.*, 1978). For the case of the uniform phantom, use of the above expression masks the effect of resolution on S/N since there is little high-frequency structure in the object. In fact, using Eq. (51) to study S/N leads (incorrectly) to the conclusion that a twofold increase in spatial resolution requires an eightfold increase in the total number of image counts to realize the same S/N when structured objects are considered (Muehllehner *et al.*, 1985; Hoffman and Phelps, 1986). As demonstrated in Table 3, when total noise e_{rms} is unchanged, improved resolution increases image contrast (local signal) and higher resolution also provides improved contrast and $\mathrm{S/N_{rms}}$, when fewer counts are present. Thus, the conclusions that apply to a large uniform distribution do not necessarily apply to structured objects. A general relationship for S/N that incorporates object contrast as a measure of signal and thereby accounts for the spatial resolution of the imaging device and uses the fact that total image noise is proportional to $N^{1/2}$ [Eq. (51)] and independent of imaging device (Muehllehner *et al.*, 1985) is given by

$$\mathrm{S/N} \propto C_0 N^{1/2}, \tag{52}$$

where N again is the total image counts and C_0 is contrast as given in Eq. (46) in the absence of noise. S/N, thus derived, is given in Table 3.

With respect to tomographic imaging and conventional filtered backprojection reconstruction, we summarize the relationship between signal, noise, S/N, resolution, and contrast as follows: In tomographic image reconstruction, true coincidence events measured through many pixels are superimposed onto a single image pixel by the reconstruction process. In the absence of noise, the signal contributed to a particular pixel's value from all other pixels is eliminated by means of the ramp reconstruction filter. However, statistical errors in detected coincidence events, instrumentational errors, and the extensive data processing involved in the corrections for scatter, randoms, and attenuation in projections are often amplified by the ramp filter and are propagated to the pixels of the resultant image during reconstruction. A complete derivation of the noise contribution of each coincidence measurement is well beyond the scope of this text, and the interested reader is referred to the suggested readings. The number of true coincidence events acquired (signal) and therefore the resultant image statistical (Poisson) noise are directly related to the system's detection efficiency. The spatial resolution and, therefore, the local signal are related to the width and the sampling distances of the system's detectors. The local signal is also determined by the object's contrast and its position in the detector system.

Improvements in image noise thus translate into a requirement for higher-sensitivity PET scanners. However, through the use of smaller-diameter systems, larger detectors, or the retraction of septa, sensitivity is increased, but only at the expense of reduced spatial resolution. In addition to increasing the total number of true coincidences, these design changes also increase the number of scatter and random coincidence events (background) and further degrade spatial resolution and resolution uniformity (Hoffman and Phelps, 1986). In high-resolution PET, only increases in intrinsic detector efficiency can increase the total number of true coincidence events relative to the number of scatter and random coincidences. This is the main reason why high detector stopping power has become one of the most attractive features in the development of modern high-resolution PET scanners.

The signal and noise characteristics in high-resolution PET can be best understood in terms of the spatial frequency response of the detectors and the spatial frequency amplification or gain of the reconstruction filter in relation to statistical noise. As detector resolution is improved, more high-frequency signal (if present) is preserved to a greater extent, and at these high frequencies, S/N is increased. During reconstruction, the reconstruction filter amplifies the amplitude of a spatial frequency component of the data according to its coefficient. The spatial frequency components of the data are eliminated above a cutoff frequency (often well below the Nyquist sampling rate). In the case where very little or no signal is present beyond the cutoff frequency of the reconstruction filter, high-frequency noise is adequately suppressed. However, when high-frequency signal is present, as is the usual case in a highly structured object such as the brain or heart, the use of a higher reconstruction-filter cutoff frequency can increase signal but also increase noise. Thus, the ability to change a reconstruction filter's cutoff allows for improved S/N usually at the expense of spatial resolution. In other words, one can produce the highest resolution by selectively amplifying the high-frequency signal and reduce noise by suppressing high frequencies where noise dominates.

6. DIAGNOSTIC QUALITY

In a clinical setting, PET images are often interpreted subjectively (i.e., "by eye") in diagnostic decision making. The visual recognition (detection) of a pattern, structure, or defect (object) is dependent on the observer's ability to delineate or distinguish one object from another. The high-frequency information of the object necessary for border definition is dependent on the spatial resolution of the system (i.e., blurring and spillover effects) and is contaminated with excessive high-frequency noise. Noise has the effect of masking the presence of objects (producing false-negative interpretations) and also can lead to the detection of apparent "objects" that are not actually present (false positives). As described above, physical measures of image quality can be useful for comparing different imaging system or techniques and establishing quality-control procedures and can provide useful estimates of minimum detectable object size and contrast. However, in most cases, the diagnostic accuracy of detection is best estimated by experiments using human observers whose interpretations are verified by actual clinical studies. The time required for a physician to extract useful information from an image and the accuracy of his decision can be improved with image-enhancement techniques. Diagnostic significance and quality of an enhancement technique can only be based on the interpretation of many actual or phantom studies similar to those found in a clinical situation.

6.1 Detectability

Numerous studies have shown that

1. for reliable visual detection of an object, at a given image contrast, a sufficient number of true coincidence events must be acquired to reduce e_{rms} and increase S/N;
2. high spatial resolution improves visual discrimination by removing the blurring between adjacent structures having different radionuclide concentrations; and
3. high object contrast obtained through proper radiopharmaceutical design improves the recognition of anatomical structures having differing physiological functions.

Although contrast, resolution, e_{rms}, and S/N are objective criteria of image quality, the true object distribution is often unknown prior to clinical interpretation (except in the use of phantoms for evaluation of a system or technique). Consequently, measuring an image's diagnostic quality by the subjective evaluations of human observers is appropriate. This is usually accomplished by showing a set of images to a cross section of viewers (receivers) and averaging their evaluations (operating characteristics). These receiver operating characteristic (ROC) evaluations include determination of the presence or absence of a disease, structure, or defect, and its location, and uses a rating scale that represents the observer's confidence in his decision. In clinical ROC studies, the absolute truth is obtained from actual clinical studies. Side-by-side comparisons of images and ranking them with a scale from best to worst can also be useful when evaluating imaging systems or techniques. In either case, subjective evaluation of the diagnostic quality of the image may result in a *usable* rating for an image, while objective evaluation of image quality might have the opposite rating and vice versa.

6.2 Information Content

The ultimate goal of PET is to provide greater accuracy and to minimize both subjectivity and bias through the representation of relevant image information for either nonquantitative visual examination or quantitative analysis. The determination of the functional state of a biologic process or structure depends on the interpretation of the physiological meaning of the information contained in an image. Our ability to take advantage of the functional image requires accurate methods of data acquisition, presentation, analysis, and recognition of the limits of these approaches in practical applications.

A practical example is in determining the statistical limitations of dynamic tomographic imaging given a scanner with fixed sensitivity and detector resolution. Two important questions of interest that determine the total number of counts in an image are these:

1. How much activity is required to provide an image with high statistical accuracy?
2. What temporal sampling frequency is required to measure the dynamic changes in the radiopharmaceutical distribution?

The amount of radioactivity is limited by the dose that can safely be administered to the subject and the counting-rate characteristics of the scanner. The duration or interval of scanning is limited by the physical half-life of the radionuclide, the biological half-life of the radiopharmaceutical (effective half-life), and other impediments such as patient motion and comfort.

Knowledge of the minimum activity required to detect or quantitate the activity concentration in a structure and of the amount of activity in the FOV above which there is no statistical benefit in acquiring more counts can aid in determining the amount of activity and the scan duration. Thus, the sensitivity of the PET system; the amount of radioactivity, size, and location of the object in the FOV; and the duration of the scan determine the number of image counts. The effects of acquiring more counts are reduced image noise and improved image quality and quantitative precision. The spatial resolution with respect to the object's size and location determines the quantitative accuracy.

In PET, information is represented by a digital image. For a digital image, its matrix size and pixel dimension determine the image FOV and detail, and its pixel depth (numerical range) determines the precision with which the number of events at a given location (pixel) can be represented. If the number of image counts is fixed, the image matrix size and pixel dimension determine the number of events per pixel and therefore the statistical noise at any pixel. The pixel dimension also determines the amount of detail in an image up to the limits of spatial resolution determined by the reconstruction filter and the detector. As a rule of thumb, the pixel dimension should be on the order of FWHM/3 to avoid loss of spatial resolution so that all information acquired will be preserved. Most systems offer pixel depths of 8 bits (256 levels) or 16 bits (65 536 levels) of dynamic range or precision with which the information (counts/pixel) is represented. However, if total information in the image has 3% e_{rms}, then there are about 32 statistically distinct levels of information represented by the image, regardless of pixel depth.

Because of the physical and biological properties of the radiopharmaceutical, images often have low counts, and statistical noise can become overwhelming. Usually, overall image quality can be improved by simple processing, but the poor quantitative information remains. In these instances, if possible, repeating scans under the identical conditions and then combining the scans can effectively reduce the amount of statistical noise and increase the information content.

6.3 Enhancement

In the previous sections, we stated the importance of the imaging protocol and the digital processing in obtaining and representing useful information degraded by statistical noise and spatial resolution. We have also stated that the reconstruction filter cutoff frequency can be adjusted to trade off image resolution and noise. In addition, other image-processing techniques, which we describe in a later section, can be used to remove unnecessary and unwanted information from the image while retaining and often enhancing relevant image information. The combinations of contrast enhancement and histogram equalization or the use of thresholding and histogram specification can have a considerable effect on the image and increase or decrease the dynamic range with which the image is presented. The selection of color scale, medium, display, brightness, hue, saturation, and the physical size with which to view the image can often simplify the identification of an object. Simple subtraction of one image from another obtained under identical scanning conditions but different physiological conditions can also be used to monitor therapy or the progression of a disease.

6.4 Interpretation

PET studies produce images from which both quantitative and nonquantitative data can be extracted. In diagnostic situations where the purpose is to determine the presence or absence of a defect or disease, images are usually visually interpreted. Quantitative data in the form of radiopharmaceutical uptake and functional parameters can be used to supplement the more subjective visual interpretation. In either quantitative or nonquantitative imaging studies, interpretation depends on the human perception of images, curves, or numbers and understanding of the underlying physiologic process or function under investigation.

Quantitative data are most often obtained from images by sampling (measuring) the values represented by a region of interest (ROI) in an image. The numeric value of an ROI can be that of a minimum, maximum, average, or summation of pixel values that represents the activity concentration or some functional or parametric value in a volume of tissue (e.g., brain, heart, or kidney). Because of partial-volume effects, some interpretation of the object is required when obtaining values with ROIs. If the object sampled is a "hot" object in a cold background and is smaller than three times the FWHM of the system, then a large ROI placed at least 1 FWHM outside of the object can be used to estimate the total activity of the object. In the same situation, if an ROI is placed within 1 FWHM of the border of the object, it can be used to estimate the activity concentration of the object. In the event that the object and the background both contain activity, the situation is more difficult to interpret.

In many studies, we are not only concerned with determining the radiopharmaceutical concentration in the structure but also the kinetic properties that determine its uptake and elimination from the structure. In such cases, a dynamic (temporal) series of images is obtained. The length of time and the duration of temporal sampling intervals and their effect on image noise have already been addressed. Although the data present in the ROI may be of sufficient precision and accuracy to permit a numerical analysis of the data, an image may not be of sufficient quality to provide sufficient information for ROI placement. Therefore, to analyze dynamic data one places an ROI either on a coregistered anatomic image or on a functional PET image that contains the most detail and then computes a time-activity curve (TAC) (activity concentration vs time) for that ROI using all the data in the dynamic sequence. A TAC can then be used with a mathematical model that describes the physiological process of the structure or the pharmaokinetic parameters of the radiopharmaceutical to extract further information.

7. IMAGE PROCESSING

The radionuclide distribution estimate obtained by computer reconstruction techniques is represented in the form of a digital image. This allows the application of a variety of digital image-processing techniques. Image-processing techniques are used to maximize and extract information and remove unwanted information through the use of arithmetic operations, transformations, and filters applied to pixels, ROIs, TACs, and images.

7.1 Arithmetic Operations

The arithmetic operations of addition, subtraction, multiplication, and division are carried out pixel by pixel on images. One of the most common operations is image summation to reduce statistical noise. As the number of images added together increases, signal increases and the variability decreases (precision increases). In practice the images must be registered to avoid blurring. Image subtraction can be used either to view or to quantitate the change of the radionuclide distribution between two images. Often images are not obtained under exactly the same conditions, and a scalar multiplication or division can be applied to normalize the data. Some examples are the normalization to injected activity or to average activity concentration. In addition the division of a subtraction image by one of the images and the scalar multiplication of each pixel by 100 can give a percentage increase or decrease relative to the image divisor. The use of point processing or pixel arithmetic operations has numerous important applications.

7.2 Transformations

Geometric translation, rotation, and scaling are used to form a new image by the mapping or converting of the original image onto a new coordinate space and are the basic transformations used to align or register one image or image volume to another. By resampling, reslicing, and reorienting an image along the planes of another data set, image surface and volume rendering employing sophisticated feature detection and warping algorithms can be used for simultaneous multimodality display. In many clinical situations (e.g., surgical planning and diagnosis), a functional PET image is combined for display purposes with structural images, such as x-ray computed tomography or magnetic resonance imaging, for precise anatomical localization of the radiopharmaceutical; and in image quantification, anatomical images are preferred for ROI placement. Anatomical images of a subject used for the correction of partial volume effects must also be coregistered with the corresponding functional PET image. Stereotaxic transformation of PET image to a standardized coordinate space of anatomic structures allows for both intersubject and intrasubject comparisons and has been widely used in functional brain mapping to interpret and communicate results.

7.3 Filters

In addition to pixel-by-pixel processing and image transformation, digital filters can be used to extract additional quantitative information and improve the statistical quality of the image. A filter is a mathematical operation applied to an image $f(x,y)$ to form a new image $f'(x,y)$ that is in some sense better, for a specific purpose, than the original image. Noise reduction, edge detection, and contrast enhancement are a few of the various possible operations provided by digital filtering. The most common method of filtering is the changing of a pixel value based on itself and its neighboring pixels. In this spatial application, the filter is an $N \times N$ matrix of coefficients, $h(x,y)$, centered over a pixel in the original image where each pixel under the filter is multiplied by the corresponding coefficient and the summation of the results is placed at the location of the central pixel in the new image. The spatial filter is then applied to the next pixel, and the process is repeated until all pixel locations have been filtered. This process, known as convolution, is given as

$$f'(x,y) = \sum_{x'=-N/2}^{N/2} \sum_{y'=-N/2}^{N/2} h(x',y') \times f(x-x',y-y'). \tag{53}$$

The application of the spatial filter at each pixel location can be computationally expensive.

As described above, an image or function in the spatial domain can be equivalently represented in the spatial frequency domain through use of the Fourier transform [Eq. (19)]. By the convolution theorem, which states that convolution in the spatial domain is the exact equivalence of multiplication in the frequency domain and vice versa, we can perform the filtering operation in the frequency domain, given by

$$F'(u,v) = H(u,v)F(u,v), \tag{54}$$

where $H(u,v)$, $F(u,v)$, and $F'(u,v)$ are the Fourier-transform representations of $h(x,y)$, $f(x,y)$, and $f'(x,y)$, respectively, and u and v are spatial frequency. The Fourier filtering approach is straightforward: We simply obtain the Fourier transform of the image, apply the Fourier filter using Eq. (54), and inverse Fourier transform the result to obtain the filtered image. Figure 18 shows the spatial and frequency-domain representations of a blurred function with different levels of noise added.

7.3.1 Classification The two methods of filtering can produce identical results and differ only in their method of implementation. Spatial filters operate on image data in a local region surrounding each point while frequency (Fourier) filters operate on the entire data. However, digital filters are best described and evaluated by the effects they have on the spatial-frequency components of the data. In fact, we have applied this concept to our discussions of the modulating effects of blurring and statistical fluctuations dominating high-frequency components of the data. We now characterize some digital filters and the effect they have on the fre-

quency components of data affected by resolution and noise.

Figure 19(a) shows a filter that passes low frequencies unaltered by multiplying the amplitude of the corresponding frequency components of the data by 1.0. The filter then rolls off, gradually reducing the amplitude of higher-frequency components of the data to zero. This low-pass "smoothing" filter has the effect of reducing high-frequency noise at the expense of spatial resolution (high-frequency signal). The filter shown in Fig. 19(b) is called the inverse filter because its coefficients are the inverse of the modulation transfer function (MTF^{-1}). Spatial resolution can be improved through the use of the inverse filter that is matched to the spatial-resolution degradation characteristics of the system. However, the inverse filter amplifies high-frequency noise as well as signal and

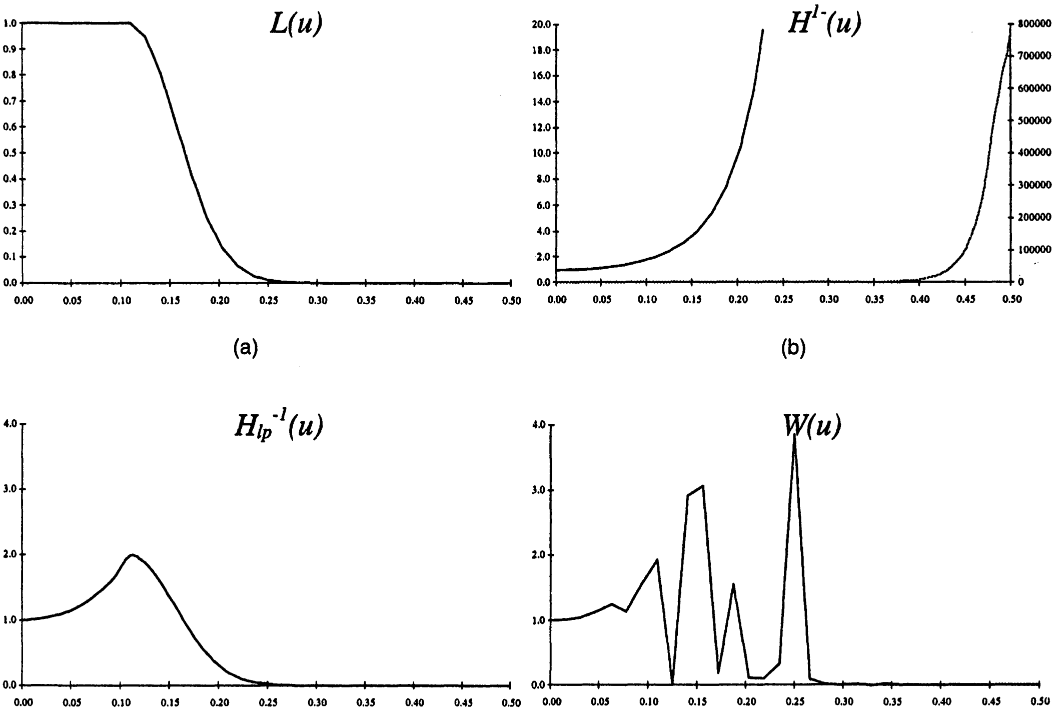

FIG. 19. The Fourier representation of (a) Low-pass, *L*(*u*), (b) inverse, $H^1(u)$, (c) inverse with a Gaussian rolloff, $H_{lp}^{-1}(u)$, and (d) Wiener, *W*(*u*), filters.

often renders the resultant image unusable. Figure 19(c) is the combination of an inverse and a low pass filter. This filter has the ability simultaneously to enhance contrast by amplifying the more reliable low- and intermediate-frequency components and to suppress noise by attenuating higher-frequency components and eventually eliminating the highest-frequency components dominated by noise. The filter shown in Fig. 19(d) is a frequency-selective filter known as the Wiener filter. Like the combination filter shown in Fig. 19(c), the Wiener filter has the ability to amplify the reliable low-frequency data and attenuate high-frequency components of noise. The Wiener filter, however, uses both the characteristics of the imaging system and the degraded image to form its frequency response.

By examination of the spatial-domain filters in Fig. 20, it is difficult to judge what a particular filter will produce. Therefore, our understanding of what these filters can produce must be developed by their effect on the frequency components of the data. However, as reflected by the MTF (see Fig. 15) and demonstrated by Fig. 18, the image information content (signal) at low spatial frequencies is greater than at high spatial frequencies where noise dominates. Therefore, the benefit of low-pass and other filters that employ a high-frequency cutoff is to effect an overall improvement in image S/N by the reduction of noise. The benefit of restoration filters that employ the inverse MTF is to remove the effects of imperfect spatial resolution by amplifying the signal at the more reliable low and intermediate frequencies and to suppress or eliminate noise at higher frequencies.

The simplest method of determining the coefficients of a spatial-domain filter is to specify a desired frequency response and then take the inverse Fourier transform of the filter, as shown in Fig. 20.

In Fig. 21, we demonstrate the application of the four filters described above to the noise-contaminated simulation data given in

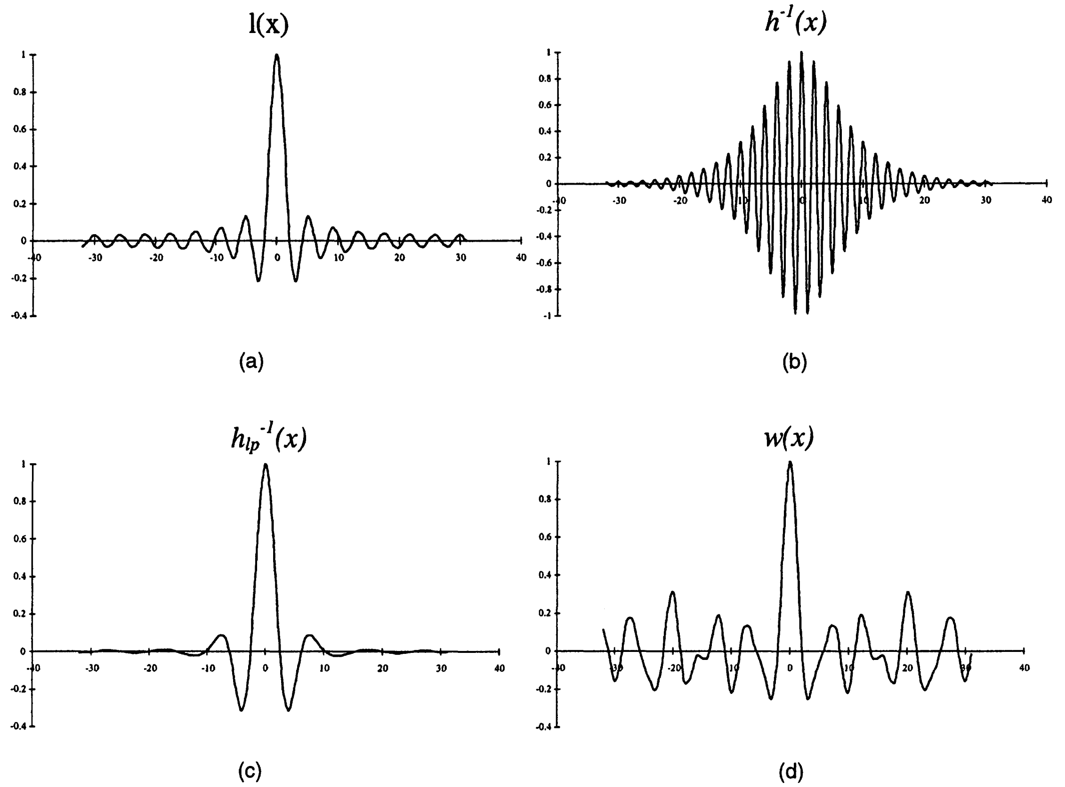

FIG. 20. The spatial representation of (a) low-pass, $l(x)$, (b) inverse, $h^{-1}(x)$, (c) inverse with a Gaussian rolloff, $h_{lp}^{-1}(x)$, and (d) Wiener filters $l(x)$, shown in Fig. 19.

Fig. 18(c). Figure 22 depicts the result of the first three applied to the noise-free simulated data [Fig. 18(b)]. Figure 22(d) shows the application of the Wiener filter to a low-noise simulation [Fig. 18(c) since its derivation defaults to the inverse filter in the absence of noise, as is discussed in the following section]. With respect to S/N_{rms}, all filters perform pretty much the same in the presence of noise [Figs. 21(a) through 21(d)] with of course the exception of the inverse filter [Fig. 21(b)]. From Fig. 22, we can deduce that the inverse filter is the best solution in the case of noise-free data; while the low-pass and modified inverse filter perform satisfactorily, we can see that their effect at high frequencies is to increase blurring as expected; and, also as expected, the Wiener filter provides a comparable restoration even in the presence of noise.

7.3.2 Derivation Carefully designed digital filters can be used to selectively enhance certain features and suppress others by considering the characteristics of the imaging device, the acquired data, and the information to be extracted. The principal objective of enhancement techniques is to process the data for some specific purpose (problem oriented); on the other hand, restoration techniques attempt to reconstruct an image that has been degraded, by modeling the process, and then applying the inverse of the modeled process to the data (model oriented). This requires knowledge of the transfer characteristics of the system (i.e., the PSF or MTF), the object, and the noise.

As we have previously stated, the resultant PET image $g(x,y)$ is a linear combination of superimposed PSFs $h(x,y)$ scaled according to the object distribution $f(x,y)$. This process can be described by the convolution of the object distribution $f(x,y)$ and the system impulse response $h(x,y)$, given by

$$g(x,y) = h(x,y)*f(x,y). \qquad (55)$$

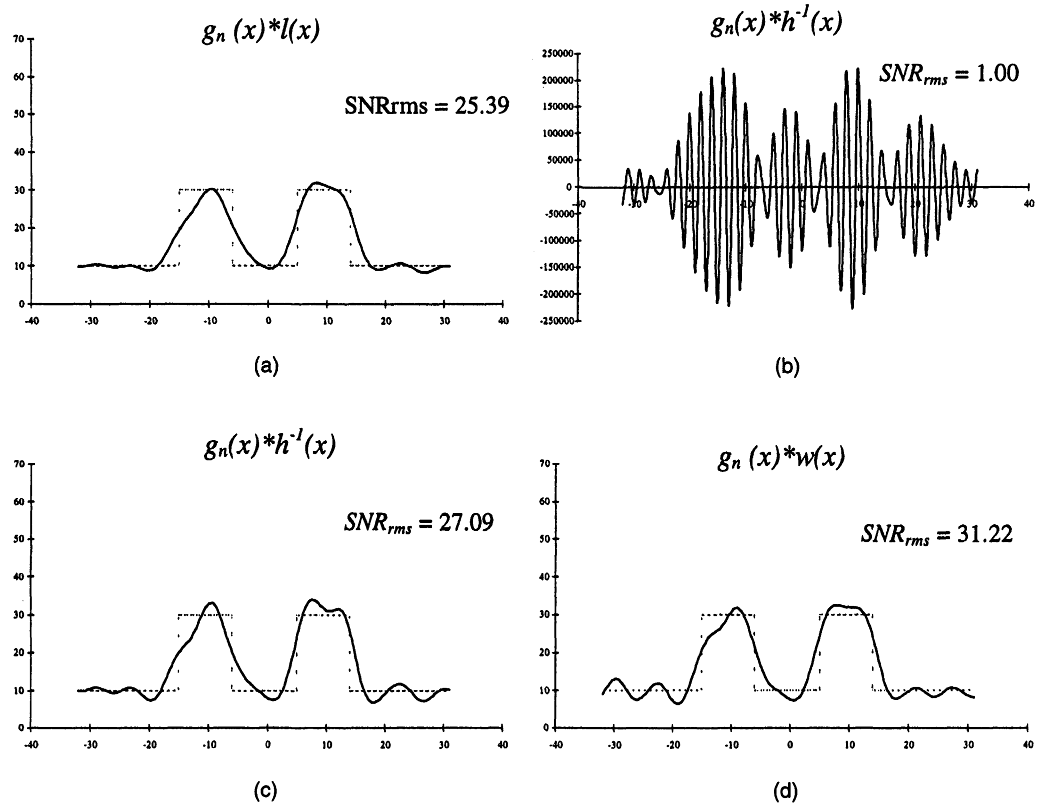

FIG. 21. Noisy simulation data filtered with the Fourier filters in Fig. 19.

where the asterisk denotes the operation of convolution, and its Fourier representation

$$G(u,v) = H(u,v)F(u,v). \tag{56}$$

The restoration solution (estimate) of the true signal $F(u,v)$ can be obtained by solving Eq. (56) for $F(u,v)$ to obtain

$$F(u,v) = H^{-1}(u,v)G(u,v). \tag{57}$$

This solution is the process known as inverse filtering. The method often does not work because $g(x,y)$ cannot be known precisely. Equation (55) is actually expressed as

$$g(x,y) = h(x,y)*f(x,y) + n(x,y). \tag{58}$$

where the asterisk again denotes the operation of convolution and $n(x,y)$ is statistical noise, and its Fourier representation is thus given by

$$G(u,v) = H(u,v)F(u,v) + N(u,v). \tag{59}$$

The optimum solution (filter), which minimizes mean squared error between the original distribution and the filtered image, is the Wiener filter, $W(u,v)$, given as

$$W(u,v) = H^{-1}(u,v)\frac{H^2(u,v)}{H^2(u,v) + N^2(u,v)/F^2(u,v)}. \tag{60}$$

8. EXAMPLE STUDIES AND IMAGES

Regional cerebral blood flow, rCBF, can be measured with $H_2{}^{15}O$. Because of the short physical half-life of ^{15}O, $H_2{}^{15}O$ measurements can be made between 10 and 15 min apart in the same subject during the same session. rCBF measured with $H_2{}^{15}O$ is currently the most popular method for PET activation studies. Within a few minutes after a bolus intravenous injection of $H_2{}^{15}O$,

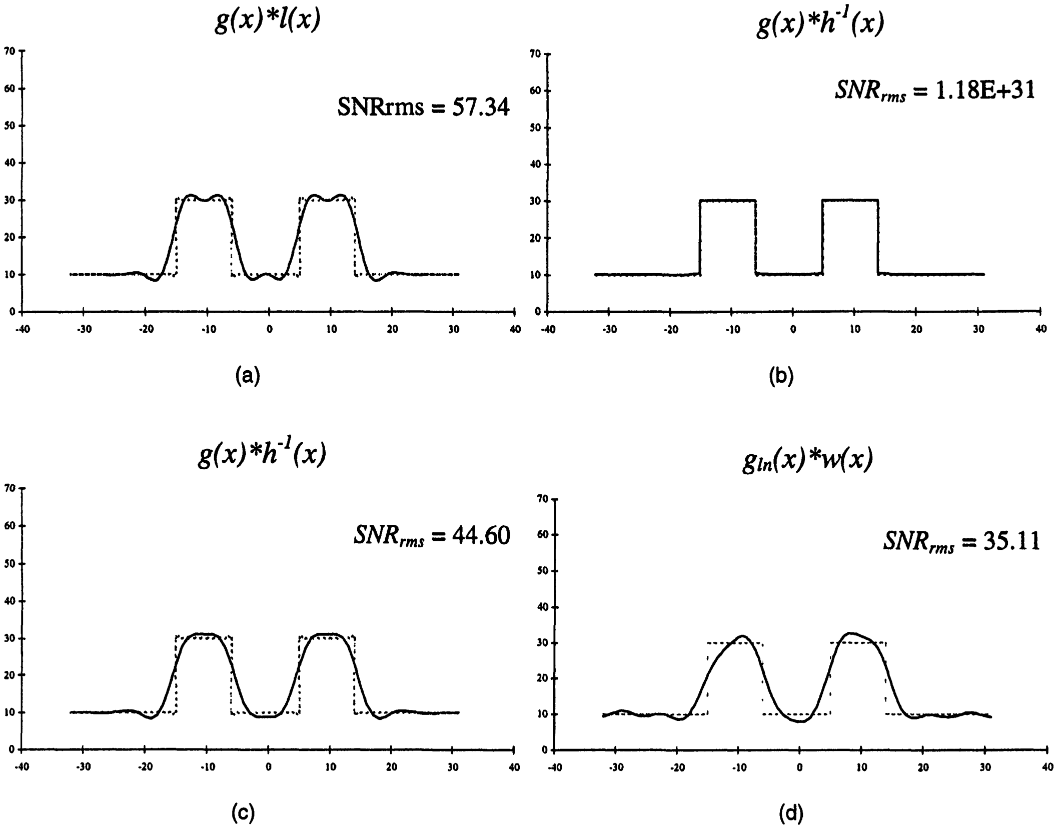

FIG. 22. Noise-free simulation data filtered with the Fourier filters of Figs. 19(a), 19(b), and 19(c). (d) The result of applying the Wiener filter to low-noise data.

quantitative rCBF measurements can be obtained. Absolute quantification requires measurement of the arterial time-activity curve, TAC (input function), but is not necessary for activation studies because rCBF and local tissue activity concentration is nearly linear. The distribution of $H_2{}^{15}O$ in human brain is shown in Fig. 23.

$H_2{}^{15}O$ is also ideal for quantitative region myocardial flow measurements because it is completely taken up by the myocardium (100% extraction) and it is not affected by metabolism. The extraction of $H_2{}^{15}O$ remains linear in the myocardium, even at high myocardial flow rates (unlike rCBF), and thus the distribution of tracer can be used to accurately reflect region perfusion.

The measurement of region cerebral metabolic rate of glucose, rCMRglu, with [^{18}F]-2-fluoro-2-deoxyglucose, FDG, is a well-established tool for diagnostic use and for the investigation of human disorders. The long half-life of ^{18}F makes it difficult to perform more than a single study in a day. The typical static FDG study requires a single scan after a 45- to 60-min uptake phase post injection and can be performed with and without arterial blood sampling depending on the need for absolute quantitation of rCMRglu or glucose uptake, respectively. Dynamic scanning, though rare, can also be used to determine rCMRglu. The distribution of FDG in human brain is shown in Fig. 24.

^{18}FDG is widely used to evaluate myocardial viability. Ischemic, but viable, myocardium utilizes glucose in preference to other substrates and will therefore exhibit increased uptake of ^{18}FDG. The determination of ischemic, but viable, myocardium is made only in relationship to perfusion. When regional myocardial ^{18}FDG uptake is increased compared with regional myocardial blood

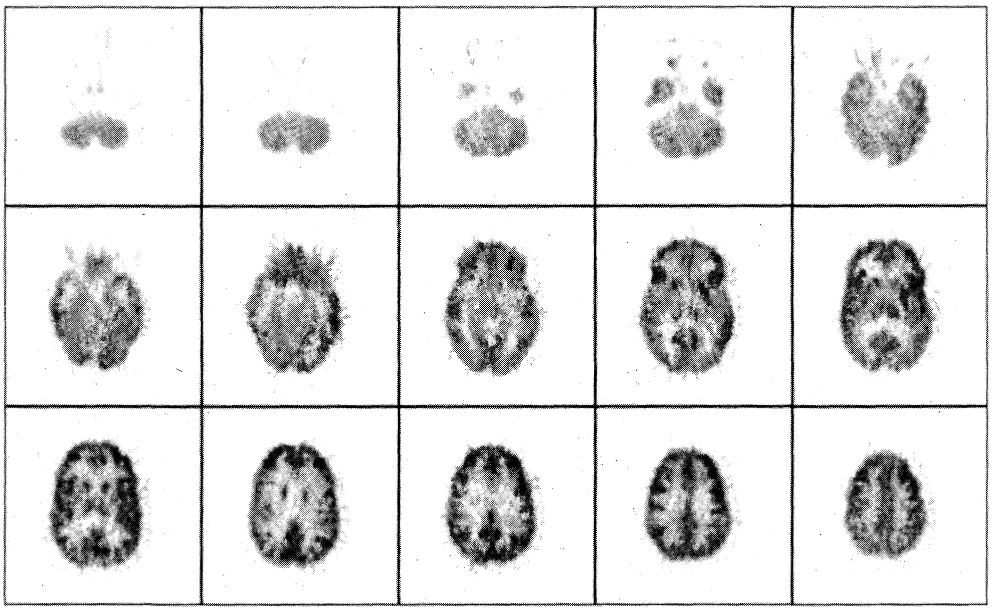

FIG. 23. Fifteen-slice PET image of rCBF acquired over 60 s after the intravenous injection of $H_2{}^{15}O$.

flow, the perfusion-metabolism mismatch is highly indicative of myocardial viability.

Using ^{18}FDG imaging, malignant tumor cells can be detected because of their enhanced glycolytic rate under anaerobic conditions as compared with nonmalignant tissue cells. Metabolic imaging of the brain using ^{18}FDG has also provided evidence for altered metabolic patterns in schizophrenia, Alzheimer's disease, and patients with a va-

riety of neuropsychiatric and neurodegenerative disorders.

Neurodegenerative disorders result from the death and or alteration of neurons. With PET it is possible to examine the many factors associated with neuroreceptor binding of PET ligands. For quantitative *in vivo* studies that measure receptor densities and affinities, the appropriate model of the pharmacokinetics of the administered neuroreceptor binding ligand, the time course of activity at the binding site, and an input function are required for the computation of the specific binding parameter. There are numerous receptors, receptor subtypes, and receptor binding ligands that can be investigated with PET. Shown in Fig. 25 is a dynamic series of human brain scans of the distribution of ^{11}C-Raclopride. The differences in image quality in dynamic scanning as compared with the static scans given in the previous examples arise from the differences in the number of acquired counts in each image. Images later in the dynamic study have fewer counts on account of temporal sampling requirements for pharmacokinetic modeling and physical decay.

GLOSSARY

Accidental Coincidence: The random overlap of two unrelated events within the coincidence resolving time of the detector.

Annihilation Photons: Two nearly collinear 511-keV photons resulting from the interaction of a positron and an electron in which their mass is converted to electromagnetic energy.

Coincidence Detection: The detection of two photons in two detectors within a small interval of time (typically less than 15 ns).

Dead Time: The time during which the scanner cannot respond to new events because of the processing of previous events.

FWHM: Full width at half maximum of a point-spread function. Usually used as a measure of spatial resolution.

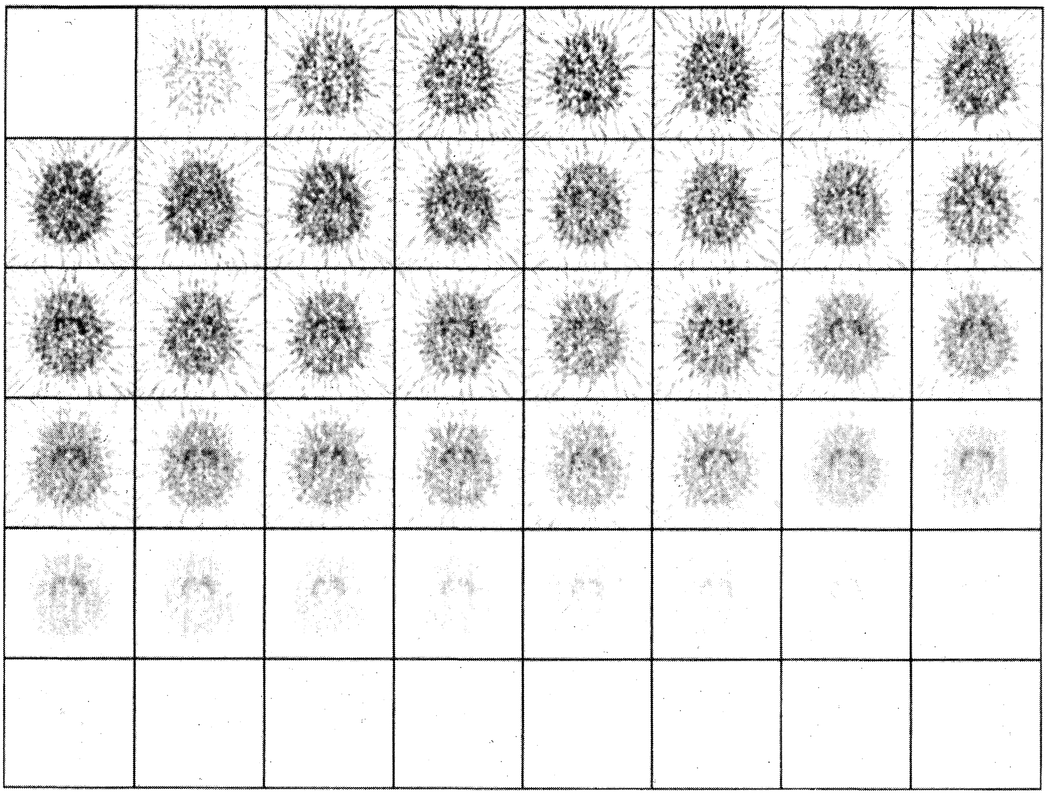

FIG. 25. A single PET slice of human brain over 60-min post-injection of ^{11}C-Raclopride.

Partial-Volume Effect: The underestimation or overestimation of radionuclide concentration in a structure that does not completely fill the sensitive volume of the resolution element of the system.

Point-Spread Function: The count profile of a line through an image of a point source of radioactivity.

Random Coincidence: See **Accidental Coincidence.**

Scatter Coincidence: A coincidence event in which one or both the photons originating from the same annihilation event have undergone Compton scattering.

Tracer: A substance used to trace or follow a chemical compound or process without perturbing the process being studied.

INTRODUCTION AND DEFINITIONAL CONSTRAINTS

Definitions of topography vary in scope immensely. Those with a basis in topographic mapping define topography as the configuration of the surface of the Earth, including its relief, the position of its streams, roads, and cities, and other geographic features. A single feature such as a river or a valley is termed a topographic feature, and these features are subdivided into hypsography (the relief features), hydrography (the water and drainage features), culture (the man-made features), and vegetation. These terms are somewhat specific to the land-surface topography, that is, the surface elevation of the features above sea level on Earth. More recent and far broader definitions do not restrict the topographic surface to the land, neither do they restrict it to a tangible surface form. Thus in oceanography and geophysics, the ocean floor's surface depicted by the measurement of bathymetry or water depth is called topography, as are not only the solid surfaces of other planetary bodies but also the distribution of continuously measurable or field variables over large areas such as salinity in the ocean or barometric pressure in the atmosphere. In the broader definition, the tendency is to consider topography as the spatial expression of a field variable in geographic space as a single-valued function, usually the outer or maximum measured value.

Terminology associated with topography includes terrain surface, land surface, and sometimes landscape for land topography, and bathymetry or ocean floor for the oceans. Maps showing topography are called topographic maps, though the means for the graphic or cartographic depiction of the surface varies substantially from map to map. In general, the lowest surface elevation within a specified area, measured with respect to some arbitrary Earth model and datum, subtracted from the highest is referred to as the relief. Thus the Earth's land topographic relief to the nearest meter is 8846 m.

The measurement of topography implies determining the surface elevation. The elevation is determined opposite to the surface "down" vector, which can vary since the Earth's gravity varies from place to place. Elevation is measured not from the Earth's center, but from a preset level known as a datum. Often, sea level forms the local datum, but precise elevation determination must account for the exact three-dimensional geometry of the Earth.

1. GEODETIC MODELS AND THE EARTH'S REFERENCE ELLIPSOID

Over time, the Earth has been considered as having three different three-dimensional

digital Encyclopedia of Applied Physics

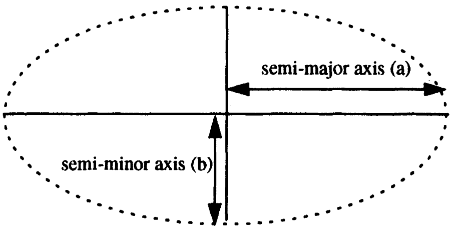
forms. The simplest, and still suitable for small-scale global mapping, is the sphere. While our planet has considerable complexity of internal structure, active tectonism, and some remarkable rifts, mountains, and ocean trenches, nevertheless the total surface relief is minor with respect to the Earth's size, a mere 0.1% of the equatorial circumference. The difference between polar and equatorial radii is also only about 0.33%, and as a result the sphere is a good first approximation of the Earth's shape for global mapping at generalized scales. In the early eighteenth century, Isaac Newton argued that the Earth should be flatter at the poles than the equator, contrary to early French estimates that had indicated the Earth to be egg-shaped, with the greatest curvature at the poles. The French Academy of Sciences sent expeditions to Peru and Lapland starting in 1735, eventually validating Newton's hypothesis and beginning a series of 26 meridional measurements to estimate the Earth's dimensions between 1799 and 1951 (Snyder, 1987).

The Earth's shape was determined to be that of an ellipse rotated about its shorter or minor axis, a figure known as an oblate ellipsoid or oblate spheroid. The ratio of the lengths of the two semiaxes of the ellipse of revolution, subtracted from 1, is termed the flattening (Fig. 1). All flattening estimates are about one part in 300. Some highly influential measurements of the lengths of the semiaxes and the flattening are those of Alexander Ross Clarke in 1860 and 1866, John Fillmore Hayford in 1909, and Clarke and Helmert in 1911. The Clarke 1866 ellipsoid used the measurements of 6 378 206.4 m for the equatorial radius and 6 356 583.8 m for the polar radius, giving a flattening of 1/294.9787. Hayford's measurement used the rounded values of 1/297 and a semimajor axis of exactly 6 378 388 m. These values were adopted by the International Union of Geodesy and Geophysics (IUGG) in 1924, and termed the International or Hayford Ellipsoid. Since mapping of the United States was already under way, the Clarke 1866 values were used for the United States. Mapping efforts worldwide have used more than a dozen different ellipsoids; for example, many African countries use the Clarke 1860 ellipsoid.



$$f = 1 - \frac{b}{a}$$

For the WGS84 (World Geodetic System)
a = 6,378,137 meters
b = 6,356,752.3 meters so f = 1/298.257223563

FIG. 1. The Earth's ellipsoid and its parameters.

Ellipsoids determined by measurement within one continent reflect minor differences in the Earth's local shape. The satellite era has allowed calculations based on the entire Earth. Two such measurements are the World Geodetic System measurement of 1972 (WGS72) and the Geodetic Reference System measurement of 1980. The latter (GRS80) was adopted by the IUGG and with other measurements has been the basis for mapping in the United States as the ellipsoid for the North American Datum of 1983 (NAD83) and the Department of Defense's WGS84. WGS84 is commonly used with the Global Positioning System (GPS) and assumes an equatorial radius of 6 378 137 m and a flattening of 1/298.257 223 563. As a result, most features on topographic maps have "shifted" as much as 300 m horizontally, though less vertically, from the older NAD27 datum based on the Clarke 1866 ellipsoid.

1.1 The Datum and Sea-Level Definitions

The third model of the Earth's shape uses the geoid, that is, the precise surface deviation from a global ellipsoid at each topographic elevation point, measured to include local gravitational field variations. With many ellipsoids, this can give several topographic surfaces. Figure 2 shows a local configuration of the measurements. A datum is defined as a numerical or geometrical quantity or set of quantities that may serve as a reference or base for other quantities. The datum associated with an ellipsoid becomes locally a reference level for measurement of

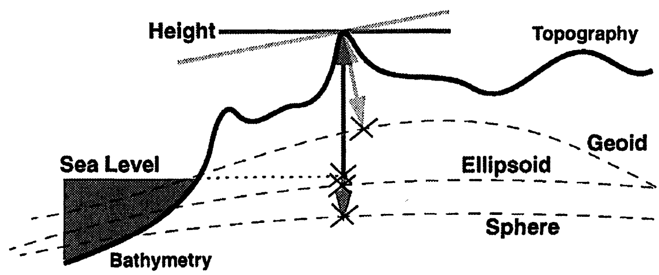


FIG. 2. Topographic elevations defined with reference to a sphere, ellipsoid, geoid, or local sea level are all different.

topographic elevation. This may be close to the sea level, but a datum can trend above and below this level, which itself varies by the tides, by the season, and over the long term for various reasons, such as sea-level change. The datum of mean sea level is common on nautical charts.

Detailed topographic mapping proceeds by extending measurements outward from known points. In much of the world, the level of geodetic precision possible with the GPS is superior to most previous measurements and has led to a resurveying of the control points used as the skeleton for topographic mapping. Even hand-held portable GPS receivers can be used to determine position and elevation locally, though accuracy varies. On most maps showing topography, therefore, the minimum requirement is to list the datum, the ellipsoid, and the measured elevation. In practice, points are extended locally from control points or bench marks with previously measured accurate elevations by traditional surveying methods.

1.2 Structure of Topographic Form

The land surface and ocean floor surface topographies at the local scale contain a set of features with common names determined mostly by their relief, absolute elevation, and shape. At the broadest scale below the planetary, landforms are the result of tectonic forces shaping the movement and position of solid continental plates floating on a more liquid mantle. Major topographic features are the result of plate collisions, dynamics at plate boundaries, hot spots or holes in the plates, and time. Gravity, volcanism, and other surface and ocean processes continuously modify the topography, so that large-scale features are constantly in flux. Landform features include mountains, hills, plateaus, lowlands, depressions, rift valleys, and mesas. Each of these can be caused by several means, including volcanism, folding, faulting, mass wasting (soil creep, slumping, and debris flow), or erosion and deposition.

Topographic features dominated by gravity include cliffs, scree slopes, alluvial fans, and lava flows. Gravity dominates in the deep ocean; waves and currents move material to form some bathymetric landforms, while chemical solution or coral growth forms others. Those landforms dominated by water erosion are valleys, channels, and gullies. Ice is a major topographic erosional feature determinant, forming hanging valleys, aretes, and U-shaped valleys. Water deposition forms deltas, flood plains, levees, and marshland, while ice deposition forms drumlins, eskers, and moraine. Wind erosion can sculpt wind caves and arches, while wind deposition can form dunes and large soil deposits known as loess. In addition, some types of geology have characteristic landforms such as the karst or sink-hole topography of chemical solution erosion on limestone. Most land features can be flooded as oceans rise or land falls and retain some of their form underwater, such as the Hudson Canyon off of New York. Many features are specific to the oceans, including the mid-ocean ridges, the deep trenches, and the continental shelves.

2. TOPOGRAPHIC MEASUREMENT

The measurement of topographic features dates from the first methods of determining height on maps by triangulation. The Romans could determine line of sight horizontally, and they must have used the clinometer to determine vertical angles. Along with the length of a line on the map, the vertical angle allows vertical elevation difference calculation and, therefore, relative elevations to be computed. This technique reached a higher degree of sophistication with the invention in the sixteenth century of the engineer's transit and later the theodolite, which used circular angle scales and pivoted telescopes to measure both horizontal and vertical angles precisely. During the nineteenth century, two additional methods became available. The altimeter is a precision barometer that allows the user to compute elevation from the relationship between air pressure and temperature and altitude above sea level. The precision or spirit level allowed horizontal lines to be extended over long distances while measuring elevation increments on calibrated poles. Most early elevation mapping used one or more of these methods, for example, the Great Topographical Survey of India in the nineteenth century.

After World War II, the science of photogrammetry reached the point where air photographs could be used to compute relief. This was done by taking two photographs from different viewpoints, say two passes over a target on different but parallel flight paths, with a substantial overlap in the images. The same objects are viewable, but with different displacements on the two photographs. Measurements from the photographs along with the plane's altitude and the focal length of the camera then allow elevations to be calculated at points. Stereophotogrammetry has reached a great degree of sophistication, and the method is now used extensively in engineering, surveying, and military intelligence. Digital soft-copy photogrammetry, with computer software taking over the tasks of matching the images and computing the elevations, has replaced a first generation of mechanical devices for these measurements. Instruments now fly on aircraft and spacecraft, and stereo cameras are even used at close range for detailed mapping—for example, of buildings and monuments, and inaccessible locations.

Several new technologies have changed topographic mapping recently. The GPS, with a system of 21 operational satellites in known orbits along tracks, each transmitting an encoded time signal, has made direct measurement of position and elevation relatively simple and possible at extreme levels of precision, such as submeter accuracy (Herring, 1996). In addition, active remote sensing in the radar part of the spectrum has proven a versatile method for terrain mapping. With use of synthetic-aperture radar from two passes together, the interference pattern can be used to calculate relief, in some cases to the millimeter level of accuracy. Pioneered over the ocean surface by SeaSat during the 1970s, radar interferometry has been accomplished for the Earth from the SIR-C, ERS, JERS, and Radarsat instruments, by Galileo for Venus, and by Magellan for Jupiter (Plate 1). In addition, many scientific satellites now use laser altimeters to measure their track altitude, allowing precision elevation measurement along a profile on the ground.

2.1 The Digital-Elevation Model

A digital-elevation model (DEM) is a data set containing topographic elevations at regularly spaced points on the ground. Known also as a digital terrain model and a topographic grid, these data have become broadly available for use in mapping and scientific analyses. A typical DEM might consist of an array of elevations in a grid of 30-m ground spacing, forming an M by N array covering a rectangular ground area. In some cases, the spatial units are geographic coordinates of latitude and longitude, so that spacing depends upon latitude and the map projection. The DEM and the alternative triangulated irregular network, in which the elevations are irregularly spaced and linked in a data structure with their nearest neighbors in a Delaunay triangulation, are the two major means by which elevation data are made available for topographic mapping and analysis. A Delaunay triangulation is a subdivision of an area into triangles such that the circumcircle of every triangle does not contain any vertex in the triangulation, and which is optimal in that narrow triangles are eliminated.

Worldwide coverage of bathymetry and land topography by DEM is available at 5 min of arc from the National Geophysical Data Center, and at about 1 km from the United States Geological Survey. Otherwise, coverage is national, and a complete survey is available on the World Wide Web at http://www.geo.ed.ac.uk/home/ded.html.

The United States has a particularly rich set of DEMs available. At the 1:250 000 map scale, and with a DEM resolution of 3 arc sec, the whole country is mapped in arrays covering 1° by 1° of arc. About half of the nation is available at the 30-m resolution. Examples of the two data sets are shown in Plate 2.

Sources of DEM data vary. Some comes from digitized contour maps, but the majority comes from the stereo models used to rectify large-scale maps to planar geometry, particularly the 1:24 000 topographic maps and the 1:12 000 Orthophoto quadrangles. Bathymetry has come from the detailed sounding data available from side-scan sonars. Accurate topography is often maintained as a military secret, usable for targeting in particular the cruise missile, and for navigating submarines. Detailed global bathymetric data released by the U.S. Navy in 1995 is an example.

The DEM has many advantages for the topographic analyst. Using the array as the basis for calculations, computation of surface aspect and slope is simple, and image-processing methods can be used for the detection of features and for further operations. The recent Geographic Information System technology (see CARTOGRAPHY) has been especially suitable for these operation.

2.2 Cartographic Depiction of Topography

Since the early origins of cartography, depiction of the land surface features has been a challenge for map makers. The oldest maps show mountains as rounded "mole hills" or triangular shapes in rows or chains as they might appear from within a valley. After the fifteenth century the symbols were aligned with the line of sight and included outlines of cone-shaped and craggy pointed mountains differentiated by size, with shadowing suggested with lines with an apparent illumination. In the sixteenth century, innovative terrain depictions by Leonardo da Vinci influenced cartography toward more natural map symbology for hills and mountains. A three-dimensional appearance was achieved through slope lines and the use of shadow hachures suitable for printing using the wood-cut method. Later, copper engraving allowed for an increase of topographic content and far finer line detail.

France's national triangulation completed in 1774 by Cassini was accompanied by advances in both geodetic and topographic survey and copper-engraving map printing. A transition to a planimetric map view of topography took place near the turn of the nineteenth century. Areas of slope were depicted with the level areas left blank and hachures drawn following the rule that the greater the slope and ruggedness, the denser and darker were the lines. In 1799 the Saxon military topographer Johann Georg Lehmann developed a system called slope hachuring, with lines drawn in the direction of slope and arranged so that their end points began and ended on what were assumed to be contour lines with regular vertical intervals. Slope hachuring became the standard means of showing terrain through the nineteenth century and up until the middle of the twentieth century with apparent directional illumination (Imhof, 1982).

An alternative method for terrain depiction was invented by Edmund Halley, although earlier versions exist such as an isobath map by Pieter Buuinss in 1584. Originally used for magnetic declination, or deviation between true and magnetic north, the technique is generically called the isoline method, but for topography it is called contour mapping for elevation or isobaths for depths. Contour lines are imaginary lines that represent the intersections that arise from horizontally slicing up landforms into equal vertical intervals. Contour lines are measured up from a base datum, while the lines measured down from the datum are called depth contours or isobaths. The vertical height difference between contours is called the contour interval. Contours have an immense advantage over other methods because they record and convey the geometric form of the terrain including numerical elevations and the angles and directions of slopes, though their interpretation can take considerable skill.

The development of lithographic printing, including color printing, in 1796 and its application to printing maps in 1826 changed the ability of maps to depict topography. Hachures were changed to brown while other elements such as contours or different land surfaces could be printed in various colors. Hachures evolved into shade tones and areas printed in continuous color. During the latter part of the nineteenth century, hypsometric tints and naturalistic and symbolic landscape tints were first used. While some national mapping efforts in this era incorporated elegant shading methods, for example, in Switzerland, in most countries including the United States the contour became the standard topographic depiction method. Various attempts have been made to draw contours in such a way that they appear three dimensional, including methods by Tanaka and Yoeli (Imhof, 1982).

Block diagrams are a pictorial method that used to be used primarily for the portrayal of geologic and geophysical relationships by showing a portion of the Earth's surface and crust from an oblique viewing angle. The origins of the block diagram were eighteenth century geological reports illustrated with cross sections. Pictorial sketching was added to the section to add realism and relate the surface expression to subsurface geology. The gridded perspective map is another popular use of the block diagram for displaying surface terrain, varying viewing parameters such as azimuth, viewing height, zenith angle, and view point (Plate 3).

2.3 Empirical Findings

Many earth scientists have sought to describe topography quantitatively. Early efforts used descriptive parameters of elevation data, stream network branching and the terrain skeleton, and spectral analysis (Warntz, 1975; Horton, 1945; Strahler, 1964; Pike and Rozema, 1975). More recent techniques have used methods of statistics as adjusted for topographic information, called geostatistics (Journel and Huijbregts, 1978), and in particular a statistical relationship between elevation variance and measurement-point separation called the semivariogram that uses regionalized variable theory. For surface elevation Z at points u and at a separation h,

$$2\gamma(h) = \mathrm{Var}\{Z(u + h) - Z(u)\}.$$

Topography has been found usually to conform to a simple type of the variogram, with elevation semivariance (γ) increasing to a constant value (the sill) at a particular distance (the range). Several models of this relationship have been proposed and are used in the statistical interpolation method known as Kriging (Burrough, 1986).

Alternative models of topography have used the fractal theory of Mandelbrot (Klinkenberg and Clarke, 1992). In the fractal model, variance is attributed to every level of aggregation within the terrain model, from the finest scale to the size of the whole landscape. Although the fractal model has not been effective at explaining all topography, it is an excellent model of some terrain and produces useful topographic simulations, in many cases hard to distinguish from reality.

3. HYDROLOGICAL AND SKELETAL TERRAIN TOPOLOGY

A terrain skeleton is the network of ridges and valleys partitioned by break points and extrema of slope in a piece of topography. Elements on the skeleton are termed "very important points" and include peaks, the bottoms of depressions, ridge and break lines, and break points along the drainage system. The terrain skeleton is identified in order to perform further analysis, such as drainage patterns or hillshading. Lines that divide up topography are called skeletal lines, structure lines, or break lines and have been used to improve the visual interpretation of hill and mountain shapes and to increase the fidelity of DEMs. The terrain skeleton has been used as a constructional aid in the representation of terrain in both manual and automated methods. Topographic skeleton features can be automatically extracted from a digital elevation model, from digitized photogrammetric data, or from topographic maps.

Geomorphologists have conducted considerable research on topographic skeletons as a way of syntactically modeling terrain. Significant features in the skeleton reduce to pits, peaks, passes, ravines (vertical surfaces), and ridges (Fig. 3). These locations define also critical points in modeling the behavior of surface water in hydrologic modeling (Band, 1986; Douglas, 1986; Mark, 1975; Woldenberg, 1969).

GLOSSARY

Bathymetry: The topography of the ocean floor, including a surface of depths representing measurements of distances from the

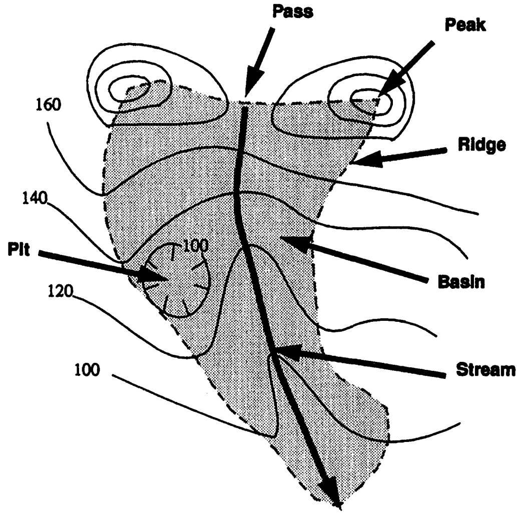

FIG. 3. Features of the terrain skeleton.

surface defined by the datum to the upper surface of the ocean floor.

Contour: A line on a map joining points of equal topographic elevation.

Datum: A reference level used to measure surface elevation, often sea level or a model of the Earth's shape such as an ellipsoid.

Digital Elevation Model: A data set containing topographic elevation measurements, usually in the form of a grid and for an *M* by *N* rectangular array.

Geoid: A more complex Earth shape model, including measured deviations from an ellipsoid.

Oblate Ellipsoid: A model of the Earth's surface shape, the locus of an ellipse rotated in space about its shorter axis.

Relief: The highest minus the lowest topographic elevation within a defined region.

Terrain Skeleton: The network of surface extrema, ridge, and stream and break lines that define a syntax for topography and partition the surface into homogeneous facets.

Topography: The spatial expression of a field variable in geographic space as a single-valued function, usually the outer or maximum measured value.

INTRODUCTION

X-ray topography is the generic name for a family of x-ray–diffraction imaging techniques capable of providing information on the character and distribution of crystallographic defects in large, nearly perfect single-crystal materials. The lesser used, more complete name of x-ray–diffraction topography is a little more informative in that it indicates that the technique is concerned with the topography of the internal diffracting planes, i.e., local changes in spacing and rotations of these planes, rather than with external surface topography, which perhaps may be misconstrued from the shortened version of the name. An x-ray topograph is a two-dimensional image obtained by projecting the distribution of diffracted intensity in an area-filling diffracted beam, produced by a low-divergence area-filling x-ray beam incident on a single crystal set at the Bragg angle, onto a two-dimensional detector (usually high-resolution x-ray film). Local differences in diffracting power between the distorted regions around defects inside the crystal and the more perfect surrounding regions lead to local intensity variations on the topograph, which are known as x-ray topographic contrast and which constitute "images" of the defects. Since no magnification is involved, the nature of the projection imaging process enables one to correlate the relative position of an image of a defect observed on an x-ray topograph with its location inside the crystal.

Quantitative information on the character of the defect (for example, the line direction and Burgers vector of a dislocation) can be obtained by detailed interpretation of the variations in contrast obtained under different diffraction conditions. Such interpretation requires an understanding of the mechanisms of contrast formation. These mechanisms are sensitive functions of the diffraction conditions and are discussed in a separate section.

1. CONTRAST AND RESOLUTION

The real information available in an x-ray topograph is manifested in the form of contrast within the projected diffraction spot. This topographic contrast arises from differences in the intensity diffracted as a function of spatial coordinate inside the crystal. Diffracted intensity is a sensitive function of local crystal perfection. For example, under

the correct diffraction conditions, highly mosaic regions of crystal (i.e., those regions comprising small subgrains that are slightly tilted with respect to the perfect crystal) will diffract kinematically, whereas more nearly perfect regions of crystal will diffract dynamically. Kinematical diffraction is characterized by an absence of the primary extinction effects that are the essence of dynamical diffraction. These primary extinction effects, created by the interference between diffracted waves and incident waves inside the crystal, lead to an overall reduction in diffracted intensity for a perfect crystal over the mosaic crystal. Conversely, there is an increase in diffracted intensity as the degree of mosaicity increases, eventually reaching the limit of the "ideally imperfect crystal" (White, 1950). The difference between the intensities diffracted from one region of crystal that diffracts kinematically and another that diffracts dynamically is one of the ways that dislocations can be rendered visible in topography (see Sec. 5). However, the situation is not as simple as this. Even for a crystal that diffracts dynamically, the diffracted intensity is a sensitive function of the local distortion in the crystal. In addition, the type of contrast that arises from a particular type of distortion is also a function of the absorption conditions in the crystal. In Sec. 5 a brief review of contrast mechanisms that arise in topography is presented, with particular attention being paid to those mechanisms that give rise to dislocation images.

It is important to point out that the contrast from individual defects will only be clearly discernible if the spatial resolution is adequate. There is no magnification involved in topography, because no lenses (in the normal sense of the word) exist for x rays, and spatial resolution is controlled solely by geometry. The geometrical factors arise as follows. The Bragg law is defined as

$$\lambda = 2d \sin\theta, \qquad (1)$$

where λ is the x-ray wavelength, d is the spacing of the diffracting planes, and θ is the angle between the incident rays and the diffracting planes, otherwise known as the "Bragg" angle. When this equation is satisfied, possible incident and diffracted beam directions lie, diametrically opposed, on the surface of a cone with semiapex angle 90° $- \theta$, the axis of which is the active reciprocal lattice vector, **g** (i.e., the normal to the diffracting planes). This cone is known as the Bragg cone. Therefore, if an x-ray source has a finite size, which it always does, the possibility arises that at a given point in the crystal the diffracting planes will receive radiation, at the correct Bragg angle, from several different points located at different positions on the source (which produce rays lying on the surface of the Bragg cone). The locus of these points on the source is the arc defined by the intersection between the operative Bragg cone and the source surface. This acceptance of rays with, for example, a finite vertical divergence imparts a finite vertical divergence to the diffracted beam that emanates from the point of interest in the crystal, and hence gives rise to a blurring effect in the resultant "image" of the point. In fact the diffracted rays emanating from the point of interest in the crystal will lie on the arc defined by the intersection between the same Bragg cone and the detector plane (the length of this arc will, of course, be defined by the divergence angle of the accepted rays from the arc on the source). This is illustrated in Fig. 1, which shows how an image of a point **P** in the crystal, recorded with rays that emanate from points lying on the arc **abc** on the source, is spread over the arc **a′b′c′** on the detector. Therefore, the angle subtended by the longest dimension of the source in the direction perpendicular to the plane of incidence (defined by the incident and diffracted beam directions, and the active reciprocal lattice vector) is the crucial parameter that should be minimized. The amount of blurring is proportional to the distance between the crystal and detector, and can be approximately written as

$$R = SD/C, \qquad (2)$$

where R is the blurring (or the effective resolution), S is the maximum source dimension in the direction perpendicular to the plane of incidence, D is the specimen–film distance, and C is the source–specimen distance. In the plane of incidence, diffraction occurs over a finite range of angles determined by acceptance angle of the crystal in that plane, or the rocking-curve width. This finite acceptance angle means that a given point in the crystal receives radiation from a

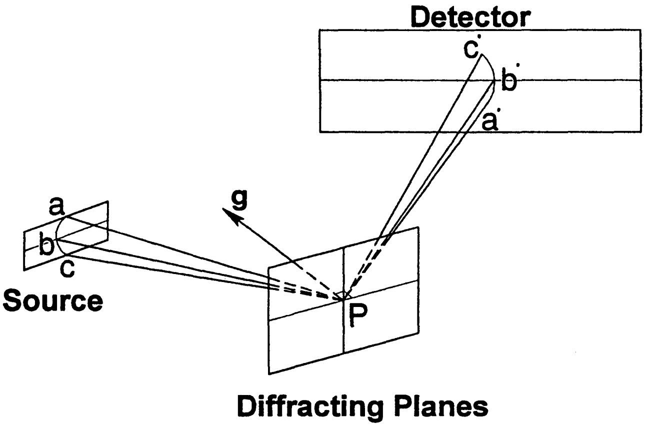

FIG. 1. Schematic diagram showing the effect of source dimension on resolution. **g** is the active reciprocal lattice vector. The angle **bPg**, which is the semiapex angle of the Bragg cone, is 90° − θ, where θ is the Bragg angle.

finite width on the source (for the case of a horizontal plane of incidence). This width can be determined by back projecting the fan of incident rays accepted at a point in the crystal to the source itself. Again a finite divergence, this time in the horizontal plane, can be attributed to the diffracted beam, and again a blurring effect will be evident. However, as can be verified by simple calculation, the limiting factor in determining spatial resolution is the finite source height (i.e., the source dimension perpendicular to the incidence plane), rather than the finite effective source width (i.e., the dimension parallel to the incidence plane).

Since the spatial resolution is proportional to the distance between the crystal and detector, this distance should be minimized. However, the optimum spatial resolution of the photographic detectors typically utilized in topography is limited, by photoelectron tracking between adjacent grains in the emulsion, to around 1 μm. The specimen–film distance is usually set to yield a calculated spatial resolution that approximately coincides with this. It should be noted that while this spatial resolution is greatly inferior to that of electron microscopy, it can be more than sufficient for the high-quality crystals of many materials that can currently be grown.

2. CONVENTIONAL RADIATION TECHNIQUES

The first techniques to be developed were designed to make use of characteristic radiation from conventional x-ray generators. These include the Berg-Barrett, Barth-Hosemann, double-crystal, and Lang techniques (for a review see Bowen and Hall, 1975). The most commonly used of these techniques is the transmission Lang technique. In this technique the crystal to be studied is set on a goniometer with the reciprocal lattice vector **g** of the intended diffracting planes lying parallel to the plane in which diffraction is to occur (usually the horizontal plane), and is then oriented for diffraction of a $K_{\alpha 1}$ characteristic line (usually from a fine-focus source, say ≈100 μm in dimension) from these planes. The resulting diffracted beam is recorded on high-resolution x-ray film. The angular resolution required to resolve this characteristic line (i.e., to separate the $K_{\alpha 1}/K_{\alpha 2}$ doublet) is usually achieved by collimation of the incident beam via an appropriately placed slit (typically a 100-μm vertical slit placed ≈50 cm from the source). This clearly results in an incident beam that has been restricted to a thin vertical "sheet" of x rays. Images recorded in this stationary configuration are known as section topographs, since under the correct conditions one can discern a cross-sectional view of the defect content of the crystal. In order to get large volume coverage, it becomes necessary to traverse the ensemble of crystal and detector in front of the incident beam. (It should be noted that the combination of drastic collimation and the necessity for translation usually leads to long exposure times, anywhere from minutes to hours, or even days). The image produced, which is essentially a two-dimensional projection of the diffracted intensity from the irradiated volume of crystal, constitutes a Lang or projection x-ray topograph. The spatial resolution attainable in the Lang technique is typically around 2 μm per centimeter of specimen–film distance.

3. SYNCHROTRON RADIATION TECHNIQUES

The advent of dedicated sources of synchrotron radiation has enabled the development of a new realm of topography, synchrotron topography. Synchrotron radiation has numerous advantages over conventional radiation when applied in topography. These advantages derive from the high brightness, tunability, and natural collimation of synchrotron radiation.

One of the most important synchrotron topographic techniques developed is white-radiation topography (Tuomi *et al.*, 1974; Miltat, 1980). This technique is basically analogous to the Laue transmission technique, except with greatly enhanced capabilities that derive from the aforementioned natural collimation and high intensity of the synchrotron beam. The natural collimation (typically $\approx 2 \times 10^{-4}$ rad in the vertical plane coupled with an acceptance angle of typically a few milliradians in the horizontal plane) allows the use of very long beamlines to maximize the area of the beam delivered at the sample without incurring significant losses in the total intensity originally available at the tangent point. This situation contrasts with that which would hold for the isotropic emission from a conventional source. The large beam area delivered at the sample location allows studies to be carried out on relatively large-scale single crystals, and crystals as large as 6 or even 12 in. (~13 or even ~25 cm) in diameter can be imaged by using precision translation stages similar to those used in the Lang technique (although exposure times are much shorter). Long beamlines also lead to small angles subtended by the source at points in the specimen, which in turn leads to excellent geometrical resolution capabilities. For example, at the Stony Brook Topography Station, on beam line X-19C at the National Synchrotron Light Source (NSLS), the optimum spatial resolution that is theoretically attainable is ≈0.04 μm per centimeter of specimen–film distance. Thus, in summary, we have in a synchrotron source a large-area x-ray beam, with inherent low divergence, and with excellent geometrical resolution capability.

Consequently, if a single crystal is oriented in this beam, and the diffracted beams recorded on a photographic detector, each diffraction spot on the resultant Laue pattern will constitute a map of the diffracting power from a particular set of planes as a function of position in the crystal with excellent point-to-point resolution (typically of the order of less than 1 μm). In other words, each diffraction spot will be an x-ray topograph.

The excellent geometrical resolution capability has another important consequence, since it relaxes to a certain extent the requirement of having very small specimen–film distances (<1 cm) in order to achieve good resolution. Thus, crystals can be surrounded with elaborate environmental chambers, necessitating considerable increases in specimen–detector distances (which would lead to intolerable resolution losses in conventional systems), without significant loss of resolution. The high intensity over the wide spectral range of the radiation emitted has several important advantages. Not only are exposure times necessary to record a topograph drastically reduced from the order of days on conventional systems to seconds on a synchrotron, but since we have a white beam, a multiplicity of images is recorded simultaneously. This leads to a great enhancement in the rate of data acquisition. The multiplicity of images also enables extensive characterization of strain fields present in the crystal. For example, instantaneous dislocation Burgers-vector analysis can become possible by comparison of dislocation images obtained on several different Laue spots (see Fig. 3, later). Similarly, lattice rotation in the specimen can be characterized by analysis of the asterism (the spreading of a Laue spot) observed on several different Laue spots. In addition, the good signal-to-noise ratios obtained associated with the high intensity also open up the possibility of direct imaging of topographs. Thus it becomes possible to conduct truly dynamic, quasi real-time studies of crystals subjected to some kind of external stimulus such as applied fields, applied stress, heating, cooling, etc.

Another important advantage of the white-beam topographic technique over conventional topographic techniques is its enhanced tolerance of lattice distortion. The wide spectral range available in the synchrotron beam allows crystals that either exhibit a uniform range of lattice orientation (for example, are uniformly bent by a small amount) or contain several regions of distinctly different orientation (for example, contain subgrains, grains, or twinned regions) or regions of different lattice parameter (for example, contain more than one phase or polytype) to be imaged in a single exposure. Analysis of Laue spot shape or Laue spot asterism (the deviation from the shape expected from an undistorted crystal) enables quantitative analysis of lattice rotation. Simultaneous measurement of the variation in diffracted wavelength as a function of position in the Laue spot—for example, using a solid-state detector—also enables determination of any variation in *d* spacing of the particular diffracting planes. For those crystals that contain several regions of distinctly different orientation, so-called orientation contrast becomes evident whereby the two neighboring regions of crystal separated by the boundary (twin boundary or grain boundary, for example) give rise to diffracted beams that travel in different directions in space and to image shifts on the detector. Analysis of the directions of these diffracted beams from the measured image shifts can enable the orientation relationships between the two regions of crystal to be established, leading to, for example, determination of twin laws. An example of a diffraction pattern recorded from a ZnTe single crystal containing twins is shown in Fig. 2. The surface of the crystal is (111). Detailed analysis of the orientation relationships between the segments of the various diffraction spots enables the twin operation to be defined as a 180° rotation about [1$\bar{1}$1].

By comparison, in the conventional topographic case, the maximum tolerable range of misorientation is defined by the convolution of characteristic linewidth with the beam divergence. Since both of these quantities are small (typical linewidths are of the order of 10^{-3} Å, equivalent to an angular divergence of approximately 100 arc sec, and typically, beam divergences must be less than approximately 20 arc sec, in order to obtain the necessary angular resolution in the plane of incidence), misorientations greater than a few arc seconds lead to the situation where only part of the crystal fulfills the diffracting condition at a given time. In other words, Bragg contours are produced. These contours delineate those regions of the crystal that are in the diffracting condition from those that are not. Since their presence means that there are regions not set for diffraction, effectively there are blind spots in the crystal. Clearly this is a very undesirable situation if dynamic-type studies in large single crystals are to be conducted. Similar problems are encountered in monochromatic synchrotron radiation topography.

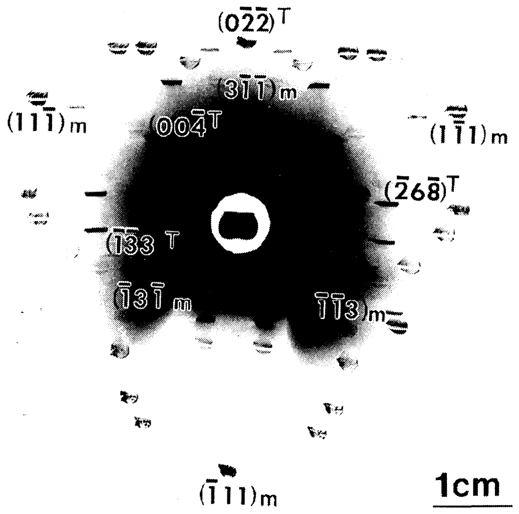

FIG. 2. Synchrotron white-beam diffraction pattern, recorded in transmission geometry (specimen–film distance 10 cm), from a twinned zinc telluride crystal. The pattern is partially indexed, with subscripts **m** and superscripts **T** indicating reflections from matrix and twin regions, respectively.

Contrast mechanisms operative in white-beam topography are largely similar to those that are operative in Lang topography (see Sec. 5), with some notable subtle differences (Hart, 1975). Some of these differences are due to the fact that in white-beam topography one can have the added complication of harmonic contamination (the presence of several orders of diffraction in a single diffraction spot), which may lead to a situation where more than one contrast mechanism operates in a single topograph. Harmonic contamination can, however, be avoided by judicious choice of diffraction geometry. In the following section a review of basic contrast mechanisms, pertinent to both Lang and white-beam topography, is presented.

4. MECHANISMS OF CONTRAST FORMATION

Apart from those defects that separate domains having different orientation, so that the domains themselves give rise to orientation contrast of the kind illustrated in Fig. 2 (simply arising from regions of differing orientation giving rise to diffracted beams that travel in different directions), the kinds of defects that can be imaged in x-ray topography are basically restricted to those that give rise to measurable differences in diffracted intensity. These include those giving rise to localized strains—for example, dislocations and precipitates—and those consisting of boundaries that either have a localized strain field associated with them or give rise to phase shifts in the x-ray wave fields propagating in the crystal—for example, stacking faults, rotational twin boundaries, mirror twin boundaries, subgrain and grain boundaries, and growth-sector boundaries. Among the defects not observable by x-ray topography are point defects.

For those defects having a strain field associated with them, the mechanism of contrast formation is a sensitive function of the diffraction conditions. It is customary to classify such contrast mechanisms according to the absorption regime within which the experiment is being conducted. Absorption conditions are usually defined by determining the product of the linear absorption coefficient μ and the thickness of crystal, t, traversed by the x-ray beam, or simply μt. Generally three regimes of absorption are identified: low, intermediate, and high, corresponding to μt values of <1–2, 3–9, and ≥ 10, respectively. To appreciate contrast formation mechanisms in the intermediate- and high-absorption regimes, an understanding of the dynamical theory of x-ray diffraction is needed. Unfortunately, a detailed treatment of dynamical theory is beyond the scope of this article. Therefore, discussions of contrast formation mechanisms will be restricted to the low absorption regime. Detailed discussion of the other regimes can be found in Tanner (1976).

Topographic contrast mechanisms under low-absorption conditions are by far the simplest to understand, and it is for this reason that topographers often strive to work within this regime, preferring to avoid the more complicated dynamical effects that can arise under higher-absorption conditions. The main mechanism of contrast formation under these conditions is related to the presence or absence of primary extinction effects. As briefly mentioned earlier, in regions of crystal that diffract dynamically, primary extinction effects are operative, whereas in regions that diffract kinematically these effects are absent. The phase shifts associated with primary extinction effects lead to an overall reduction in diffracted intensity, so that the absence of primary extinction effectively leads to enhanced diffracted intensities. Consequently, if the mode of diffraction—dynamical or kinematical—varies as a function of location in the crystal, contrast should become evident according to these differences in diffracted intensity.

By way of illustration consider the distortion field around a dislocation in an otherwise perfect single crystal. It has been shown (Authier, 1967, 1970) that there is a region of crystal that surrounds the dislocation line where the distortion field is such that dynamical diffraction, along with its associated extinction effects, is no longer operative. Rather, the region behaves like a miniature mosaic crystal that is embedded in the parent crystal and that diffracts kinematically. This effect can be quantified as follows. When a crystal diffracts dynamically, it does so over a finite range of incidence angles δ, known as the perfect-crystal rocking-curve width. This range is determined by the particular diffraction conditions and is typically of the order of a few seconds of arc. Usually the divergence of the incident beam is somewhat greater than this, which means that typically only a small proportion of a given incident beam will actually undergo diffraction, with most of the incident beam passing straight through the crystal, and simply undergoing normal photoelectric absorption. However, if the undiffracted portion of the incident beam should encounter distorted regions present inside the crystal, it becomes possible that these regions be set at the correct orientation for diffraction of this portion of the beam, provided that their misorientation, or what the x-ray beam detects as a misorientation (see next paragraph), is not greater than the incident-beam divergence.

Basically, in diffraction of a monochromatic x-ray beam, there are two ways a distortion field can influence the local diffracting conditions: it can either change the spacing of the diffracting planes or change the orientation of the diffracting planes, or both. Both of these translate, as far as the incident beam is concerned, into a misorientation, as illustrated in the differential form of Braggs law,

$$\Delta\theta = \frac{\delta d}{d}\tan\theta \pm \omega, \tag{3}$$

where ω is the contribution of lattice rotation to the misorientation.

It is usual to define this misorientation with respect to some reference orientation, such as the condition for exact fulfillment of the Bragg condition. This latter misorientation is referred to as the deviation from the exact Bragg condition, $\Delta\theta$. Generally an incident beam will not initially be set exactly in fulfillment of the Bragg condition, i.e., it will start out in the perfect region of crystal with a finite deviation. Subsequently, a distortion field may give rise to a further deviation, and it is then customary to define an "effective misorientation," $\delta(\Delta\theta)$ (Authier, 1967), which is simply the change in the deviation from exact Bragg condition that is encountered by the incident beam as it traverses the crystal. If this effective misorientation is larger than the perfect-crystal rocking-curve width, yet smaller than the effective beam divergence, then the distorted region will give rise to a new diffracted beam. Further, if the distorted region is small in size, as is the case for the volume of interest surrounding the dislocation, then the region itself should diffract kinematically. In addition, since the distorted region is misoriented with respect to the parent crystal, the resulting diffracted beam will not be at the correct orientation with respect to the relevant perfect-crystal planes to undergo the primary extinction effects that are otherwise operative. As a result the diffracted beam that emanates from the distorted volume of crystal will only undergo normal photoelectric absorption on passing through the crystal and will not suffer the effective enhanced absorption associated with extinction effects to which the diffracted beams from the perfect region of crystal are subjected. Hence there is an enhancement of diffracted intensity from this volume compared to the rest of the crystal, or topographic contrast. This is known as direct or kinematical image formation. Note that in thicker crystals (μt > 3–4) the diffracted beam from the distorted region will not survive the photoelectric absorption in the crystal, and thus the effect disappears.

It should be noted that in the white-beam technique, contributions from slightly different wavelengths have to be taken into account in considering direct image formation. This requires a modification of Authier's effective misorientation formula to take energy dispersion into account. This leads to the definition of a different parameter, the "effective deviation," which can then be used to predict the size and shape of direct dislocation images on white-beam topographs (for details see Dudley *et al.*, 1995). The requirement that the divergence of the incident beam be greater than the inherent rocking-curve width of the crystal for direct image formation to be possible may not be fulfilled in some monochromatic techniques (conventional or synchrotron) where the incident beam is of very low divergence. In such cases, no direct image formation is expected, even under low μt conditions.

5. EXAMPLES OF APPLICATIONS OF X-RAY TOPOGRAPHY

5.1 Dislocation Analysis

Topography, both synchrotron and conventional, is well suited for analysis of low densities ($<10^6$ cm^{-2}) of dislocations in crystals. The restriction to low densities arises from the fact that topographic dislocation images can be anywhere from around 5 to around 15 μm wide, so that greater densities would lead to image overlap and therefore loss of information.

5.1.1 Determination of Line Direction For dislocations created by slip processes, knowledge of the line direction as well as detailed information on the Burgers vector of the dislocations is required to assign the active slip system fully. Knowledge of both line direction and Burgers vector of crystal-growth–induced dislocations is also very important in understanding their origin and for the development of strategies to reduce the density of such dislocations. The projected directions of direct images of growth dislocations have also been used very successfully to compare with line-energy calculations designed to determine why particular line directions are preferred by such dislocations in crystals (for review see Klapper, 1980).

The line direction of a dislocation can be obtained by analyzing its direction of projection on two or more topographs recorded with different reciprocal lattice vectors. The use of analytical geometry enables the line direction to be determined either directly from the measured direction of projection (see Yuan and Dudley, 1992) or indirectly by comparing calculated projected directions of expected dislocation line directions for the material of interest with the measured projection directions (see Miltat and Dudley, 1980). Such analysis is most readily carried out on direct images of dislocations, since they are the most well defined, although similar analysis can be performed on dynamical or intermediary images.

5.1.2 Determination of Burgers-Vector Direction For sufficiently low dislocation densities, standard Burgers-vector analysis, which enables the determination of the direction of the Burgers vector, is readily carried out in the low-absorption regime, using the criterion $\mathbf{g}\cdot\mathbf{b} = 0$ for invisibility of screw dislocations, and the combination of $\mathbf{g}\cdot\mathbf{b} = 0$ and $\mathbf{g}\cdot\mathbf{b}\times\mathbf{l} = 0$ criteria for invisibility of edge or mixed dislocations (where $\mathbf{b}$ is the dislocation Burgers vector, and $\mathbf{l}$ is the dislocation line direction). These criteria are also used in the analysis of transmission electron microscopy images of dislocations. An example of dislocation analysis in a single crystal of silicon is presented in Fig. 3. The dislocations shown in these figures form slip bands and were introduced as a result of bending stresses experienced during rapid thermal annealing. The surface orientation of the crystal is (111), and the dislocations shown lie in the $\bar{1}11$ slip plane. Three kinds of dislocation segment are visible in Fig. 3(a) ($\mathbf{g} = 11\bar{1}$, $\lambda = 0.68$ Å), labeled **a**, **b**, and **c**. Line-direction analysis (Miltat and Dudley, 1980) shows that segment **a** has line direction [110], while segments **b** and **c** have line directions $[0\bar{1}1]$ and [101], respectively. Segment **a** is clearly visible on the $11\bar{1}$ reflection [Fig. 3(a)], but invisible on the $\bar{1}11$ and $1\bar{1}1$ reflections [Figs. 3(b) and 3(c), respectively]. Application of the criterion $\mathbf{g}\cdot\mathbf{b} = 0$ to possible $\frac{1}{2}\langle 110\rangle$ type Burgers vectors, which lie on the $\bar{1}11$ slip plane, shows that segment **a** has Burgers vector $\frac{1}{2}[110]$, so that it is pure screw. Segments **b** and **c** also show weak contrast on the $\bar{1}11$ and $1\bar{1}1$ reflections and are also clearly part of the same dislocation loop as segments of kind **a**, so that they also must have Burgers vector $\frac{1}{2}[110]$, and are thus of 60° character (i.e., the Burgers vector makes a 60° angle with the respective line directions). Minimum contrast for the 60° segments is obtained on reflections for which the criteria $\mathbf{g}\cdot\mathbf{b} = 0$ and $\mathbf{g}\cdot\mathbf{b}\times\mathbf{l} = 0$ are both satisfied, which in this case corresponds to $\mathbf{g} = 2\bar{2}4$. Note that the incomplete disappearance of segments **a** in Figs. 3(b) and 3(c) is due to a modification of the dislocation strain field at its intersection with the crystal surface due to the effects of surface relaxation (Wu *et al.*, 1992).

5.1.3 Determination of Burgers-Vector Sense and Magnitude The determination of the actual sense and magnitude of the Burgers vector of a dislocation once the Burgers-vector direction has been determined by $\mathbf{g}\cdot\mathbf{b}$ analysis requires more detailed analysis. Chikawa (1965) developed conventional-radiation, divergent-beam techniques for the determination of the sense of both edge and screw dislocations through measurement of the sense of tilt of lattice planes surrounding the dislocation core. For the case of screw dislocations, Mardix *et al.* (1971) subsequently further developed Chikawa's divergent-beam technique to enable the magnitude of this tilt to be measured as a function of distance from the core. This could then be fitted to the corresponding theoretical expression, enabling the Burgers-vector magnitude to be determined. Si *et al.* (1996) and Dudley *et al.* (1997) recently developed two methods, one section and one projection, that are analogous to those of Chikawa and of Mardix *et al.*, but that make use of synchrotron white radiation. In these techniques the lattice tilt surrounding dislo-

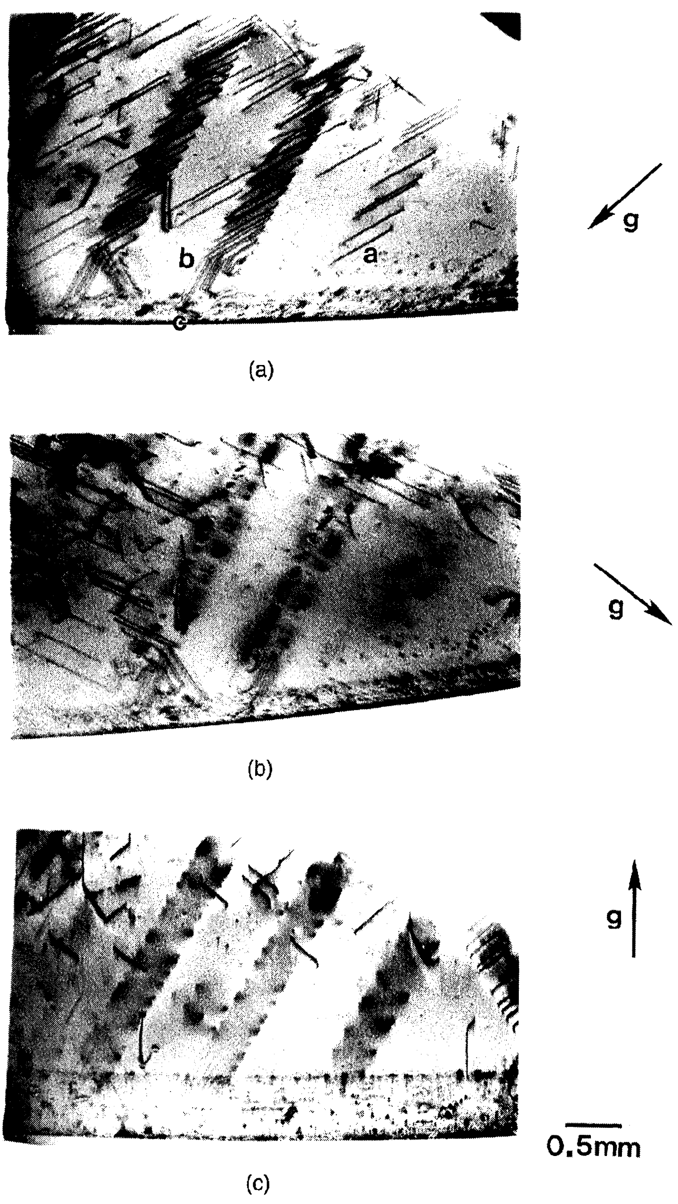

FIG. 3. Synchrotron white-beam topographs, taken from a single diffraction pattern recorded in transmission geometry (specimen–film distance 10 cm), from a silicon single crystal containing slip dislocations: (a) **g** = $11\bar{1}$, λ = 0.68 Å; (b) **g** = $\bar{1}11$, λ = 0.68 Å; (c) **g** = $1\bar{1}1$, λ = 0.68 Å. Note the disappearance of segments **a**, and the weak contrast from segments **b** and **c**, in (b) and (c).

cations of mainly screw character was measured with an accuracy that was significantly improved on account of the relaxation of the requirement for short specimen–film distances that is inevitable in conventional-radiation techniques.

A recent study of individual superscrew dislocations in 6H-SiC using synchrotron white-beam x-ray topography serves well to illustrate the principles of the two techniques. Let us consider first the projection technique, which enables the magnitude of the Burgers vector to be determined from the magnitude of the tilt of the lattice planes on both sides of the dislocation core. This simple method can be illustrated as follows: The lattice tilt ϕ around the screw dislocation, at distance r from the dislocation core, can be described by $\phi = b/2\pi r$, where b is the magnitude of the Burgers vector. In projection topographs ($\mathbf{g} = 0006$, $\lambda = 0.89$ Å) such as those shown in Figs. 4(a) and 4(b), this lattice tilt manifests itself in the form of a mutual longitudinal shift S of the two parallel components of the bimodal dislocation images (black lines), which is observable at the outcrop of the dislocations on the as-grown surface. By changing the sample-to-film distance D_{sf}, ϕ can be determined from the slope k of the linear plot of S versus D_{sf} (where $k = 4\phi$), which is shown in Fig. 4(c). Since the superscrew dislocations in this material always have groups of basal-plane dislocations attached to them, and these basal-plane dislocations have edge components, the bimodal image width of the superscrew dislocations diverges as D_{sf} increases. In order to obtain the value of r corresponding to the measured tilt angle ϕ, the width of the bimodal image is plotted as a function of D_{sf} as shown in Fig. 4(d). The image width W_0 at $D_{sf} = 0$, obtained by extrapolation, corresponds to $2r$. This enables the magnitude of the Burgers vector to be determined from the equation $b = \pi W_0 k/4$. For the dislocation shown in Figs. 4(a)–4(d), the Burgers-vector magnitude was found to be 52.6 Å, corresponding to (3–4)c (where c is the lattice constant along [0001] axis, $c = 15.17$ Å), and the sense is left-handed.

As for the section technique, this method consists of illuminating the sample by a strip of highly collimated white beam (less than 20 μm across). In this case, section topographs were recorded in symmetric transmission, i.e., using Bragg planes perpendicular to the thin crystal platelet, but that were also perpendicular to the screw dislocation.

(c) (d)

FIG. 4. The projection topographic determination of the Burgers vector of superscrew dislocations in 6H-SiC: (a) projection topograph, $\mathbf{g} = 0006$, $\lambda = 0.89$ Å, $D_{sf} = 5$ cm; (b) projection topograph, $\mathbf{g} = 0006$, $\lambda = 0.89$ Å, $D_{sf} = 17$ cm; (c) bimodal image shift S vs D_{sf}; and (d) bimodal image width W vs D_{sf}.

In such cases the lattice tilts are easily derived from the linear displacements of Bragg-diffracted beams. In principle, the lattice tilt ϕ around the screw dislocation can be described as $\phi = b/2\pi r$, where b is the magnitude of the Burgers vector, r is the distance from the dislocation core. As to the white-beam diffraction geometry, the deviation of Bragg angle $\Delta\theta_B$ would be 2ϕ. Assuming the incident beam is strictly parallel, the displacement Y recorded in the x-ray film at sample-to-film distance D_{sf} would be $Y \approx D_{sf}\Delta\theta_B$ ($\Delta\theta_B$ is very small) $= 2\ D_{sf}\phi$, thus $b = \pi Yr/D_{sf}$.

Figure 5(a) shows the lattice tilt ϕ around a screw dislocation, and Fig. 5(b) shows a white-beam section topograph of a screw dislocation, D_{sf} = 16 cm, **g** = 0006, λ = 0.89 Å. From the hyperbolas drawn on the pictures, the magnitude of the Burgers vector is 62.6 Å (upper left lobe), and 45.0 Å (lower right lobe), which again corresponds to $3c$ to $4c$ (c is the lattice constant along the [0001] axis, c = 15.17 Å).

5.2 In Situ Studies of Crystals Subjected to External Stimuli

The high intensity of synchrotron radiation sources and the subsequently short exposure times (coupled with high signal-to-noise ratios) in synchrotron white-beam x-ray topography open up the possibility of conducting such experiments in a dynamic fashion. For example, images can be recorded sequentially while crystals are being subjected to some kind of external stimulus such as heat, magnetic field, electric field, etc. Alternatively, such images can be recorded in a quasi real-time fashion, using, for example, charge-coupled device (CCD) detectors (see CHARGE-COUPLED DEVICES). In either case, information can be gathered *in situ* while the crystals are undergoing, for example, plastic deformation (see, for example, Dudley *et al.*, 1984; Wu and Dudley, 1993; Liu *et al.*, 1993, 1995a, 1995b), chemical reactions (for review, see Dudley *et al.*, 1991), or phase transitions (see, for example, Dudley and Yao, 1993). Figures 6 and 7(a)–7(e) show an example of images recorded both before and during plastic deformation, in this case induced by compressive loading of an ice bicrystal. The dislocation structures originally present, which are generated at facets $\mathbf{F_i}$, are seen to be modified, in particular via the generation and propagation of $[11\bar{2}0]$ line direction screw dislocation segments [see Liu *et al.* 1995a,b for details]. Figures 8(a)–8(d) and 9(a)–9(d) show an example of images recorded as a crystal are cycled through a phase transition, in this case in a $LaAlO_3$ crystal, which undergoes a second-order rhombohedral-to-cubic phase transition on heating through 450°C. The microstructure of the room-temperature rhom-

bohedral phase comprises a preponderance of twins. These twins are seen to disappear gradually as the rhombohedral structure gradually distorts to the high-temperature cubic structure [see Dudley and Yao (1993) for details].

6. COMPARISON WITH TRANSMISSION ELECTRON MICROSCOPY

X-ray topographic imaging is in many ways complementary to transmission electron microscopy (TEM) imaging. The principles of dark-field TEM are indeed close to those of x-ray topography. Generally speaking, both x-ray topography and TEM rely on an understanding of dynamical diffraction theory for the interpretation of contrast. Both are capable of detailed analysis of defect structures in crystals. X-ray topography, on the one hand, is capable of analyzing defects, nondestructively, in very large single crystals [wafers as large as 12 in. (25 cm) in diameter can be routinely examined, with thicknesses ranging from a few hundred microns to greater than 1 mm, depending on the x-ray absorption, for transmission geometry, and unlimited thicknesses for reflection geometry]. TEM, on the other hand, can only examine much smaller-dimension sections of either polycrystals or single crystals. Thicknesses of less than one thousand angstroms are typically required to achieve electron

transparency, while the fields of view can range from a few millimeters at low magnification to tens of angstroms at high magnification.

The relatively broad dislocation image width in x-ray topography (typically 5–10 μm), which derives from the high strain sensitivity of the technique, means that image overlap occurs for dislocation densities in the vicinity of 10^6 cm^{-2}. On the other hand, the very narrow dislocation image width in TEM (typically around 5 nm) means that dislocations cannot be resolved at low densities. This also means that dislocation densities in excess of 10^9 cm^{-2} are required to make TEM analysis realistically feasible.

GLOSSARY

Direct Dislocation Image: Dislocation image whose contrast arises from the difference in diffracted intensity between the distorted region immediately surrounding the dislocation, which diffracts kinematically, and the surrounding perfect regions of crystal, which diffract dynamically.

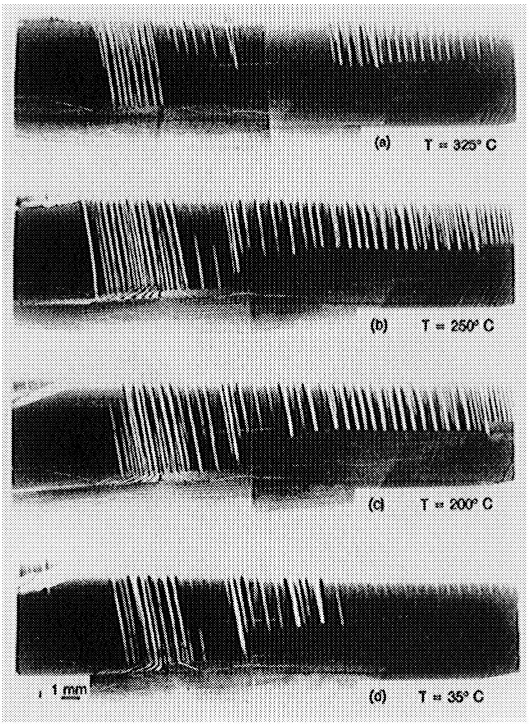

FIG. 9. Series similar to Fig. 8, recorded with decreasing temperature. For details see Dudley and Yao (1993).

Dynamical Diffraction: The kind of x-ray diffraction produced by nearly perfect crystals wherein primary extinction effects are present.

Kinematical Diffraction: The kind of x-ray diffraction produced by ideally imperfect crystals or regions of crystal wherein primary extinction effects are absent.

Mosaic Crystal: Crystal made up of small subgrains that are mutually misoriented by a small angle.

Mosaicity: The range of misorientations present in a mosaic crystal.

Orientation Contrast: Contrast resulting from the overlap or separation of parts of an x-ray topographic image arising from misorientations between adjacent regions of crystal.

Primary Extinction: Phenomenon encountered during diffraction of x rays by a nearly perfect crystal whereby interference between scattered and incident rays inside the crystal leads to an overall reduction in diffracted intensity.

X-Ray Topographic Contrast: Local intensity differences within an x-ray topographic image.

INTRODUCTION

In an article published in 1984, Sir Michael Berry (Berry, 1984) found that a quantum system undergoing adiabatic evolution acquires a phase factor of purely geometrical origin. This discovery, now called the Berry phase or the geometric phase, initiated a tremendous surge of research in a range of disciplines across physics. Berry and subsequent workers quickly established connections to a number of apparently disparate phenomena, including among others the Aharonov–Bohm effect (Aharonov and Bohm, 1959), its molecular physics analog (Mead and Truhlar, 1979), polarization optics (Pancharatnam, 1956), the quantum Hall effect (Thouless *et al.*, 1982), and the Foucault pendulum (Eco, 1989). Beyond providing a unified description of these phenomena, the geometric phase led to predictions of new effects, subsequently observed experimentally, and a number of substantial extensions and generalizations. Among these, the discovery by Hannay (1985) of an analogous effect in classical mechanics, the Han-

digital Encyclopedia of Applied Physics

nay angle, stimulated much new research in purely classical physics.

The mathematical phenomenon that underlies the geometric phase is holonomy. Holonomy describes transformations in a quantity induced by cyclic changes in the variables that control it. An example from geometry is the rotation of vectors parallel transported along closed paths on a curved surface. The mathematics of holonomy and curvature has long played a role in physics through general relativity and quantum field theory. With Berry's work came the appreciation of a broader scope of application. Whenever a physical system is divided into parts and one attempts to describe a subsystem in isolation, the influence of the excluded part of the system is manifested through geometric-phase effects. The pervasiveness throughout physics of this reductive procedure accounts for the ubiquity of the geometric phase. Introducing a collection of major articles in the field, Shapere and Wilczek (1989a) wrote, "We believe that the concept of a geometric phase, repeating the history of the group concept, will eventually find so many realizations and applications in physics that it will repay study for its own sake, and become part of the *lingua franca.*"

An introductory account of the geometric phase is given in Sec. 1. This is followed in Sec. 2 by a discussion of several theoretical developments. Applications to classical systems, optics, and molecular and condensed-matter physics are given in Secs. 3–5. The topics chosen for discussion are meant to be representative rather than comprehensive. Among several omissions, we mention the theory of fractional statistics, which is covered extensively in the volume by Shapere and Wilczek (1989a), and applications to elementary-particle physics, which are reviewed by Aitchison (1987). The historical development of the subject is discussed by Berry (1990a).

1. BASIC ACCOUNT OF THE GEOMETRIC PHASE

The geometric phase was discovered by Sir Michael Berry in 1983 in the course of a critical re-examination of the adiabatic theorem in quantum mechanics. This theorem says, in essence, that if a quantum system is changed sufficiently slowly, it does not undergo transitions. Thus a system initially in an eigenstate of a slowly changing Hamiltonian remains in the evolved eigenstate. Berry considered the overall phase accumulated by the changing eigenstate and found an unexpected contribution. This extra phase is of a geometrical nature, in that it does not depend on the rate at which the adiabatic process is carried out.

One way that a slowly varying Hamiltonian can arise physically is when the system under consideration interacts with another, much slower system. This leads to the consideration of the quite general problem of two coupled systems evolving on different time scales. In this context, the geometric phase describes an effect on the fast system produced by the slow one. As action in physics is accompanied by reaction, there is a reciprocal effect on the slow system generated by the fast. This takes the form of an effective vector potential in the slow Hamiltonian; the associated Lorentz-type force is called geometric magnetism. The same geometry underlies both geometric magnetism and the geometric phase.

This geometrical structure is intimately connected to degeneracies in the energy spectrum. A typical Hamiltonian has a nondegenerate spectrum (excepting systematic degeneracies due to symmetry, which are discussed in Sec. 2.2). Varying a single parameter (e.g., time itself in the case of a time-dependent Hamiltonian) is unlikely to produce any degeneracies; typically two or three parameters (the number depends on whether time-reversal symmetry is present or not) must be adjusted independently in order to find one. Nevertheless, the presence of degeneracies in Hamiltonians that are, in some sense, near the Hamiltonians of the adiabatic process are largely and sometimes wholly responsible for the geometric phase. This connection underlies several applications, including the quantum Hall effect (Sec. 5.3).

1.1 Quantum Adiabatic Theorem

Adiabatic invariants are quantities that are nearly conserved when the environment of an isolated system is slowly changed (slowly means in comparison with the system's internal dynamics). Adiabatic theorems provide estimates as to how accurately this conservation is respected. In quantum mechanics, the adiabatic invariants are the probabilities $P_n = |\langle n|\psi\rangle|^2$ to be in energy eigenstates. These are constant for stationary Hamiltonians but vary if H is time dependent. The quantum adiabatic theorem states that as dH/dt goes to zero, so do the probabilities of transitions between eigenstates (the rate depends on how smooth dH/dt is), so that the P_n are nearly constant. Therefore, within the adiabatic approximation, dynamics under a slowly varying Hamiltonian $H(t)$ is essentially no more complicated than under a stationary one. In particular, if $|\psi\rangle$ begins in an eigenstate, it remains in one (nonadiabatic transitions are discussed in Sec. 2.5), and its evolution is determined up to a phase factor.

We shall now examine this phase. Suppose that at $t = 0$, $|\psi\rangle$ is in the nth eigenstate $|n\rangle$ (assumed to be nondegenerate) of H. For its subsequent evolution we may write

$$|\psi(t)\rangle \approx \exp\left(-\frac{i}{\hbar}\int_0^t E_n(\tau)d\tau\right)|n(t)\rangle. \tag{1}$$

In so doing we have explicitly identified part of the overall phase, the time integral of the frequency $E_n/\hbar$, which is called the *dynamical phase.* It is just the phase one would expect for a solution of the Schrödinger equation. Any remaining phase is contained implicitly in the eigenstate $|n(t)\rangle$. This phase is determined by requiring that $\langle n|(i\hbar\partial_t - H)|\psi\rangle$ vanish [it would automatically if $|\psi(t)\rangle$ were an exact solution of the Schrödinger equation]. This requirement leads to the condition

$$\langle n|\dot{n}\rangle = 0, \tag{2}$$

which determines the phase of $|n(t)\rangle$ given an initial choice at $t = 0$.

1.2 The Geometric Phase

What Berry discovered is that condition (2) yields a path-dependent phase factor. This phase factor is particularly interesting when the Hamiltonian is cycled, i.e., made to return to itself after some time. Then it depends only on the cycle itself, and not, in contrast to the dynamical phase, on the rate at which the Hamiltonian is cycled. For this reason it is called, as well as the Berry phase, the *geometric phase.*

To discuss this further, it helps to formulate the problem slightly differently. Suppose the time dependence of the Hamiltonian is expressed through its dependence on some external parameters $\mathbf{R} = (X,Y,Z)$, which are made to vary slowly in time along a path $\mathbf{R}(t)$. Then the eigenstates $|n(\mathbf{R})\rangle$ depend on $\mathbf{R}$ as well, and (assuming no degeneracies) are determined for each $\mathbf{R}$ up to an overall phase. Let us fix this phase so that it varies smoothly but otherwise arbitrarily with $\mathbf{R}$. By fixing the phase independently of the dynamics, we may no longer satisfy the condition (2) along every path $\mathbf{R}(t)$. We therefore allow for an additional phase factor $\exp[i\gamma_n(t)]$ in the adiabatic *Ansatz* (1), which becomes

$$|\psi(t)\rangle \approx \exp\left(-\frac{i}{\hbar}\int_0^t E_n(\mathbf{R}(\tau))d\tau\right) \times \exp[i\gamma_n(t)]|n(\mathbf{R}(t))\rangle. \tag{3}$$

The condition $\langle n|(i\hbar\partial_t - H)|\psi\rangle = 0$ now yields an evolution equation for γ_n. This may be written in the form $\dot{\gamma}_n(t) = -\mathbf{A}_n(\mathbf{R}(t))\cdot\dot{\mathbf{R}}(t)$, where $\mathbf{A}_n(\mathbf{R})$ is a vector field in parameter space given by

$$\mathbf{A}_n(\mathbf{R}) = \mathrm{Im}\langle n(\mathbf{R})|\nabla n(\mathbf{R})\rangle, \tag{4}$$

or equivalently, in terms of eigenfunctions $\psi_n(\mathbf{r},\mathbf{R}) = \langle \mathbf{r}|n(\mathbf{R})\rangle$, by

$$\mathbf{A}_n(\mathbf{R}) = \mathrm{Im}\int \psi_n^*(\mathbf{r},\mathbf{R})\nabla\psi_n(\mathbf{r},\mathbf{R})d^3r$$

(here ∇ acts on the parameters $\mathbf{R}$).

If the Hamiltonian is cycled around a closed curve C in parameter space, then $|\psi(t)\rangle$ acquires a geometric phase

$$\gamma_n(C) = -\int_0^T \mathbf{A}_n\cdot\dot{\mathbf{R}}dt = -\oint_C \mathbf{A}_n\cdot d\mathbf{R}. \tag{5}$$

Its expression as a line integral reveals its geometrical character; the geometric phase depends only on the cycle C, and not on the manner in which the cycle is traversed in time. Using Stokes's theorem, γ_n can be expressed as

$$\gamma_n(C) = -\int_S \mathbf{V}_n(\mathbf{R})\cdot d\mathbf{S}, \tag{6}$$

the flux of the vector field $\mathbf{V}_n = \nabla \times \mathbf{A}_n$ through a surface S in parameter space bounded by C. $\mathbf{V}_n$ is given by

$$\mathbf{V}_n = \mathrm{Im}\langle \nabla n | \times | \nabla n \rangle. \tag{7}$$

From (6) it is evident that only cycles that enclose nonzero area can have nontrivial geometric phases. For example, $\gamma_n(C)$ vanishes for cycles consisting of a path and its retrace.

It is easy to see that the geometric phase does not depend on the choice of phase for $|n(\mathbf{R})\rangle$. Indeed, under the change of phase

$$|n(\mathbf{R})\rangle \rightarrow \exp[i\chi(\mathbf{R})]|n(\mathbf{R})\rangle, \tag{8}$$

$\mathbf{A}_n$ transforms according to $\mathbf{A}_n(\mathbf{R}) \rightarrow \mathbf{A}_n(\mathbf{R}) + \nabla\chi(\mathbf{R})$; this shift in $\mathbf{A}_n$ by a perfect gradient leaves its integral around a closed loop, $\gamma_n(C)$, and its curl, $\mathbf{V}_n$, unchanged. Thus, the geometric phase is an intrinsic property of the family of eigenstates $|n(\mathbf{R})\rangle$.

It is useful to draw an analogy with electromagnetism, in which $\mathbf{A}_n$ corresponds to the vector potential and $\mathbf{V}_n$ to the magnetic field. The geometric phase γ_n corresponds to a magnetic flux. The change of phase (8) corresponds to a gauge transformation, which shifts the vector potential by a gradient and leaves the magnetic field unchanged.

Substituting the first-order perturbation expansion

$$|\nabla n\rangle = \sum_{m \neq n} \frac{\langle m|\nabla H|n\rangle}{(E_n - E_m)} |m\rangle + \langle n|\nabla n\rangle|n\rangle \tag{9}$$

into (7) leads to a useful formula,

$$\mathbf{V}_n = \mathrm{Im} \sum_{m \neq n} \frac{\langle n|\nabla H|m\rangle \times \langle m|\nabla H|n\rangle}{(E_n - E_m)^2}. \tag{10}$$

In this form, the independence of $\mathbf{V}_n$ on the eigenstate phases is manifest. Another formula with this property is

$$\mathbf{V}_n = \mathrm{Im}\,\mathrm{Tr}(\rho_n \nabla \rho_n \times \nabla \rho_n), \tag{11}$$

where $\rho_n = |n\rangle\langle n|$ is the density operator. It too is useful in applications.

One of the applications discussed by Berry (1984) is to the Aharonov–Bohm effect (Aharonov and Bohm, 1959). The Aharonov–Bohm effect describes the dependence of quantum mechanics on electromagnetic fields in regions of space that are physically inaccessible. This dependence is mediated through the vector and scalar potentials, whose relation to the electric and magnetic fields is nonlocal. The most celebrated example concerns an electron moving in the vicinity of an impenetrable perfect solenoid of infinite extent. Since outside the solenoid the magnetic field is zero, the classical mechanics of the electron is insensitive to any magnetic flux inside the solenoid. But the quantum-mechanical behavior of the electron does depend on the interior flux, as Aharonov and Bohm showed by calculating its scattering cross section (a prediction subsequently experimentally confirmed by Chambers, 1960).

The Aharonov–Bohm effect can be understood in terms of interference between de Broglie waves passing on opposite sides of the solenoid. The phase difference between the two waves includes the integral

$$\gamma_{\mathrm{AB}} = -\frac{e}{\hbar c} \oint_C \mathbf{A}^{(s)}(\mathbf{R}) \cdot d\mathbf{R} \tag{12}$$

of the vector potential $\mathbf{A}^{(s)}$ of the solenoid around a loop C enclosing it. [In (12), c is the speed of light and $-e$ is the electron charge.] The Aharonov–Bohm phase γ_{AB} is just 2π times the magnetic flux in the solenoid measured in units of the flux quantum hc/e.

It may be regarded as a geometric phase in the following manner. We imagine the electron confined to a large box, centered at $\mathbf{R}$, which is not penetrated by the solenoid. The eigenstates of the electron $|n(\mathbf{R})\rangle$ depend parametrically on $\mathbf{R}$; specifically, changes in $\mathbf{R}$ induce gauge transformations in the eigenfunctions. One finds that $\mathrm{Im}\langle n(\mathbf{R})|\nabla n(\mathbf{R})\rangle = (e/\hbar c)\mathbf{A}^{(s)}(\mathbf{R})$, so that in this case the geometric vector potential (4) coincides with the physical vector potential of the solenoid. On being transported (not necessarily adiabatically in this case) around the solenoid, the electron eigenstates acquire a geometric phase, which is precisely the Aharonov–Bohm phase.

1.3 Two-State Systems

Two-state systems provide a canonical example of the geometric phase. The requisite calculations are easily carried out, and the main features of the general case are represented. The parametrized family of Hamiltonians can be written in the form

$$H(\mathbf{R}) = E(\mathbf{R})\mathbf{I} + \mathbf{F}(\mathbf{R})\cdot\boldsymbol{\sigma}, \tag{13}$$

where **I** is the two-by-two identity matrix and $\boldsymbol{\sigma}$ are the Pauli spin matrices. The term $E(\mathbf{R})\mathbf{I}$ shifts the energy by a constant and affects neither the eigenstates nor their geometric phases. Both of these are determined by the field $\mathbf{F}(\mathbf{R})$.

An illustrative example is a spin-$\frac{1}{2}$ particle in a uniform magnetic field $\mathbf{B}(\mathbf{R}) = \mathbf{R}$. The parameters **R** are just the components of the magnetic field, so that $\mathbf{F}(\mathbf{R}) = \mu\mathbf{R}$, where $-\mu$ is the magnetic moment. The eigenstates

$$|+(\mathbf{R})\rangle = \begin{pmatrix} \cos\theta/2 \\ e^{i\phi}\sin\theta/2 \end{pmatrix}, \quad |-(\mathbf{R})\rangle = \begin{pmatrix} -\sin\theta/2 \\ e^{i\phi}\cos\theta/2 \end{pmatrix} \tag{14}$$

depend on the polar angles (θ,ϕ) of **R**, and the energy levels $E_\pm(\mathbf{R}) = \pm\mu R$ on its magnitude. Straightforward calculation using (4) and (7) yields

$$\mathbf{A}_\pm(\mathbf{R}) = \pm\frac{1}{2}\frac{1-\cos\theta}{R\sin\theta}\hat{\phi}, \quad \mathbf{V}_\pm(\mathbf{R}) = \pm\frac{1}{2}\frac{\mathbf{R}}{R^3}. \tag{15}$$

Thus, $\mathbf{A}_\pm$ and $\mathbf{V}_\pm$ are respectively the vector potential and magnetic field of a magnetic monopole of strength $\pm 2\pi$ at the origin. Under the influence of a slowly varying magnetic field $\mathbf{R}(t)$ taken through a cycle C, a spin initially in an "up" state, say, returns to itself with a dynamical phase $-(\mu/\hbar)\int_0^T R dt$ and a geometric phase $\gamma_+(C) = -\int_S \mathbf{V}_+\cdot d\mathbf{S}$. Gauss's law implies that

$$\gamma_+(C) = -\tfrac{1}{2} \times \text{solid angle subtended by } C. \tag{16}$$

This spin-$\frac{1}{2}$ geometric phase has been observed in neutron spin-rotation experiments by Bitter and Dubbers (1987).

A special case is when C is confined to a plane containing the origin. Then its solid angle is 2π times the number of times m the origin is enclosed, and the corresponding phase factor is $(-1)^m$. This corresponds to the well-known sign change of spin-$\frac{1}{2}$ particles under rotations through 2π.

It is straightforward to generalize these results to the case of arbitrary $\mathbf{F}(\mathbf{R})$ in (13). The flux field is then given by

$$\mathbf{V}_\pm(\mathbf{R}) = \pm\tfrac{1}{2}\epsilon_{ijk}F_i\nabla F_j \times \nabla F_k/F^3 \tag{17}$$

(ϵ_{ijk} is the antisymmetric Levi–Cevita symbol), and it has monopole sources at points where $\mathbf{F}(\mathbf{R})$ vanishes. The monopoles have strength $\pm 2\pi\sigma$, where σ is the sign of the (assumed nonvanishing) determinant $\det(\partial F_i/\partial R_j)$ evaluated where $\mathbf{F} = 0$.

As is familiar from Dirac's analysis of magnetic monopoles (Dirac, 1931), attached to the monopole there is necessarily a string of singularities of the vector potential. The position of the string depends on the choice of gauge, and Dirac's quantization condition for electric charge follows from demanding that all gauges be physically indistinguishable. In the context of the two-state geometric phase, the monopole strings of $\mathbf{A}_\pm(\mathbf{R})$ lie along discontinuities in the phases of $|\pm(\mathbf{R})\rangle$. When the eigenstates are chosen as in (14), these discontinuities lie along the negative z axis. By varying the phase of the eigenstates [as in (8)], the string can be made to pass in and out of a given cycle C. As it does, the geometric phase $\gamma_\pm(C)$ changes by $\pm 2\pi$. Therefore, the geometric phase factor $\exp[i\gamma_\pm(C)]$ remains unchanged, and there are no observable consequences.

1.4 Degeneracies

In the preceding example of a spin-$\frac{1}{2}$ particle in a magnetic field, the flux fields $\mathbf{V}_\pm(\mathbf{R})$ are generated by point sources of strength $\pm 2\pi$ at the origin $\mathbf{R} = 0$. What makes the origin special is that it is the only point in parameter space where the energy levels are degenerate. This relationship between the geometric phase and energy level degeneracies turns out to be quite general.

In the absence of symmetries, a typical Hamiltonian in a parametrized family has a nondegenerate spectrum. However, at certain points in parameter space, belonging to the so-called *degenerate set,* two (or more) energy levels become degenerate. In the absence of time-reversal symmetry (the time-reversal symmetric case is discussed in the following section), the dimension of the degenerate set is typically three less than the dimension of parameter space itself (von Neumann and

Wigner, 1929). Thus, for the three-parameter families $H(\mathbf{R})$ we have been considering, degeneracies occur at isolated points. We have already seen this to be the case in the spin-$\frac{1}{2}$ example. (Note that there, the magnetic field is responsible for breaking time-reversal symmetry.)

More generally, let us consider the behavior of the flux field $V_n(\mathbf{R})$ in the neighborhood of a point of degeneracy $\mathbf{R}_*$ between two eigenstates, say the nth and $(n - 1)$st, of an arbitrary family of Hamiltonians. As $E_n(\mathbf{R}) - E_{n-1}(\mathbf{R})$ is small near $\mathbf{R}_*$, perturbation theory [cf. (9)] implies that the dominant component of $|\nabla n\rangle$ lies along the ket $|n - 1\rangle$. Therefore, for the purposes of approximating $\mathbf{V}_n$ (which is defined in terms of $|\nabla n\rangle$), the Hamiltonian can be restricted to the nearly degenerate subspace spanned by the states $|1\rangle \overset{\text{def}}{=} |n(\mathbf{R}_*)\rangle$ and $|2\rangle \overset{\text{def}}{=} |n - 1(\mathbf{R}_*)\rangle$. One obtains in this way a two-state system of the form (13), where the field $\mathbf{F}(\mathbf{R})$ is given by

$$F_x = \mathrm{Re}\langle 1|H(\mathbf{R})|2\rangle, \quad F_y = -\mathrm{Im}\langle 1|H(\mathbf{R})|2\rangle,$$
$$F_z = \frac{\langle 1|H(\mathbf{R})|1\rangle - \langle 2|H(\mathbf{R})|2\rangle}{2}. \tag{18}$$

In the neighborhood of $\mathbf{R}_*$, $\mathbf{V}_n(\mathbf{R})$ is given approximately by (17). There it has a single monopole source at the point of degeneracy $\mathbf{R}_*$ of strength $\pm 2\pi$. We may apply a similar analysis in the neighborhood of each degeneracy of $|n(\mathbf{R})\rangle$ to obtain

$$\nabla \cdot \mathbf{V}_n = \sum_{\mathbf{R}_*} \pm 2\pi\delta^3(\mathbf{R} - \mathbf{R}_*). \tag{19}$$

Thus, the flux field for the nth eigenstate has monopole sources of strength $\pm 2\pi$ at points where $|n\rangle$ is degenerate. [The sign of the monopole depends on whether the degeneracy is with the state above or below, and also on the sign of the determinant det $(\partial F_i(\mathbf{R}_*)/\partial R_j)$.] $\mathbf{V}_n$ may in addition have a purely divergenceless contribution.

It follows that the flux of $\mathbf{V}_n$ through a closed surface in parameter space is 2π times the number of degeneracies, counted with their signs, contained within.

1.5 Time-Reversal Symmetry

The presence of time-reversal symmetry imposes constraints on the geometric phase. These are strongest when the eigenstates themselves are time-reversal symmetric. We consider such cases first. Then the wave functions $\psi_n(\mathbf{r},\mathbf{R}) = \langle \mathbf{r}|n(\mathbf{R})\rangle$ can be chosen to be real, and the geometric phase factor is necessarily a sign ± 1, so that γ_n is an integer multiple of π. In this case, the geometric phase depends only on the topology of the closed curve, not on its geometry. As C is deformed, unless $\gamma_n(C)$ changes discontinuously, it necessarily remains constant. It can change (discontinuously) when C passes through degeneracies (points $\mathbf{R}_*$ where $|n\rangle$ is degenerate). For systems with time-reversal symmetry, the dimension of this degenerate set is typically two less than the dimension of parameter space (von Neumann and Wigner, 1929), so that it consists of lines in three-dimensional parameter space or points in two-dimensional parameter space. The geometric phase $\gamma_n(C)$ is π times the number of degeneracies enclosed by C, counted with the appropriate sign. An important consequence is that the flux field $\mathbf{V}_n$ has delta-function singularities at the energy-level degeneracies and is zero elsewhere.

The example of a spin $\frac{1}{2}$ in a magnetic field (cf. Sec. 1.3) provides an illustration if we fix Y (the y component of the magnetic field) to be zero. Then the spin Hamiltonian $\frac{1}{2}\mu\mathbf{B}\cdot\boldsymbol{\sigma}$ is real symmetric rather than complex Hermitian, and we can take its eigenvectors to be real. The parameter space is the XZ plane, and the solid angles subtended by curves in this plane are multiples of 2π. The geometric phase $\gamma_\pm(C)$ is just $\pm\pi$ times the number of times C encircles the origin. Another example concerns the electronic states of triatomic molecules X_3 (cf. Sec. 5.1).

In cases where the eigenstates are themselves not time-reversal symmetric, and instead occur in pairs related by time reversal, the constraints on the geometric phases are weaker. They are no longer necessarily multiples of π (i.e., the phase factors are no longer necessarily real). However, geometric phases for states related by time reversal necessarily have opposite signs.

1.6 Experimental Observation

Since the physical properties of a quantum system do not depend on its overall phase, one could wonder whether the geometric phase is observable. Numerous experiments have shown that it is.

Most direct experimental studies of the geometric phase belong to one of three types. The first is the "one state, two Hamiltonian" experiment. An ensemble of states initially in an energy eigenstate is coherently divided into two streams. The first evolves under a constant Hamiltonian, while the Hamiltonian driving the second is cyclically varied. The two streams are then recombined and allowed to interfere, and their relative phase determined. The relative phase includes both dynamical and geometric contributions, and to extract the geometric component the dynamical phase must be either made to vanish or else subtracted off explicitly. Examples include the optical polarization experiments discussed in Sec. 4.2.

The second type is the "two state, one Hamiltonian" experiment. Here an initial state $|\psi_i\rangle$ is prepared in a superposition $\alpha_i|m\rangle + \beta_i|n\rangle$ of energy eigenstates. The Hamiltonian governing the evolution is taken through an adiabatic cycle. The final state $|\psi_f\rangle = \alpha_f|m\rangle + \beta_f|n\rangle$ is physically distinguishable from the initial one, as the relative phase of the superposed eigenstates has changed. Part of this (observable) change in the relative phase involves the difference $\gamma_m - \gamma_n$ in geometric phases. The observation of optical activity in coiled fibers by Tomita and Chiao (1986) (see Sec. 4.1) provides an example of this second type.

In the third type of experiment, the adiabatic cycle is performed not once but repeatedly, with period T. With each cycle, $|n\rangle$ acquires a phase $\phi_n = -\int_0^T E_n(\mathbf{R}(t))dt/\hbar + \gamma_n$, so that there appears in its mean angular frequency $\omega_n = \phi_n/T$ a geometric shift $\Delta\omega_n = \gamma_n/T$. This frequency shift can be detected in spectroscopic measurements and is the basis for nuclear-magnetic-resonance studies of the geometric phase (cf. Sec. 5.2).

1.7 Geometric Magnetism

So far we have been regarding the evolution of the parameters $\mathbf{R}$ as externally prescribed. Now let us suppose the parameters of the Hamiltonian $H(\mathbf{R})$ are dynamical variables in their own right. For example, they could be the coordinates of a heavier (and therefore slower) system to which the original one, the fast system, is coupled. For definiteness, we take the Hamiltonian of the coupled system to be of the form $\mathbf{P}^2/2M + H(\mathbf{R})$, where $\mathbf{P}$ is the momentum of the slow system, and the dependence on the fast coordinates and momenta is left implicit in $H(\mathbf{R})$. Both systems are to be treated quantum mechanically. The geometric phase describes an effect on the fast system due to the slow. There is a corresponding influence on the slow system due to the fast.

This is the natural setting for the Born–Oppenheimer approximation, in which the fast and slow systems are the electrons and nuclei of a molecule. (For consistency with the preceding discussion, we denote the nuclear coordinates by a single vector $\mathbf{R}$; it is easy to adapt the notation to accommodate more than one nucleus.) By assuming that the electronic state adjusts rapidly to changes in the nuclear configuration, one is led to look for approximate eigenfunctions of the form $\Psi_n(\mathbf{r},\mathbf{R}) = \phi_n(\mathbf{R})\psi_n(\mathbf{r},\mathbf{R})$, where the electronic wave function $\psi_n(\mathbf{r},\mathbf{R})$ is an eigenstate with energy $E_n(\mathbf{R})$ of the electronic Hamiltonian $H(\mathbf{R})$, in which the nuclear coordinates appear as parameters. The nuclear wave function $\phi_n(\mathbf{R})$ is an eigenstate of the nuclear Hamiltonian $-\hbar^2\nabla^2/2M + E_n(\mathbf{R})$; the electronic energy plays the role of a potential. The Born–Oppenheimer approximation consists of neglecting the relatively slow dependence of the electronic wave function $\psi_n(\mathbf{r},\mathbf{R})$ on the nuclear coordinates. [It is essentially the adiabatic approximation (1) adapted to coupled systems.]

This was the context for the seminal work of Mead and Truhlar (1979). The primary objective of this work, which anticipated certain aspects of the geometric phase, was to derive corrections to the Born–Oppenheimer approximation. Such corrections appear when the momentum operator $\mathbf{P} = -i\hbar\nabla$ is applied to the putative eigenstate $\phi_n(\mathbf{R}) \times |n(\mathbf{R})\rangle$. The result, $-i\hbar(\nabla\phi_n|n\rangle + \phi_n|\nabla n\rangle)$, is no longer proportional to the electronic eigenstate $|n(\mathbf{R})\rangle$. However, if we neglect electronic components orthogonal to $|n\rangle$, we obtain $-i\hbar(\nabla\phi_n + \langle n|\nabla n\rangle)|n\rangle$, which is. The effect on the nuclear Schrödinger equation is to redefine the momentum operator,

$$\mathbf{P}\phi \overset{\text{def}}{=} (-i\hbar\nabla + \mathbf{A}_n)\phi, \tag{20}$$

where $\mathbf{A}_n(\mathbf{R})$ is given by (4). Thus, the field whose line integral gives the electronic geometric phase appears as a vector potential in the nuclear Hamiltonian. There it corresponds to an effective magnetic field $\mathbf{V}_n = \nabla \times \mathbf{A}_n$ that modifies the nuclear dynamics. This is called *geometric magnetism.*

The situation described above is quite general. Whenever there are two coupled systems evolving on different time scales, we can obtain an approximate description of the slow system by averaging over the fast motion. There appears in the slow dynamics an effective vector potential and associated magnetic field. The vector potential and magnetic field are precisely the fields whose line integrals and fluxes describe the geometric phase. (In cases where the coupling involves not only the slow coordinates but the slow momenta as well, this description has to be modified somewhat.)

Geometric magnetism is responsible for a variety of phenomena. Mead and Truhlar (1979) analyzed its effects in nuclear rotation–vibration spectra, which have since been observed experimentally (cf. Sec. 5.1). These effects can be nontrivial even when time-reversal symmetry is present (cf. Sec. 1.5), because of the change in sign of the electronic wave function $\psi_n(\mathbf{r},\mathbf{R})$ when the nuclear coordinates $\mathbf{R}$ are carried around a degenerate configuration. Like the magnetic field of the Aharonov–Bohm effect (Sec. 1.2), the flux field $\mathbf{V}_n(\mathbf{R})$ in this case vanishes everywhere except at these degenerate configurations, where it is singular. Mead (1980) has called this the "molecular Aharonov–Bohm effect."

Geometric magnetism survives in the classical limit. When this limit is applied to the slow system alone, it leads to geometric phase modifications of the semiclassical (Bohr–Sommerfield) quantization conditions. These are discussed by Kuratsuji and Iida (1985), Wilkinson (1984), and Littlejohn and Flynn (1992).

The situation where both the fast and slow systems are fully classical is discussed in Sec. 3.1.5. Here let us mention a simple but compelling illustration discussed by Li and Mead (1992). Let us consider the Born–Oppenheimer approximation applied to an atom rather than a molecule. The electronic energy levels $E_n(\mathbf{R})$ depend on the atom's center of mass $\mathbf{R}$, and appear as potentials in the equations of motion $M\ddot{\mathbf{R}} = -\nabla E_n + \mathbf{F}(\mathbf{R})$, along with any external force $\mathbf{F}(\mathbf{R})$. In the absence of external potentials, the energy levels are independent of $\mathbf{R}$, and $\mathbf{F} \equiv 0$; the center of mass behaves as a free particle. Now suppose the atom moves in a uniform magnetic field $\mathbf{B}$. The energy levels are still $\mathbf{R}$ independent (by translation invariance), but there now appears in the center-of-mass dynamics a Lorentz force, so that $M\ddot{\mathbf{R}} = \mathbf{F} = +Ze\dot{\mathbf{R}} \times \mathbf{B}$. The predictions of this analysis are spectacularly unphysical; walking through the Earth's magnetic field, you would experience a vertical force sufficient to hurl you into the air. What is missing from this analysis is the geometric magnetism from the electrons; the field $\mathbf{V}_n(\mathbf{R})$ introduces into the center-of-mass dynamics a second Lorentz force that either exactly or nearly (in case the electronic eigenstate has a nonzero magnetic moment) cancels the first.

2. THEORETICAL DEVELOPMENTS

A number of theoretical developments of the geometric phase are described. These include its mathematical setting in terms of holonomy under parallel transport, as well as several generalizations that remove the assumptions of nondegeneracy and adiabaticity.

2.1 Geometric Phase as Holonomy

Objects rigidly transported around a closed path in a curved space can return with a different orientation—this is *holonomy.* Here is a simple (and surely physical) example. Hold your right arm outstretched before you with your palm facing down. Keeping your wrist rigid, swing your arm into your chest, then raise it clockwise in front of you, and finally swing it away downward until it is outstretched before you again. Your arm has returned to its original position, but your hand has turned clockwise through 90°.

The mathematical setting for this phenomenon is the theory of connections on fiber bundles. What follows in Secs. 2.1.1–2.1.4 is an informal account of the relation between this theory and the geometric phase. No attempt is made at mathematical precision; the intention is to convey a sense of the principal ideas involved. Two references on fiber bundles oriented toward physicists are Eguchi *et al.* (1980) and Nash and Sen (1983).

2.1.1 Fiber Bundles A *fiber bundle E* is a space, or manifold, composed of two smaller ones, the *base manifold M* and the *fiber F.* The fiber bundle is constructed by attaching a copy of the fiber to each point of the base in a particular way. The simplest case, a *trivial* fiber bundle, is where E is just the Cartesian product $M \times F$ of the base with the fiber. A general fiber bundle cannot be so expressed. While it is always possible to partition it into smaller pieces that are themselves Cartesian products $M_\alpha \times F$ of subsets of the base with the fiber, these pieces may fit together in an interesting and nontrivial way, which reflects the topological properties of the bundle.

The configuration space E of an outstretched arm can be described as a fiber bundle. In this case, the base manifold M is the unit sphere, whose polar coordinates (θ,ϕ) determine the arm's direction. The fiber F is the unit circle, whose single angle coordinate χ describes the orientation of the hand relative to some reference position. In this case E is not simply the Cartesian product $M \times F$. This is because it is not possible to assign, in a continuous way, a reference hand position for every arm direction. This is a consequence of the "hairy ball theorem," i.e., the fact that it is impossible to comb flat a hairy ball without introducing singularities (e.g., crowns, cowlicks, bald patches).

As in the arm example, it is often the case in physical applications that the fiber describes internal degrees of freedom. Usually the fiber has some additional mathematical structure as well. If it is a real or complex vector space (describing spin degrees of freedom, for example), then E is called a *real* or *complex vector bundle.* If the vector space is one dimensional, E is called a *line bundle* (real or complex). Or else, the fiber might be a group (for example, the two- or three-dimensional rotation group, describing the axial or spatial orientation of a rigid body). Then E is called a *principal bundle.*

2.1.2 Connections and Curvature To a given path P on the base there correspond innumerable paths in the fiber bundle that project down to it; a motion in the base leaves the fiber motion undetermined. A *connection* is a rule for associating to P a particular path $\hat{P}$ through a given point in the bundle, the *lifted path* (see Fig. 1). A point moving along the lifted path $\hat{P}$ is said to be *parallel transported.* The connection rule is expressed in differential form by making the fiber velocity a linear function of the base velocity; this function can also depend on the base and fiber positions. For vector bundles, the dependence on fiber position should be linear as well. There are analogous restrictions in the case of principal bundles. In physical applications, a particular connection is often suggested by kinematical or dynamical considerations, e.g., moving your arm without unnecessarily twisting your wrist.

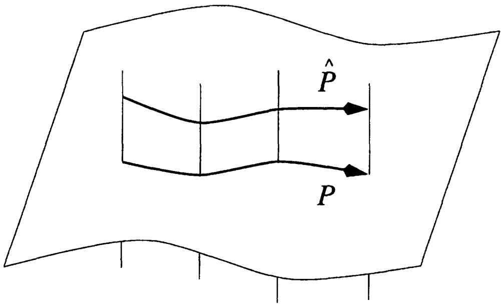

FIG. 1. A path P on the base manifold and its lift $\hat{P}$ in the fiber bundle.

Let us consider the lift $\hat{C}$ of a closed path C on the base (see Fig. 2). Its end points necessarily lie in the same fiber, but they need not coincide. If they do not, the difference between the end points is called the *holonomy* of C. In the outstretched-arm example, C is the spherical right triangle described by your arm, and its holonomy is the $\pi/2$ turn

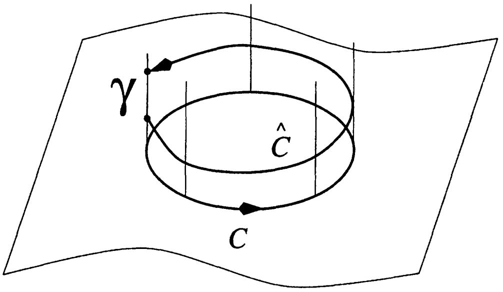

FIG. 2. A closed path C on the base manifold and its lift $\hat{C}$ in the fiber bundle. The difference between the end points of $\hat{C}$, a displacement within a single fiber, is the holonomy of C.

of your hand that results from traversing it in the manner prescribed. In case there is holonomy for arbitrarily small closed paths, the connection is said to have *curvature.* Curvature describes the infinitesimal holonomy acquired around an infinitesimal closed path, and may be expressed in terms of derivatives (a generalized curl) of the connection.

Let us consider a very simple example. We take the base M to be three-dimensional Euclidean space $\{\mathbf{R} \in \mathbb{R}^3\}$, the fiber F to be one-dimensional complex vector space $\{z \in \mathbb{C}\}$, and the bundle E to be their Cartesian product $\{(\mathbf{R},z) \in \mathbb{R}^3 \times \mathbb{C}\}$. Thus E is a trivial complex line bundle. A connection specifies the fiber velocity $\dot{z}$ as a function of the fiber position z, the base position $\mathbf{R}$, and the base velocity $\dot{\mathbf{R}}$; the dependence on z and $\dot{\mathbf{R}}$ is linear. The general form of such a relation is given by $\dot{z} = [\mathbf{W}(\mathbf{R})\cdot\dot{\mathbf{R}}]z$, where $\mathbf{W}(\mathbf{R})$ is a complex vector field. $\mathbf{W}$ is called the connection form, or simply the connection.

Given a motion $\mathbf{R}(t)$ in the base, its lifted motion in the fiber is given by $z(t) = \exp(\int_{\mathbf{R}(t)}\mathbf{W}\cdot d\mathbf{R})z_0$, where z_0 denotes the initial position in the fiber of the lifted path. If $\mathbf{R}(t)$ describes a closed path, then its holonomy is the scalar factor $\exp\Gamma$, where $\Gamma = \oint_{\mathbf{R}(t)}\mathbf{W}(\mathbf{R})\cdot d\mathbf{R}$. Using Stokes's theorem, we may express Γ as the flux of a vector field $\mathbf{V} = \nabla \times \mathbf{W}$ through a surface S bounded by C. $\mathbf{V}$ is the curvature of the connection $\mathbf{W}$.

Of particular relevance to the geometric phase is the case in which the connection preserves the length $|z(t)|$ of vectors along the lifted path. Then the connection is said to be *Hermitian.* The connection form $\mathbf{W}$ is purely imaginary and may be written as $i\mathbf{A}$, where $\mathbf{A}(\mathbf{R})$ is real.

2.1.3 The Geometric Phase Revisited

Simon (1983) observed that the Berry phase finds its natural mathematical expression as the holonomy of a connection on a fiber bundle. The fiber bundles in question are the complex line bundles $E^{(n)}$ associated with nondegenerate eigenstates of a quantum Hamiltonian $H(\mathbf{R})$. The base manifold is the parameter space (we continue to assume this to be $\mathbb{R}^3$), and the fibers are vectors $|\psi\rangle$ in Hilbert space that satisfy the Schrödinger equation $[H(\mathbf{R}) - E_n(\mathbf{R})]|\psi\rangle = 0$; these are just the unnormalized nth eigenstates, related to each other by a complex scalar.

Given an eigenstate $|\psi\rangle$ of $H(\mathbf{R})$, a connection determines an eigenstate $|\psi\rangle + |d\psi\rangle$ of the nearby Hamiltonian $H(\mathbf{R} + d\mathbf{R})$ by fixing its norm and phase. On physical grounds it is sensible to require that the connection conserve probability, i.e., that $|\psi\rangle + |d\psi\rangle$ and $|\psi\rangle$ both have unit norm. This implies that $\mathrm{Re}\langle\psi|d\psi\rangle = 0$. The simplest rule for fixing the phase of $|\psi\rangle + |d\psi\rangle$ is to take $\mathrm{Im}\langle\psi|d\psi\rangle = 0$ as well. This determines completely a connection on $E^{(n)}$, which is defined by the relation

$$\langle\psi|d\psi\rangle = 0. \tag{21}$$

Under parallel transport around a closed path C, an eigenstate $|\psi\rangle$ acquires a phase factor $\exp(i\gamma_n)$. This phase factor, the holonomy of C, is precisely the geometric phase factor. This follows by noting that the connection (21) is just the condition (2) derived from adiabatic evolution.

There is an exact mathematical analogy between the outstretched arm and a variant of the spin example of Sec. 1.3. If a spin-1 (instead of a spin-$\frac{1}{2}$) particle, initially in its "down" state, is driven by a magnetic field that is slowly cycled around a closed path C, then its geometric phase γ_1 is precisely the turn in the hand of an arm describing the same circuit. Both are equal to the solid angle subtended by C.

2.1.4 Chern Classes

Some fiber bundles are trivial Cartesian products $M \times F$, and others are not. Topology lies at the root of this distinction, and *characteristic classes* make this distinction precise. They describe an intrinsic twistedness in fiber bundles that cannot be combed away. Bundles whose characteristic classes are the same can be smoothly transformed into one another; bundles whose characteristic classes are different cannot.

For complex vector bundles, the characteristic classes are called *Chern classes.* The number of Chern classes is equal to the dimension of the fiber. The rth Chern class associates an integer $c_r(N)$, the *Chern number,* to every $2r$-dimensional, boundaryless subspace N of the base manifold M. Thus, the first Chern class assigns an integer $c_1(S)$ to every closed surface S in M. There are various ways to calculate Chern numbers. Among these, there are formulas in terms of integrals over the subspace N of the curvature and functions thereof.

An illustrative example is the celebrated Gauss–Bonnet theorem from classical differential geometry. The theorem states that the integral $\int_S K dS$ of the Gaussian curvature K over a closed one-sided surface S is equal to 2π times an integer χ, the Euler characteristic. The Euler characteristic is a topological feature of the surface. It is related by the formula $\chi = 2 - 2g$ to the genus g, the number of handles on S when it is regarded through a topologist's eyes as a many-handled sphere. The Gauss–Bonnet theorem can be verified immediately for the unit sphere ($K = 1$, $g = 0$). What is remarkable is the implication that $\int_S K dS = 4\pi$ for any surface smoothly deformable to a sphere, but $\int_S K dS \neq 4\pi$ for any surface (such as a torus) that is not.

The Gauss–Bonnet theorem can be formulated in terms of fiber bundles. The bundle consists of the surface S (the base) together with its tangent vectors at each of its points (the fibers). A connection is defined through the Riemannian rule for parallel transport on a curved surface. By identifying two-dimensional real tangent vectors with one-dimensional complex ones, the fiber bundle may be regarded as a complex line bundle, and its first Chern number $c_1(S)$ turns out to be $1/2\pi$ times the integral $\int_S K dS$ of the Gaussian curvature.

Returning to considerations of the geometric phase, let us consider the complex line bundles $E^{(n)}$ of quantum eigenstates, discussed in the preceeding section. Each has a single Chern class $c_1^{(n)}$ that assigns an integer to every closed surface S in parameter space. This integer is given by

$$c_1^{(n)}(S) = \frac{1}{2\pi}\oint_S \mathbf{V}_n \cdot d\mathbf{S} = \frac{1}{2\pi}\int_B \nabla \cdot \mathbf{V}_n d^3R, \tag{22}$$

where in the second equality we have used the divergence theorem; B is the three-dimensional region bounded by S. From (19), the last expression is precisely the number of energy-level degeneracies [points $\mathbf{R}_*$ where $E_n(\mathbf{R}_*) = E_{n\pm1}(\mathbf{R}_*)$] contained in S, counted with their appropriate sign (see Sec. 1.4). In terms of the electromagnetic analogy (Sec. 1.2), the Chern number is the number of magnetic monopoles in S counted with their charge. Thus, energy-level degeneracies manifest themselves in the nontrivial topology of the eigenstate line bundles $E^{(n)}$.

2.2 Degenerate Eigenstates and Non-Abelian Geometric Phases

If a system possesses a sufficient degree of symmetry, its energy levels will be degenerate. Two examples are the angular-momentum multiplets of rotationally symmetric systems, and Kramers degeneracy in systems with time-reversal symmetry and an odd number of fermions. If the symmetry persists throughout the parametrized family $H(\mathbf{R})$, then so do these degeneracies. Under a slowly varying Hamiltonian $H(\mathbf{R}(t))$, the adiabatic theorem implies that transitions to states outside a degenerate multiplet are small. However, transitions to states within the multiplet need not be, no matter how slow the variation (transitions between degenerate states cost no energy).

Wilczek and Zee (1984) generalized Berry's analysis to degenerate eigenstates. They showed that under adiabatic cycling around a closed circuit C, such states need not return to themselves up to a phase, but instead can evolve into new states within the multiplet. The transformation from initial to final states is generated by a unitary matrix $U(C)$, called the *non-Abelian geometric phase.* Non-Abelian geometric phases can be interpreted as holonomy, but of a more general sort than was considered in Sec. 2.1.3. There is a corresponding generalization of geometric magnetism.

The analysis, which runs parallel to the nondegenerate case, proceeds as follows. Let $E(\mathbf{R})$ denote an r-fold degenerate energy level whose degenerate eigenspace is spanned by an orthonormal basis $|j(\mathbf{R})\rangle$, $j = 1, 2, \ldots, r$. We consider the evolution under a slowly changing Hamiltonian $H(\mathbf{R}(t))$ of states $|\psi_j(t)\rangle$ initially equal to $|j(\mathbf{R}(0))\rangle$. Neglecting transitions to states outside the multiplet, we look for approximate solutions of the form

$$|\psi_j(t)\rangle = \exp\left(-\frac{i}{\hbar}\int_0^t E(\mathbf{R}(\tau))d\tau\right) \times \sum_{k=1}^{r} U_{jk}(t)|k(\mathbf{R}(t))\rangle, \qquad U_{jk}(0) = \delta_{jk}, \tag{23}$$

i.e., a superposition of evolving degenerate eigenstates multiplied by an overall dynamical phase factor. For the inner products $\langle \psi_k(t)|\psi_j(t)\rangle$ to be conserved in time, the $r \times r$ matrix $\boldsymbol{U}(t)$ must be unitary. Its evolution is determined by requiring $\langle k(\mathbf{R}(t))|(i\hbar\partial_t - H)|\psi_j(t)\rangle$ to vanish for each k (it would automatically if $\psi_j(t)$ were an exact solution of the Schrödinger equation). This requirement leads to the equation of motion

$$\dot{\boldsymbol{U}}(t) = -i\boldsymbol{U}(t)\mathsf{A}(\mathbf{R}(t))\cdot\dot{\mathbf{R}}(t) = -i\boldsymbol{U}(t)\boldsymbol{A}(t), \tag{24}$$

where $\mathsf{A}(\mathbf{R}) = (\boldsymbol{A}^{(1)},\boldsymbol{A}^{(2)},\boldsymbol{A}^{(3)})(\mathbf{R})$ is a vector of $r \times r$ Hermitian matrices whose matrix elements are given by

$$A_{jk}^{(l)}(\mathbf{R}) = -i\langle k(\mathbf{R})|\nabla_l j(\mathbf{R})\rangle, \tag{25}$$

and $\boldsymbol{A}(t) = \mathsf{A}(\mathbf{R}(t))\cdot\dot{\mathbf{R}}(t)$.

The solution of (24) is given by the time-ordered product

$$\begin{aligned}\boldsymbol{U}(t) &= T\exp\left(-i\int_0^t \boldsymbol{A}(\tau)d\tau\right)\\ &= \boldsymbol{I} - i\int_{0<\tau<t} \boldsymbol{A}(\tau)d\tau\\ &\quad - \iint_{0<\tau<\tau'<t} \boldsymbol{A}(\tau)\boldsymbol{A}(\tau')d\tau d\tau' + \cdots,\end{aligned} \tag{26}$$

where $\boldsymbol{I}$ is the $r \times r$ identity matrix. The time ordering indicates that in expanding the exponential of the integral, all matrices are to be ordered with later times to the right. If the matrices $A(\tau)$ at different times commute with each other, then the ordering of the factors is irrelevant, and the right-hand side of (26) simplifies to

$$\begin{aligned}&\boldsymbol{I} - i\int_{0<\tau<t} \boldsymbol{A}(\tau)d\tau - \left[\int_{0<\tau<t} \boldsymbol{A}(\tau)d\tau\right]^2\Big/2! + \cdots\\ &\quad = \exp\left(-i\int_0^t \boldsymbol{A}(\tau)d\tau\right),\end{aligned}$$

i.e., simply the exponentiated integral. In particular, if $r = 1$, then $A(\tau)$ is a scalar, and $U(t)$ is a phase factor.

Suppose the Hamiltonian is taken around a closed cycle C. Then the relation between initial and final states is described, apart from the dynamical phase factor, by the unitary matrix

$$\boldsymbol{U}(C) = T\exp\left(-i\oint_C \mathsf{A}(\mathbf{R})\cdot d\mathbf{R}\right). \tag{27}$$

$\boldsymbol{U}(C)$ is the non-Abelian geometric phase. The terminology derives from the fact that the factors $\mathsf{A}(\mathbf{R})\cdot d\mathbf{R}$ in the time-ordered product do not in general commute. They do, however, in the nondegenerate case $r = 1$; then $U(C)$ is just the ordinary (Abelian) geometric phase factor $\exp[i\gamma(C)]$. Like the ordinary geometric phase, $U(C)$ depends only on the path C and not on the rate at which it is traversed.

For infinitesimal circuits, $U(C)$ is of the form $\boldsymbol{I} + i\Gamma(C)$, where $\Gamma(C)$ is an infinitesimal Hermitian matrix given by (minus) the flux of the covariant curl of A,

$$\mathsf{V} = \nabla \times \mathsf{A} - i\mathsf{A} \times \mathsf{A}, \tag{28}$$

through the infinitesimal area bounded by C. (Note that because the components of A are matrices, the cross product $\mathsf{A} \times \mathsf{A}$ does not vanish, just as the cross product $\boldsymbol{\sigma} \times \boldsymbol{\sigma} = i\boldsymbol{\sigma}$ of Pauli matrices does not vanish.) This result does not extend to finite circuits, though, as there is no non-Abelian version of Stokes's theorem.

Like the ordinary geometric phase, $U(C)$ may be interpreted as holonomy, but now on a complex r-dimensional vector bundle rather than a line bundle. The base manifold is parameter space ($\mathbb{R}^3$ in the examples considered here), and the fibers are the degenerate eigenspaces spanned by $|j(\mathbf{R})\rangle$. The matrix-valued vector field $\mathsf{A}(\mathbf{R})$ is the connection form, which describes how states in the fibers are parallel transported along paths $\mathbf{R}(t)$ in the base. $\mathsf{V}(\mathbf{R})$ is the associated curvature form.

The non-Abelian geometric phase does not depend on the choice of basis $|j(\mathbf{R})\rangle$ in any intrinsic way. Under a unitary change of basis

$$|j(\mathbf{R})\rangle \rightarrow |\bar{j}(\mathbf{R})\rangle = \sum_{k=1}^{r} W_{jk}(\mathbf{R})|k(\mathbf{R})\rangle, \tag{29}$$

the non-Abelian version of the gauge transformation (8), $\boldsymbol{U}(C)$ transforms according to $\boldsymbol{U}(C) \rightarrow \boldsymbol{W}\boldsymbol{U}(C)\boldsymbol{W}^{\dagger}$. This unitary conjugation represents simply the change of basis applied to $\boldsymbol{U}(C)$ and leaves its observable properties unchanged. The fields A(**R**) and V(**R**) transform according to

$$\mathsf{A} \rightarrow W\mathsf{A}W^{\dagger} - i\nabla W W^{\dagger}, \quad \mathsf{V} \rightarrow W\mathsf{V}W^{\dagger} \qquad (30)$$

under (29). These transformation properties characterize the potential and field strength of Yang–Mills field theories, generalizing the electromagnetic analogy with the geometric phase (cf. Sec. 1.2) to the non-Abelian case.

Given a particular closed circuit C, one can choose the basis $|j(\mathbf{R})\rangle$ so as to diagonalize $U(C)$. Then under parallel transport around C, each basis state returns to itself up to a phase factor. Under certain conditions, one can find a basis that diagonalizes every non-Abelian geometric phase, regardless of C. In such cases, the degenerate and nondegenerate cases are essentially the same. In general, though, there is no choice of basis that renders every $U(C)$ diagonal. What distinguishes the general case is that the generators of the symmetries responsible for the degeneracies depend on parameters themselves. A particular example, the Λ-doubling of electron doublets in diatomic molecules, is discussed by Moody *et al.* (1986).

The discussion of geometric magnetism in the Born–Oppenheimer approximation (cf. Sec. 1.7) can also be generalized to the degenerate case. As before, we regard the parameters **R** as the coordinates of a slow system to which the original one, the fast system, is coupled. The Hamiltonian is given by $P^2/2M + H(\mathbf{R})$, where **P** is the slow momentum, and the dependence on the fast coordinates and momenta is left implicit in $H(\mathbf{R})$. We look for approximate eigenfunctions of the coupled system in which the fast system belongs to a degenerate multiplet of $H(\mathbf{R})$. These are of the form $\Psi(\mathbf{r},\mathbf{R}) = \Sigma_{j=1}^{r}\phi_j(\mathbf{R})\psi_j(\mathbf{r},\mathbf{R})$, where $\psi_j(\mathbf{r},\mathbf{R}) = \langle \mathbf{r}|\, j(\mathbf{R})\rangle$ are the fast eigenfunctions (which depend parametrically on the slow variables **R**). Substituting this *Ansatz* into the stationary Schrödinger equation and making approximations similar to those in the nondegenerate case (the details are omitted), one sees that the slow system is described by a multicomponent wave function $\phi(\mathbf{R}) = (\phi_1(\mathbf{R}), \ldots, \phi_r(\mathbf{R}))$ that is an eigenfunction of the matrix-valued Hamiltonian

$$\boldsymbol{H} = (\mathbf{P}\boldsymbol{I} - \mathsf{A})^2/2M + E(\mathbf{R})\boldsymbol{I}. \qquad (31)$$

Here A(**R**) is the matrix-valued vector potential of (25) and $\boldsymbol{I}$ is the $r \times r$ identity matrix. Thus, coupling to a degenerate fast eigenstate introduces a generalized form of geometric magnetism, in which the slow Hamiltonian acquires spin degrees of freedom that are coupled to a Yang–Mills-like field.

Finally, there is a connection between the non-Abelian geometric phase and higher-order degeneracies, i.e., points in parameter space where two or more degenerate levels coalesce. These points act as generalized monopole sources for the Yang–Mills field V.

2.3 Nonadiabatic Evolution

Geometric phases appear in contexts other than adiabatic evolution. An important generalization was found by Aharonov and Anandan (1987), who showed that geometric phases accompany any cyclic evolution, not necessarily adiabatic, of a quantum state. Subsequently, Samuel and Bhandari (1988) showed that geometric phases can arise in evolutions that are nonunitary, not cyclic, and not even continuous. What underlies these generalizations is a natural prescription for the parallel transport of quantum phase factors.

The setting for the Aharonov–Anandan phase is quite general. A state $|\psi(t)\rangle$ evolves according to the Schrödinger equation $[i\hbar\partial_t - H(t)]|\psi\rangle = 0$ under a (usually) time-dependent Hamiltonian $H(t)$. After a time T the state is presumed to return to itself up to a phase factor, so that $|\psi(T)\rangle = \exp(i\beta)|\psi(0)\rangle$. In the trivial case where H is time independent and $|\psi\rangle$ is an eigenstate, β is simply the dynamical phase $-ET/\hbar$. Guided by this simple case, we are led to subtract from β a generalized dynamical phase, namely, the time integral of the expectation value of energy,

$$\beta_d = -\frac{1}{\hbar}\int_0^T \langle\psi|H|\psi\rangle dt = \mathrm{Im}\int_0^T \langle\psi|\dot{\psi}\rangle dt. \qquad (32)$$

The phase that remains, $\beta_g \overset{\mathrm{def}}{=} \beta - \beta_d$, is given by

$$\beta_g = \beta - \beta_d = \arg\langle\psi(0)|\psi(T)\rangle - \mathrm{Im}\int_0^T \langle\psi|\dot{\psi}\rangle dt. \qquad (33)$$

What makes the decomposition $\beta = \beta_d +$

β_g of the total phase interesting is that β_g is, in a sense to be explained, a geometric phase. First, β_g depends only on the path through Hilbert space described by $|\psi(t)\rangle$ and not on the rate at which this path is traversed. Indeed, the state $|\tilde{\psi}(t)\rangle = |\psi(\tau(t))\rangle$ traverses the same path but, because of the time reparametrization $t \to \tau(t)$, at a different rate. However, it is easy to verify that its geometric phase β_g, as given by (33), is the same as that of $|\psi(t)\rangle$, even though its dynamical phase is different. [Note that $|\tilde{\psi}(t)\rangle$ might not even satisfy the Schrödinger equation.] Second, β_g does not depend on the overall phase of $|\psi(t)\rangle$. Indeed, if in (33) $|\psi(t)\rangle$ is replaced by $|\tilde{\psi}(t)\rangle = \exp[i\phi(t)]|\psi(t)\rangle$, a simple calculation shows that β_g is unchanged.

As $|\psi(t)\rangle$ is periodic up to a phase, the density matrix $\rho_\psi(t) = |\psi(t)\rangle\langle\psi(t)|$ is strictly periodic, and over the time interval $0 < t < T$ describes a closed curve C in the space of density matrices. What the preceding discussion shows is that β_g is a geometric property of C. It does not depend on the rate at which C is traversed, and it can be computed with (33), substituting any state $|\tilde{\psi}(t)\rangle$ whose density matrix $|\tilde{\psi}(t)\rangle\langle\tilde{\psi}(t)|$ is equal to $\rho_\psi(t)$.

The geometric phase for adiabatic cycles can be obtained as a special case of (33). Within the adiabatic approximation, a solution to the Schrödinger equation for a slowly cycled Hamiltonian $H(\mathbf{R}(t))$ is given by $|\psi(t)\rangle = \exp[i\beta(t)]|n(\mathbf{R}(t))\rangle$ [cf. (3)]. From (32), the dynamical phase β_d is given by $-(1/\hbar)\int_0^T E_n(\mathbf{R}(t))dt$. The geometric phase is easily computed from (33) if $|\tilde{\psi}(t)\rangle = |n(\mathbf{R}(t))\rangle$ is substituted for $|\psi(t)\rangle$ (this is permissible, since the two states differ by an overall phase). Since $\arg\langle n(\mathbf{R}(0))|n(\mathbf{R}(T))\rangle = 0$, β_g is given by $-\mathrm{Im} \int_0^T\langle\tilde{\psi}|\dot{\tilde{\psi}}\rangle dt = -\mathrm{Im}\oint\langle n(\mathbf{R})|\nabla n(\mathbf{R})\rangle\cdot d\mathbf{R}$, in agreement with (5).

What underlies this general setting for the geometric phase is once more the mathematics of connections and fiber bundles. However, now the entire Hilbert space is to be regarded as a fiber bundle! The base manifold $\bar{\mathcal{H}}$ consists of all pure-state density matrices ρ, normalized so that $\mathrm{Tr}\rho = 1$. (This is sometimes called the *projective* Hilbert space.) The fiber attached to ρ consists of all state vectors $|\psi\rangle$ whose density matrices $|\psi\rangle\langle\psi|$ are equal to ρ. (Thus, states in the same fiber differ only by a phase factor.) To an infinitesimal displacement $d\rho$ in the base, there corresponds displacements $|d\psi\rangle$ in the fiber satisfying $|\psi + d\psi\rangle\langle\psi + d\psi| = \rho + d\rho$. With a little algebra, this reduces to $|d\psi\rangle - \langle\psi|d\psi\rangle|\psi\rangle = d\rho|\psi\rangle$. This equation does not determine $|d\psi\rangle$ uniquely; to any solution $|d\psi\rangle$ can be added an infinitesimal imaginary component $id\alpha|\psi\rangle$ along $|\psi\rangle$. A connection fixes this component and determines a particular $|d\psi\rangle$ for a given $d\rho$. A natural choice is to require that

$$\langle\psi|d\psi\rangle = 0. \tag{34}$$

This connection is precisely the condition (2) found by Berry for adiabatic cycles, but now generalized to arbitrary cycles in Hilbert space. Its holonomy is precisely the geometric phase β_g given by (33).

This setting admits further generalizations (Samuel and Bhandari, 1988). For example, one can calculate a geometric phase for a nonunitary evolution $|\phi(t)\rangle$, for which $\langle\phi|\phi\rangle$ is no longer constant, simply by evaluating (33) with $|\psi(t)\rangle \overset{\text{def}}{=} |\phi(t)\rangle/\langle\phi|\phi\rangle^{1/2}$.

In fact, one can calculate a geometric phase for an open path $|\psi(t)\rangle$, where $|\psi(T)\rangle$ and $|\psi(0)\rangle$ are no longer proportional. The formula (33) for β_g can be computed for open paths, and the result does not depend on the parametrization in time of $|\psi(t)\rangle$, and remains unchanged by the change of phase $|\psi(t)\rangle \to \exp[i\phi(t)]|\psi(t)\rangle$. Further insight into the interpretation of the geometric phase for open paths is given in Sec. 2.4.

There is also a discrete version of the formula (33). Given a sequence of states $|\psi_1\rangle$, $|\psi_2\rangle, \ldots |\psi_N\rangle$, one can associate a phase according to the formula

$$\beta_g = \arg\langle\psi_1|\psi_2\rangle\langle\psi_2|\psi_3\rangle \ldots \langle\psi_N|\psi_1\rangle. \tag{35}$$

One sees easily that β_g does not depend on the overall phases of the states $|\psi_j\rangle$. If there are just two states, then $\beta_g = \arg|\langle\psi_1|\psi_2\rangle| = 0$ identically. But if $N > 2$, the phase β_g is typically nonvanishing. Note that $|\psi_N\rangle$ need not be proportional to $|\psi_1\rangle$; the sequence of states need not close on itself.

The formula (35) is the discrete analog of (33), and defines a geometric phase for discontinuous evolutions. Thus, a geometric phase can be defined for processes that include measurements and wave-function collapse. A version of formula (35) appears in

Pancharatnam's study of optical polarization dynamics, in which the $|\psi_j\rangle$ represent polarization states. Pancharatnam's phase is discussed in Sec. 4.2.

2.4 Geometric Metric Tensor

How close are two quantum states $|\psi\rangle$ and $|\phi\rangle$? The usual quantum mechanical measure of distance is the Hilbert-space norm $\langle\psi - \phi|\psi - \phi\rangle^{1/2}$ of their difference. There is another, introduced by Provost and Vallee (1980), namely, the quantity $s^2(\psi,\phi) \overset{\text{def}}{=} 1 - |\langle\psi|\phi\rangle|^2/\langle\psi|\psi\rangle\langle\phi|\phi\rangle$. Clearly, this vanishes if the states are the same. What distinguishes it from the Hilbert-space norm is that it is unchanged if either $|\psi\rangle$ or $|\phi\rangle$ is multiplied by a complex scalar. In fact, what this quantity really describes is the distance between their normalized density matrices $\rho_\psi = |\psi\rangle\langle\psi|/\langle\psi|\psi\rangle$ and $\rho_\phi = |\phi\rangle\langle\phi|/\langle\phi|\phi\rangle$, and indeed can be alternatively expressed as $1 - \text{Tr}\rho_\psi\rho_\phi$. For infinitesimally displaced states $|\phi\rangle = |\psi + d\psi\rangle$, a little algebra gives

$$\begin{aligned} ds^2(d\psi) &\overset{\text{def}}{=} s^2(\psi, \psi + d\psi) = 1 - \text{Tr}(\rho_\psi\rho_{\psi+d\psi}) \\ &= \tfrac{1}{2}\,\text{Tr}(d\rho_\psi^2) = \frac{\langle d\psi|I - \rho_\psi|d\psi\rangle}{\langle\psi|\psi\rangle}, \qquad (36) \end{aligned}$$

where $d\rho_\psi = \rho_{\psi+d\psi} - \rho_\psi$ and I is the identity operator. Equation (36) defines a metric on the space of normalized density matrices $\bar{\mathcal{H}}$ (or equivalently, the projective Hilbert space).

The quantum metric enters into the analysis of the geometric phase in a number of interesting ways. Below we describe two aspects: a deeper understanding of the geometric phase for open paths and physically significant corrections to the Born–Oppenheimer approximation.

The quantum metric determines geodesics, i.e., curves $\rho(s)$ that minimize, or at least render stationary, the distance between two given density matrices in $\bar{\mathcal{H}}$. These are most easily described in terms of their corresponding state vectors; it may be shown that if $|\psi(s)\rangle$ satisfies the differential equation $d^2|\psi\rangle/ds^2 + |\psi\rangle = 0$, and if the vectors $|\psi(0)\rangle$ and $|\psi'(0)\rangle$ are normalized and orthogonal to one another, then the curve $\rho_\psi(s) = |\psi(s)\rangle\langle\psi(s)|$ is a geodesic with respect to the metric (36), and the parameter s along the curve is the arc length. [The solutions $|\psi(s)\rangle$ are of the form $\cos s|\psi(0)\rangle + \sin s|\psi'(0)\rangle$.]

A simple illustration is provided by two-state systems. In this case, $\bar{\mathcal{H}}$ may be identified with the unit sphere (in the context of polarization optics, this is the Poincaré sphere—see Sec. 4.2); each density matrix ρ may be expressed in the form $(I + \mathbf{\hat{e}}\cdot\boldsymbol{\sigma})/2$, where $\mathbf{\hat{e}}$ is a unit vector and $\boldsymbol{\sigma}$ are the Pauli matrices. The quantum metric (36) reduces to the usual metric on the sphere (up to a scalar factor), and the geodesics are the arcs of great circles.

As discussed in Sec. 2.3, geometric phases can be defined via (33) for open as well as closed paths in $\bar{\mathcal{H}}$. The two cases may be related as follows. An open path P may be closed by joining its end points with a geodesic. The resulting closed path, it turns out, has the same geometric phase as P. The geometric phases for continuous and discontinuous evolutions, (33) and (35), may be similarly related; given a closed sequence of density matrices $\rho_1, \rho_2, \ldots \rho_N, \rho_1$, we can construct a closed polygonal path $\rho(s)$ in $\bar{\mathcal{H}}$ by connecting its points with geodesics. $\rho(s)$ turns out to have the same geometric phase as the discrete sequence ρ_j.

The quantum metric also plays a role in the Born–Oppenheimer description of the dynamics of a slow system coupled to a fast one (cf. Sec. 1.7). There it appears in the slow Hamiltonian as an additional scalar potential $\Phi_n(\mathbf{R}) = \Sigma_\alpha ds^2|\nabla_\alpha n(\mathbf{R})\rangle/2M$, which produces a "geometric electric" force. The scalar potential appears at a higher order of adiabatic expansion than the vector potential $A_n(\mathbf{R})$; with appropriate scalings, the geometric magnetic force $\dot{\mathbf{R}} \times \mathbf{V}_n$ is of the order of the square root $\sqrt{m/M}$ of the mass ratio of the fast and slow systems, whereas the geometric electric force $-\nabla\Phi$ is of the order m/M. However, the electric force can become significant in the vicinity of degeneracies $\mathbf{R}_*$ [i.e., points where the fast energy level $E_n(\mathbf{R})$ becomes degenerate]. There the force is repulsive and so tends to steer the slow dynamics away from points where the Born–Oppenheimer approximation would break down. A discussion of the scalar potential can be found in the reviews of Berry (1989) and Jackiw (1988). Additional terms in the slow dynamics of comparable order to geometric electricity have also been found by Weigert and Littlejohn (1993).

2.5 Beyond Adiabaticity

2.5.1 Corrections to the Geometric Phase For the adiabatically cycled eigenstates described by Eq. (3), the dynamical and geometric phases are but the first two terms in an asymptotic expansion for the total phase. An elegant iterative scheme for evaluating higher-order corrections was developed by Berry (1987c). These corrections to the geometric phase turn out to be geometric phases themselves. The full asymptotic series diverges in a manner that reveals the breakdown of the adiabatic approximation.

The method is illustrated by the example of a spin-$\frac{1}{2}$ particle in a magnetic field (cf. Sec. 1.3). We consider a time-dependent Hamiltonian $H_0(\tau) = \mu\mathbf{B}_0(\tau)\cdot\boldsymbol{\sigma}$, cyclic over the infinite time interval $[-\infty,\infty]$ with $\mathbf{B}_0(\pm\infty) = B_*\hat{\mathbf{z}}$. $\mathbf{B}_0(\tau)$ is assumed to be analytic, and we assume as well that $B_0(\tau) \geq B_{\text{min}}$ for all τ, so that the Hamiltonian does not pass through any degeneracies. $\tau = \epsilon t$ is a dimensionless time, and ϵ a small parameter (with dimensions of frequency) describing the slow rate of change of the Hamiltonian. (The corresponding dimensionless small parameter is $\delta = \epsilon\hbar/\mu B_{\text{min}}$.) Let us consider the evolution of a spin state $|\psi(t)\rangle$ with initial condition $|\psi(-\infty)\rangle = |-\rangle$. The analysis is facilitated by transforming to a rotating frame in which the direction $\hat{\mathbf{b}}_0$ of the magnetic field is fixed (say, for definiteness, along $\hat{\mathbf{z}}$). Such a frame is described by a rotation matrix $\mathcal{R}_1(\tau)$ satisfying

$$\hat{\mathbf{b}}_0(\tau) = \mathcal{R}_1(\tau)\cdot\hat{\mathbf{z}}. \tag{37}$$

This condition does not determine $\mathcal{R}_1(\tau)$ uniquely, but only up to a rotation (applied from the left) about $\hat{\mathbf{b}}_0$. Differentiating with respect to τ (this is denoted by an overdot), we obtain a condition

$$\dot{\hat{\mathbf{b}}}_0(\tau) = \boldsymbol{\omega}_1(\tau)\times\hat{\mathbf{b}}_0(\tau) \tag{38}$$

on the angular velocity $\boldsymbol{\omega}_1$ of the frame, where $\omega_{1i} = \frac{1}{2}\Sigma_{jkl}\epsilon_{ijk}\mathcal{R}_{1kl}\dot{\mathcal{R}}_{1jl}$ (ϵ_{ijk} is the antisymmetric Levi–Cevita symbol). (38) does not determine $\boldsymbol{\omega}_1$ uniquely, but only up to its component along $\hat{\mathbf{b}}_0$. We fix this indeterminacy (and the corresponding indeterminacy in $\mathcal{R}_1$) by requiring that

$$\boldsymbol{\omega}_1\cdot\hat{\mathbf{b}}_0 = 0. \tag{39}$$

(39) is a condition for parallel transport, analogous to the requirement of moving your arm without unnecessarily twisting your wrist (cf. Sec. 2.1).

In the rotating frame, the Hamiltonian $H_1(\tau)$ is given by $\mu\mathbf{B}_1(\tau)\cdot\boldsymbol{\sigma}$, where

$$\mathbf{B}_1(\tau) = B_0(\tau)\hat{\mathbf{z}} - \mathbf{B}_{L1}(\tau) \tag{40}$$

is the effective magnetic field. $\mathbf{B}_{L1}(\tau) = \epsilon\hbar/\mu\mathcal{R}_1^{-1}(\tau)\cdot\boldsymbol{\omega}_1(\tau)$ is the Larmor field induced in the rotating frame (the magnetic analog of the Coriolis force). As the rotation is slow, the Larmor field is small (of order ϵ), and in the lowest-order adiabatic approximation (cf. Secs. 1.1 and 1.2), it is simply neglected. Then $H_1(\tau)$ is diagonal, and the time-dependent Schrödinger equation is easily solved. The geometric phase $\gamma_-(C_0)$, half the solid angle of the cycle C_0 described by $\mathbf{B}_0(\tau)$, appears as a direct consequence of the parallel transport condition (39) when the solution is transformed back to the fixed frame.

If the Larmor field is not neglected, then $\mathbf{B}_1(\tau)$ may be regarded as a slowly varying magnetic field to which the above procedure may be applied as before. That is, we transform to a second rotating frame $\mathcal{R}_2(\tau)$ in which $\hat{\mathbf{b}}_1(\tau)$ is fixed along z. The frame is uniquely determined by imposing the parallel-transport condition $\boldsymbol{\omega}_2\cdot\hat{\mathbf{b}}_1 = 0$, where $\boldsymbol{\omega}_2$ is the angular velocity of the frame $\mathcal{R}_2$. Note that because $\hat{\mathbf{b}}_1$ differs from $\hat{\mathbf{z}}$ by terms of order ϵ, the angular velocity $\boldsymbol{\omega}_2$ is of order ϵ. In this second frame, $H_2(\tau) = \mu\mathbf{B}_2(\tau)\cdot\boldsymbol{\sigma}$, where the effective magnetic field $\mathbf{B}_2(\tau)$ is given by $B_1(\tau)\hat{\mathbf{z}} - \mathbf{B}_{L2}(\tau)$, with $\mathbf{B}_{L2}(\tau) = (\epsilon\hbar/\mu)\mathcal{R}_2^{-1}(\tau)\cdot\boldsymbol{\omega}_2(\tau)$. The new Larmor field $\mathbf{B}_{L2}$ is of order ϵ^2.

It is easy to see that this procedure can be iterated; we can transform through successive rotating frames $\mathcal{R}_{n+1}(\tau)$ to compensate for the Larmor fields $\mathbf{B}_{Ln}(\tau)$ induced in the preceding ones. The geometric phase and its corrections emerge when the sequence of rotations is unraveled and the solution transformed back to the fixed frame. One obtains a formal series

$$\gamma_-(C_0) + \sum_{k=1}^{\infty}\gamma_-(C_k), \tag{41}$$

in which the corrections to the geometric phase are themselves geometric phases; $\gamma_-(C_k)$ is half the solid angle of the cycle C_k described by $\mathbf{B}_k(\tau)$.

It turns out that the series (41) is divergent. Although successive cycles C_k initially decrease in extent by a factor of ϵ, asymptotically the terms $\gamma_-(C_k)$ behave as $\epsilon^k k!$, a form characteristic of divergent asymptotic series (Dingle, 1973). An optimal approximation is obtained by truncating the series at its smallest term $k \sim 1/\epsilon$, for which $\epsilon^k k! \sim \exp(-1/\epsilon)$ is exponentially small.

That the series (41) diverges can be understood on general grounds. If, on the contrary, the series converged, along with the infinite sequence of rotating frames, then upon transforming back to the fixed frame, we would obtain an exact solution $|\psi(t)\rangle$ of the Schrödinger equation that would begin and end, at $t = -\infty$ and $t = +\infty$, respectively, in the spin-down state $|-\rangle$. This would imply a vanishing transition probability $\langle +|\psi(+\infty)\rangle$. But it is known that, with the exception of some special Hamiltonians, the transition probability is not zero, but instead [for $\mathbf{B}_0(\tau)$ analytic] is exponentially small, of order $\exp(-1/\epsilon)$ (Dykhne, 1962). These exponentially small transitions (the subject of the following section) signal the ultimate failure of the adiabatic approximation and cannot be captured by the iterative scheme. It follows that this scheme must inevitably diverge.

2.5.2 The Geometric Amplitude Adiabatic evolution is an approximation. For typical slowly varying Hamiltonians $H(\tau)$, where $\tau = \epsilon t$, no matter how small the rate of change ϵ, there are transitions between evolving eigenstates. The transition probability vanishes as ϵ goes to zero, and if H depends analytically on τ, it does so exponentially rapidly (faster than any power of ϵ).

In a study of adiabatic evolution in two-state systems, Berry (1990b) found that this transition probability may contain a geometric factor. The setting is similar to that of Sec. 2.5.1. We consider a two-state Hamiltonian $H(\tau) = \mathbf{R}(\tau)\cdot\boldsymbol{\sigma}$, where $\mathbf{R}(\tau)$ is analytic in the dimensionless time $\tau = \epsilon t$ and is nonvanishing for real τ. As $\tau \to \pm\infty$, $\mathbf{R}(\tau)$ approaches limiting values $\mathbf{R}_{\pm *}$, which need not coincide, so that $\mathbf{R}(\tau)$ need not be closed. From (3), the adiabatic solution for the up state is given by $|\psi(t)\rangle = \exp[i\delta_+(t) + i\gamma_+(t)] \times |+(\mathbf{R}(\tau))\rangle$, where the eigenstates $|\pm(\mathbf{R})\rangle$ are given by (14) and the evolving dynamical and geometric phases $\delta_+(t)$ and $\gamma_+(t)$ are given explicitly by

$$\delta_+(t) = -\frac{1}{\epsilon\hbar}\int_0^\tau R(\tau)d\tau,$$

$$\gamma_+(t) = -\tfrac{1}{2}\int_0^\tau (1-\cos\theta)\dot{\phi}d\tau. \qquad (42)$$

Here (R,θ,ϕ) denote the polar coordinates of $\mathbf{R}(\tau)$, and the overdot denotes the derivative with respect to τ. We have used (15) for the vector potential $\mathbf{A}_+(\mathbf{R})$.

Nonadiabatic transitions may be attributed to roots of $R(\tau)$ in the complex τ plane. The dominant contribution to the transition amplitude comes from the root τ_c closest to the real axis. [We assume that τ_c is a simple zero of $R^2(\tau)$, so that it is a square-root branch point of $R(\tau)$.] Davis and Pechukas (1977) showed that the transition amplitude may be obtained by analytically continuing the adiabatic solution around the branch point τ_c. [Under this continuation, the up and down states $|+(\mathbf{R}(\tau))\rangle$ and $|-(\mathbf{R}(\tau))\rangle$ are interchanged.] The transition probability $P_{+-} = |\langle -(\mathbf{R}(\infty))|\psi(\infty)\rangle|^2$ is given by a product of factors $\exp(-2|\Delta_+|)\exp(2\Gamma_+)$, whose exponents are obtained from the analytical continuation of the dynamical and geometric phases. Explicitly, we have that

$$\Delta_+(t) = \frac{2}{\hbar\epsilon}\,\mathrm{Im}\int_0^{\tau_c} R(\tau)d\tau,$$

$$\Gamma_+ = -\tfrac{1}{4}\,\mathrm{Im}\oint \cos\theta\, d\phi. \qquad (43)$$

In the expression for Γ_+, the contour is taken around the cut joining τ_c and its complex conjugate τ_c^*.

The factor $\exp(\Gamma_+)$ is the geometric amplitude. It depends only on the cycle followed by $\mathbf{R}(\tau)$, not on the slowness parameter ϵ nor on $\hbar$. It can be shown to vanish if $\mathbf{R}(\tau)$ lies in a plane, or if $\mathbf{R}(\tau)$ can be rotated into itself about an axis through the origin. Thus it vanishes for the well-known Landau–Zener model $\mathbf{R}(\tau) = (a,a,A\tau)$ (Zener, 1932), for which $\mathbf{R}(\tau)$ describes a vertical line. A simple example with nonzero geometric amplitude is $\mathbf{R}(\tau) = (a\cos(\omega\tau^2), a\sin(\omega\tau^2), A\tau)$. It describes a helix on the cylinder of radius a, which winds for $\tau < 0$ and unwinds for τ

> 0. For this curve Γ_+ is given by $-a^2\omega \operatorname{sgn} A/A^2$.

The geometric amplitude was observed by Zwanziger *et al.* (1991) in a nuclear-magnetic-resonance experiment (cf. Sec. 5.2). A time-dependent spin Hamiltonian with the requisite properties was generated by applying a modulated rf magnetic field to a sample of spin-$\frac{1}{2}$ nuclei, and the induced magnetization was observed in a rotating frame. The logarithm of the transition probability P_{+-} was plotted as a function of the slowness parameter ϵ. Theory predicts that this plot should be linear (because of the dynamical amplitude) with a nonzero intercept (due to the geometric amplitude). This behavior was confirmed in the experiment, with good quantitative agreement between the observed and predicted values of Γ_+.

3. CLASSICAL SYSTEMS

Following Berry's discovery of the geometric phase, Hannay (1985) found an analogous phenomenon in classical mechanics. Adiabatically cycled classical oscillators undergo a shift in their phase of oscillation. Part of this shift is simply the time integral of the frequency. But there appears in addition a purely geometrical contribution, now known as the Hannay angle. The Hannay angle includes and generalizes such well-known phenomena as the precession of the Foucault pendulum. In many cases it may be directly observed. The Hannay angle emerges as the classical ($\hbar \to 0$) limit of the Berry phase (in cases where chaos is absent from the classical dynamics). In the context of coupled systems, it leads to classical geometric magnetism in the slow dynamics.

Shapere and Wilczek (1989b–1989d) studied phenomena in classical kinematics similar to the Hannay angle. A simple example is the manner in which falling cats and platform divers change their spatial orientations through a cycle of internal motions. Provided their (conserved) angular momentum is zero, the change in their orientation does not depend on the rate at which the internal motions are performed. Classical geometric phases of this type have been investigated systematically by Marsden, Montgomery, and co-workers (Marsden *et al.*, 1991; Marsden, 1992) as part of a general theory of Hamiltonian dynamics with symmetry.

3.1 The Hannay Angle

3.1.1 The Classical Adiabatic Theorem

Imagine a swinging pendulum slowly shortened to half its original length. During this process, is anything conserved, either exactly or approximately? This question is addressed by the classical adiabatic theorem. While energy is not conserved (work is being done), there is an approximately conserved quantity, namely, the classical adiabatic invariant, or the *action.*

The classical adiabatic theorem is most simply described for systems of one degree of freedom, and so we concentrate on this case. The dynamics in the two-dimensional phase plane is described by Hamilton's equations $\dot{q} = \partial_p H$, $\dot{p} = -\partial_q H$. The classical Hamiltonian $H(q,p,\mathbf{R})$ is taken to depend on a vector $\mathbf{R}$ of parameters (like the quantum Hamiltonians of Sec. 1). If these are held fixed, then energy is conserved, and orbits lie on contours of H. Let us assume that the motion is bounded, so that the energy contours are closed. The orbits go around them periodically with oscillation frequency $\omega = (\partial_E I)^{-1}$, where

$$I(E,\mathbf{R}) = \frac{1}{2\pi}\int_{H(q,p,\mathbf{R})\leq E} dq\,dp \tag{44}$$

is the action. Apart from the factor of 2π, the action is just the area enclosed by the orbit of energy E. If the parameters vary in time, then energy is no longer conserved. However, if the variation is slow compared to the oscillation frequency ω, then the action (44) is nearly conserved, and the variation of the energy is determined implicitly by

$$I(E(t),\mathbf{R}(t)) = I_0 \overset{\text{def}}{=} I(E(0),\mathbf{R}(0)). \tag{45}$$

This is the classical adiabatic theorem.

In higher dimensions, the classical adiabatic theorem generalizes provided the dynamics is either *integrable* or *ergodic.* Integrable systems are characterized by a high degree of symmetry. They possess N independent constants of the motion (where N is the number of degrees of freedom), which are in involution (that is, the Poisson bracket between any pair of them vanishes). Typical orbits in an integrable system execute periodic or quasiperiodic motion on N-dimensional tori embedded in the $2N$-dimensional phase space, and the equations of motion may be solved more or less explicitly. In sharp contrast stand ergodic systems, for which energy is the only constant of the motion. Typical orbits cover the $(2N - 1)$-dimensional energy surface uniformly, so that time averages and microcanonical ensemble averages coincide. The adiabatic theorems in higher dimensions are rather more difficult to state and considerably harder to prove. The difficulty is related to the fact that the adiabatic invariants are not so well conserved as in the one-dimensional case (Lochak and Meunier, 1988).

3.1.2 Basic Account of the Hannay Angle The classical adiabatic theorem (45) determines the time evolution of the energy of a one-dimensional oscillator under a slowly changing Hamiltonian. Hannay (1985), motivated by Berry's analysis of the quantum geometric phase, asked a more refined question: What is the evolution of the phase of the oscillator?

To frame this question precisely we introduce canonical coordinates, the *action–angle variables* (θ,I). These are related to (q,p) by a canonical transformation $q = q(\theta,I,\mathbf{R})$, $p = p(\theta,I,\mathbf{R})$ that depends on parameters. The action I, the generalized momentum, determines the energy of the oscillator according to (44). The angle θ, the generalized coordinate, describes the phase of the oscillator, and varies periodically around the orbit in the phase plane with period 2π. Expressed in terms of action–angle variables, the Hamiltonian $H(I,\mathbf{R})$ is independent of θ, so that the canonical equations of motion, $\dot{\theta} = \partial_I H$, $\dot{I} = -\partial_\theta H$, imply that I is constant while θ evolves at a constant frequency $\omega \overset{\text{def}}{=} \partial_I H$.

Now suppose the parameters $\mathbf{R}$ of the Hamiltonian are taken slowly around a closed cycle C, returning to their original values $\mathbf{R}(0)$ after a time T. Since the action is nearly conserved, a trajectory returns approximately to the orbit, or contour of $H(I,\mathbf{R}(0))$, on which it started. Of course, it will be displaced by an angle $\Delta\theta$ from its initial position. Hannay obtained the two dominant contributions to $\Delta\theta$ (further corrections are of order $1/T$). The first is the *dynamical angle* $\theta_d = \int_0^T \omega(I,\mathbf{R}(t))dt$. It is simply the time integral of the frequency, taking into account its slow variation with parameters. The second, unexpected, contribution,

$$\psi_g(I,C) = -\partial_I \oint_C \mathbf{A}(I,\mathbf{R})\cdot d\mathbf{R}, \tag{46}$$

is the *geometric angle*, or the *Hannay angle*. It is expressed in terms of the line integral around C of a vector field $\mathbf{A}(I,\mathbf{R})$ given by

$$\mathbf{A}(I,\mathbf{R}) = \frac{1}{2\pi}\int_0^{2\pi} p(\theta,I,\mathbf{R})\nabla q(\theta,I,\mathbf{R})d\theta. \tag{47}$$

The Hannay angle is geometric in the same sense as is the geometric phase; it depends only on the parameter cycle C and not on the rate at which it is traversed. Using Stokes's theorem, the Hannay angle can also be expressed as the surface integral $-\partial_I\int_S \mathbf{V}(I,\mathbf{R})\cdot d\mathbf{S}$, where S is a surface bounded by C and $\mathbf{V} = \nabla \times \mathbf{A}$. From (47),

$$\mathbf{V}(I,\mathbf{R}) = \frac{1}{2\pi}\int_0^{2\pi} \nabla p(\theta,I,\mathbf{R}) \times \nabla q(\theta,I,\mathbf{R})d\theta. \tag{48}$$

As with the geometric phase, the presence of time-reversal symmetry (cf. Sec. 1.5) imposes constraints on the Hannay angle. In particular, if the orbits themselves are time-reversal symmetric (for all values of parameters), then the Hannay angle vanishes identically.

Like the geometric phase, the Hannay angle may be interpreted as the holonomy of a connection on a fiber bundle (cf. Sec. 2.1.3). The parameters $\mathbf{R}$ constitute the base manifold, and the fibers attached to them are orbits of the Hamiltonian $H(q,p,\mathbf{R})$ with given action I. These orbits are parameterized by the angle θ, and the connection $\partial_I\mathbf{A}(I,\mathbf{R})$ describes how θ changes under parallel transport.

The Hannay angle can be detected by determining the initial and final angles of an adiabatically cycled oscillator, and subtracting from their difference the dynamical angle θ_d. As θ_d depends only on the parameter cycle $\mathbf{R}(t)$, it can be computed without solving the equations of motion explicitly. In this way, Hannay's analysis, together with the adiabatic theorem (45), provides a complete asymptotic solution of the equations of motion for slowly varying Hamiltonians in one dimension. The analysis generalizes directly to integrable systems in higher dimensions, where there are as many Hannay angles as there are degrees of freedom. However, detecting them can be a more delicate matter, as the adiabatic theorem and corrections thereto become more complicated in higher dimensions (Golin *et al.*, 1989). For ergodic systems, there is no general analog of the Hannay angle, though a related holonomy phenomenon emerges in some special cases (Robbins, 1994; Jarzynski, 1995; Schroer, 1996).

3.1.3 Examples A bead moving freely around a planar wire loop provides a simple example of the Hannay angle. Suppose the bead has unit mass, and the loop has circumference C, area A, and is otherwise arbitrary in shape. While the system as a whole has time-reversal symmetry, the individual orbits do not (they are either clockwise or counterclockwise). The action I is just the velocity v, and the angle $\theta = 2\pi s/C$ is proportional to the distance s along the wire. Suppose the loop is slowly rotated once around an interior point over a time T, and let Δs denote the total distance the bead has traveled during this time. The dynamical contribution s_d (which is $C/2\pi$ times the dynamical angle θ_d) is just vT (v is the adiabatic invariant). The geometric contribution s_d may be computed to be $-4\pi A/C^2$. It accounts for the distance the bead has slipped as the wire turned. For a fixed circumference C, $-s_d$ assumes its maximal value, C, for a circular loop; in this case, the bead simply slips a full revolution. For thin, elongated loops, s_d approaches zero; the only slippage occurs at the hairpin turns.

The second example is the family of harmonic oscillators $H = (Z - X)p^2/2 + Ypq + (Z + X)q^2/2$, where the term in qp breaks time-reversal symmetry. For $X^2 + Y^2 < Z^2$, the motion is bounded and oscillatory, and we consider adiabatic cycles confined to this region of parameter space. The flux field $\mathbf{V}$ of (48) may be computed to be

$$\mathbf{V}(I,\mathbf{R}) = -\frac{I}{2}\frac{\mathbf{R}}{(Z^2 - X^2 - Y^2)^{3/2}}. \qquad (49)$$

Note that because $\mathbf{V}$ is linear in I, the Hannay angle θ_g is independent of I. θ_g may be described geometrically as follows. We regard the parameter space as three-dimensional Minkowski space, in which X and Y are spacelike coordinates, Z is timelike, and the region $X^2 + Y^2 < Z^2$ is the interior of the light cone. Then $\theta_g(C)$ is the area of the projection of the closed curve C onto the unit mass shell $Z^2 - X^2 - Y^2 = 1$.

The precession of a Foucault pendulum is yet another example of a Hannay angle. Consider a spherical pendulum initially set to oscillate in a plane. During the course of a day, the axis of gravity (whose direction represents the parameters of the pendulum) is carried once around a line of latitude α. At the day's end, the plane of oscillation has turned through an angle $2\pi(1 - \cos\alpha)$. This is just the solid angle described by the axis of gravity and may be computed as a Hannay angle using (46). Indeed, the phenomenon described by the Hannay angle is more general. If one turned the Earth about its center adiabatically (but otherwise arbitrarily) before returning it to its original orientation, the plane of oscillation of the spherical pendulum would still precess through an angle equal to the solid angle described by the Earth's axis.

The spherical pendulum is a two-degree-of-freedom system, integrable because of its axial symmetry. Therefore, it has two Hannay angles, one each for its polar and azimuthal degrees of freedom. For planar oscillations, however, only the azimuthal Hannay angle, which describes the Foucault precession, is nonzero.

Let us briefly mention two final examples drawn from plasma physics and astronomy, respectively. Littlejohn (1988) found a Hannay angle in the cyclotron oscillations of charged particles in strong magnetic fields. Berry and Morgan (1996) (see also Golin *et al.*, 1989) compute "the Hannay angle of the world," an annual displacement of the Earth along its orbit of approximately -150 m (or -2×10^{-4} arc sec) caused by the adiabatic and periodic variation of Jupiter's gravitational field.

3.1.4 Semiclassical Limit Following Hannay's work, Berry (1985) showed that the Hannay angle emerges in the semiclassical limit of the geometric phase. The precise relation between the two is given by

$$\gamma_{n+1}(C) - \gamma_n(C) \xrightarrow{\hbar\to 0, n\to\infty} -\theta_g(I,C), \tag{50}$$

in which the classical action is related to the quantum number by the semiclassical quantization condition $I = n\hbar$. Expression (50) conforms to the usual relation between quantum phases and classical angles, the most familiar instance being the relation $(E_{n+1} - E_n)/\hbar \to \omega$ between energy levels and frequencies, whose time integral connects the dynamical phase and the dynamical angle. The result (50) is derived by substituting the WBK approximation for the eigenstates $|n(\mathbf{R})\rangle$ into formula (4) for the quantum vector potential $\mathbf{A}_n$. One obtains thereby expression (47) for the classical vector potential. This analysis extends to integrable systems in more than one dimension, for which semiclassical eigenfunctions may be similarly determined.

On the other hand, for systems whose classical dynamics is chaotic, the quantum geometric phase has no classical limit in general. However, the vector field $\mathbf{V}_n$, when averaged over quantum number, does have a classical limit (Robbins and Berry, 1992), which turns out to play a role in the classical Born–Oppenheimer approximation (cf. Sec. 3.1.5). The classical limit

$$\begin{aligned}\mathbf{V}(E,\mathbf{R}) = {} & \frac{1}{2\partial_E \Omega(E,\mathbf{R})} \\ & \times \partial_E\left[\partial_E \Omega(E,\mathbf{R}) \int_0^\infty \langle \nabla H_t(\mathbf{q},\mathbf{p},\mathbf{R}) \right. \\ & \left. \times \nabla H(\mathbf{q},\mathbf{p},\mathbf{R})\rangle_E dt\right]\end{aligned} \tag{51}$$

is expressed in terms of the time integral of an antisymmetric correlation function of the parameter gradient of the Hamiltonian, $\nabla H(\mathbf{q},\mathbf{p},\mathbf{R})$. $\Omega(E,\mathbf{R}) = \int_{H(\mathbf{q},\mathbf{p},\mathbf{R})\leq E} d^N q d^N p$ denotes the phase volume inside the energy shell $H = E$, $\langle\cdot\rangle_E$ denotes the normalized microcanonical average, and ∇H_t denotes the function ∇H evolved for a time t with the classical dynamics. In one dimension, (51) is equivalent to (48).

3.1.5 Classical Reaction Forces As in Sec. 1.7, we suppose that the parameters $\mathbf{R}$ are no longer externally prescribed, but instead are the coordinates of a slow system to which the original one, the one-dimensional oscillator of Sec. 3.1.1, is coupled. Both systems are governed by classical mechanics. We take their Hamiltonian to be $\mathbf{P}^2/2M + H(q,p,\mathbf{R})$, where $\mathbf{P}$ is the slow momentum. The Hannay angle describes a holonomy in the fast dynamics induced by the slow dynamics. As in the quantum case, there is a reciprocal effect on the slow dynamics induced by the fast dynamics. This effect is found by averaging over the fast motion. According to the adiabatic theorem, the action of the fast system is nearly constant. In the lowest-order approximation, we treat the action as strictly constant. Then the energy $H(I,\mathbf{R})$ acts as a potential in the slow dynamics, whose effective Hamiltonian is given by $\mathbf{P}^2/2M + H(I,\mathbf{R})$. This is the classical analog of the Born–Oppenheimer approximation.

First-order corrections account for the fluctuations of the action about its mean. These generate an effective vector potential in the slow Hamiltonian, so that $\mathbf{P} \to \mathbf{P} - \mathbf{A}(I,\mathbf{R})$. The vector potential is precisely the field (47) whose line integral gives the Hannay angle. This is classical geometric magnetism.

One example of geometric magnetism is the precession of a symmetric top (Berry and Robbins, 1993a). In this case, the top's axis is the slow system, and the rotation about this axis is the fast system. Another example from plasma physics is the drift of the guiding center of electrons in strong, slowly varying magnetic fields (Littlejohn, 1988). The guiding center, i.e., the center of the instantaneous Larmor orbit, constitutes the slow degrees of freedom (it remains fixed in constant fields), and the motion about the guiding center, the fast degrees of freedom.

Geometric magnetism generalizes to higher-dimensional fast systems, both integrable and chaotic. In the latter case, geometric magnetism is partnered by an additional dissipative force, deterministic friction (Wilkinson, 1990); the slow dynamics is no longer conservative, as the chaotic motion of the fast system acts as an effective heat bath. The magnetic and dissipative forces appear as the antisymmetric and symmetric parts of a linear-response tensor (Berry and Robbins, 1993b; Jarzynski 1993).

3.2 Symmetry and Kinematic Geometric Phases

Kinematic geometric phases arise in systems with symmetry. They describe the evolution in degrees of freedom upon which the symmetry acts (e.g., orientational degrees of freedom in case of rotational symmetry). Their structure depends only on how the symmetry is realized and not on the details of the dynamics. The geometric character of their evolution is exactly enforced by the equations of motion and does not depend on assumptions of adiabaticity. In the following sections, two different treatments of kinematic geometric phases are described.

3.2.1 Falling Cats and Swimming Paramecia Even with nothing to push against, bodies in free fall, such as cats and platform divers, can change their orientation through internal motions. Perhaps counterintuitive at first, this phenomenon is a direct consequence of conservation of angular momentum and can be calculated as such. The main difficulty in doing so lies in the definition of the body's orientation. This problem does not arise for rigid bodies, whose every configuration is related to a chosen reference by a unique rotation. But for a body that can bend and twist and stretch, i.e., that has internal degrees of freedom, it is not clear which configurations are "upright" and which ones are "tilted."

There are various prescriptions for determining orientation. One is to refer to the orientation of the principal axes of inertia. Another is through the Eckart frame, a common convention in molecular physics. Both prescriptions have particular advantages; neither is well defined in all cases.

In fact, the structure of the solution emerges most clearly if the definition of orientation is made more or less arbitrarily. This is the point of view taken by Shapere and Wilczek (1989b). For simplicity, suppose the body consists of a finite number N of masses m_α at positions $\mathbf{r}_\alpha$. No assumption is made concerning their dynamics, except that they obey Newton's laws and that there are no external forces. By choosing a suitable reference frame, we may assume that the center of mass $\Sigma_\alpha m_\alpha \mathbf{r}_\alpha / \Sigma_\alpha m_\alpha$ begins and remains at the origin.

By some means, certain configurations $(\mathbf{R}_1, \ldots, \mathbf{R}_N)$ are designated to be "upright." This designation must be consistent, in that if two configurations are related by a rotation, then only one of them can be upright. It must also be complete, so that every configuration can be made upright by applying a rotation. If both these conditions hold, then every configuration $(\mathbf{r}_1, \ldots, \mathbf{r}_N)$ can be obtained by applying a unique rotation $\mathcal{R}$ to a unique upright configuration $(\mathbf{R}_1, \ldots, \mathbf{R}_N)$. The body's motion,

$$\mathbf{r}_\alpha(t) = \mathcal{R}(t) \cdot \mathbf{R}_\alpha(t), \qquad \alpha = 1, \ldots, N, \tag{52}$$

is then determined by the evolution of its orientation $\mathcal{R}(t)$ and its internal dynamics $\mathbf{R}_1(t), \ldots, \mathbf{R}_N(t)$. In the language of rigid-body dynamics, $\mathbf{R}_\alpha(t)$ describes the motion in the body frame, and $\mathbf{r}_\alpha(t)$, the motion in the space frame.

An object fixed in the space frame appears to rotate with angular velocity $-\boldsymbol{\Omega}(t)$ in the body frame. $\boldsymbol{\Omega}(t)$ is defined by the relation

$$\dot{\mathcal{R}} \cdot \mathbf{X} = \mathcal{R} \cdot (\boldsymbol{\Omega} \times \mathbf{X}), \tag{53}$$

which can be made to hold for arbitrary vectors $\mathbf{X}$.

Regardless of the details of the dynamics, the total angular momentum $\mathbf{l} = \Sigma_\alpha m_\alpha \mathbf{r}_\alpha \times \mathbf{v}_\alpha$ in the space frame must be conserved. Conservation of angular momentum leads to the relation

$$\boldsymbol{\Omega}(t) = \boldsymbol{I}^{-1} \cdot \left(\mathbf{L} - \sum_\alpha m_\alpha \mathbf{R}_\alpha \times \mathbf{V}_\alpha \right) \tag{54}$$

between the angular velocity $\boldsymbol{\Omega}$ and the angular momentum $\mathbf{L} = \mathcal{R}^{-1} \cdot \mathbf{l}$, velocities $\mathbf{V}_\alpha = \dot{\mathbf{R}}_\alpha$, and inertia tensor $I_{ij} = \Sigma_\alpha m_\alpha (R_\alpha^2 \delta_{ij} - R_{\alpha i} R_{\alpha j})$ in the body frame. Once the internal dynamics $\mathbf{R}_\alpha(t)$ is known, the relations (53) and (54) may be used to determine the orientation $\mathcal{R}(t)$.

The case of zero angular momentum ($\mathbf{l} = \mathbf{L} = 0$) is particularly interesting. Then one can show that the orientation $\mathcal{R}(t)$ does not depend on the rate of the internal dynamics. [One can, in effect, multiply through by dt in (53) and (54).] In particular, if the internal motion is periodic along a cycle C, then after one period it generates an overall rotation $\mathcal{R}_g = \mathcal{R}(T)\mathcal{R}(0)^{-1}$ of the body. The rotation $\mathcal{R}_g$ depends only on the cycle C, and not on the rate at which it is traversed. It is a purely geometrical quantity, a non-Abelian analog (rotations do not commute) of the Hannay angle. It is the means by which a cat dropped upside down manages to land on its feet.

Like the other geometric phases considered so far, this can be described in terms of holonomy on a fiber bundle. The fiber bundle is the configuration space of the masses m_α, constrained to have their center of mass at the origin. The base manifold consists of the distinct internal configurations, no two of which can be made to coincide by a rotation. (Mathematically, this is the quotient of the configuration space by the rotation group.) It can be parametrized by the upright configurations, provided these are always well defined. The fiber consists of the different possible orientations of a given internal configuration and may be parametrized by the rotation group. A connection determines an infinitesimal rotation $\delta\mathcal{R}$ for an infinitesimal change of internal configuration $\delta\mathbf{R}_\alpha$, and the physically relevant connection is determined by conservation of angular momentum. Parallel transport around a closed cycle C in the base yields the holonomy $\mathcal{R}_g$. The curvature of this connection, which describes the net rotation after an infinitesimal cyclic change of shape, may be computed with a formula analogous to (28).

The designation of upright configurations is arbitrary, and one can always choose them differently. It can be verified that the holonomies $\mathcal{R}_g$ do not depend intrinsically on this choice and that the various quantities that describe the orientation transform appropriately when a different choice is made. In particular, the curvature and connection transform according to equations similar to (30).

A more complex example studied by Shapere and Wilczek (1989c) concerns swimming through viscous fluids at low Reynolds number. High viscosity and low velocity means that bodies remain at rest unless acted upon by a force—a realization of Aristotelian mechanics! Bodies locomote by executing a series of internal motions, i.e., swimming strokes. Conservation of linear and angular momentum determine the consequent changes in position and orientation, but now the motion of the fluid must be taken into account. Solving the fluid-dynamical problem leads to a relation similar to (54) for both the linear and angular velocity in terms of rates of change of shape. Applications in biology include locomotion of microorganisms.

3.2.2 Geometric Phases and Reduction

Kinematic geometric phases can be framed in terms of the general theory of symmetry in Hamiltonian systems, called *reduction.* This formulation, extensively developed by Marsden, Montgomery, and co-workers (Marsden *et al.*, 1991; Marsden, 1992), has led to a unified perspective on a variety of geometric-phase phenomena as well as a number of interesting examples.

Dynamics is simplified by the presence of symmetry, and Hamiltonian dynamics especially so. A symmetry always reduces the dimension of a dynamical system by one, but in the Hamiltonian case, it reduces it by two. Indeed, when there is sufficient symmetry, the system is integrable, and the dynamics can be solved analytically (cf. Sec. 3.1.1).

The simplest symmetry is translation invariance in an ignorable coordinate q_N. Hamilton's equation $\dot{p}_N = -\partial H/\partial q_N = 0$ (or, more generally, Noether's theorem) implies that the conjugate momentum p_N is conserved. Fixing its value $p_N = p_{N0}$ leads to a Hamiltonian $H(q_1, \ldots, q_{N-1}, p_1, \ldots, p_{N-1}, p_{N0})$ in two fewer variables. Once their dynamics is obtained, the evolution of the ignorable coordinate may be determined by integrating Hamilton's equation $\dot{q}_N = \partial_{p_N} H(q_1, \ldots, q_{N-1}, p_1, \ldots, p_{N-1}, p_{N0})$. The theory of reduction extends this analysis to general symmetries. As in the simple example, the analysis consists of two stages. The first is reduction, wherein the conserved momenta are fixed, the ignorable coordinates ignored, and Hamilton's equations expressed in terms of a reduced set of coordinates. In all but the simplest cases, finding these coordinates is a nontrivial task (Jacobi's "elimination of the node" in the rotationally symmetric N-body problem is a representative example). The second state is reconstruction, wherein the evolution of the ignorable coordinates is determined from the reduced dynamics. It is in the reconstruction stage that kinematic geometric phases can appear. It turns out that the equations of motion for the ignorable coordinates can be separated into dynamical and geometric terms. The geometric term depends only on the path described by the reduced dynamics, and not on the rate at which it is traversed. The dynamical term, by contrast, does depend on the rate. Moreover, the form of the geometrical term depends only on the realization of the symmetry, and not on the details of the Hamiltonian.

In the example discussed in the preceding section, the flexible body composed of N point masses, the ignorable coordinates correspond to $\mathcal{R}$, the body's orientation; the conserved momentum to the space-fixed angular momentum $\mathbf{l}$; and the internal coordinates $\mathbf{R}_\alpha(t)$ to the reduced system. The evolution of $\mathcal{R}(t)$ is obtained by integrating the linear system (53), in which angular velocity $\boldsymbol{\Omega}(t)$ is given in terms of the reduced dynamics by (54). Equation (54) is an example of a reconstruction formula divided into its dynamical and geometric parts. The first term, $\boldsymbol{I}^{-1}\cdot\mathbf{L}$, is the dynamical contribution. The second, $\boldsymbol{I}^{-1}\cdot(\Sigma_\alpha m_\alpha \mathbf{R}_\alpha \times \mathbf{V}_\alpha)$, is the geometric contribution. As discussed above, its integral depends only on the path C described by the internal dynamics $\mathbf{R}_\alpha(t)$.

Montgomery (1991) found an even simpler example in the dynamics of a free rigid body. Its configuration (with its center of mass fixed at the origin) is described by a rotation $\mathcal{R}$, for which it will be convenient to use the Euler-angle parametrization, $\mathcal{R} = \mathcal{R}_z(\phi)\mathcal{R}_y(\theta)\mathcal{R}_z(\psi)$. The space-fixed angular momentum $\mathbf{l}$ is a constant of the motion, and without loss of generality we can assume it lies in the z direction. The body-fixed angular momentum $\mathbf{L}(t) = \mathcal{R}(t)\cdot\mathbf{l}$ has polar coordinates $(\theta(t),\phi(t))$ on the sphere of constant radius $L = |\mathbf{L}| = |\mathbf{l}|$. Its dynamics is determined by the Euler equations $\dot{\mathbf{L}} = \boldsymbol{\Omega} \times \mathbf{L}$, where $\boldsymbol{\Omega} = \boldsymbol{I}^{-1}\cdot\mathbf{L}$ is the angular velocity and $\boldsymbol{I}$ is the inertia tensor. The Euler equations describe the reduced dynamics, in which $\mathbf{L}$, or equivalently θ and ϕ, are the reduced coordinates. The ignorable coordinate is the third Euler angle ψ.

Under the Euler equations, $\mathbf{L}$ executes a periodic motion with period T. The fact that $\mathbf{L}(T) = \mathbf{L}(0)$ implies that the rigid body returns after one period to its original orientation, up to a rotation about the direction of $\mathbf{L}(T)$. The amount of rotation is just $\Delta\psi = \psi(T) - \psi(0)$, the shift in the ignorable coordinate ψ.

With a little algebra, the equation of motion for ψ may be written in the form

$$\dot{\psi} = 2E/L + \cos\theta\dot{\phi}, \qquad (55)$$

where $E = \frac{1}{2}\mathbf{L}\cdot\boldsymbol{I}^{-1}\cdot\mathbf{L}$ is the conserved rotational energy. Equation (55) is another example of a reconstruction formula divided into dynamical and geometric contributions. In this case, the dynamical contribution integrates to $2ET/L$, whereas the geometric contribution gives (modulo 2π) the solid angle $\oint_C \cos\theta d\phi$ described by the body-fixed angular momentum $\mathbf{L}(t)$ over a single period.

Another example, due to Alber and Marsden (1992), concerns phase shifts in soliton collisions. A fundamental property of certain nonlinear partial differential equations, such as the Korteweg-de Vries equation $U_t + 6UU_x + U_{xxx} = 0$, is the existence of *solitons.* These are wave forms $U(x - vt)$ that propagate at a fixed velocity v while maintaining their shape, the nonlinearity in the wave dynamics just balancing the dispersion. When two solitons collide, they emerge after a complicated but transient period of interaction essentially intact. The only signature of their collision is a shift Δx in their position $x \pm \Delta x - vt$ (+ for the faster soliton, − for the slower one). This shift, which may be determined from an asymptotic analysis of the exact solutions, can be interpreted as a geometric phase. The same analysis applies to a variety of integrable nonlinear partial differential equations, including the nonlinear Schrödinger equation and the Klein–Gordon equation.

3.2.3 Optimization and Control

The study of kinematic geometric phases suggests a problem in optimization. What is the most efficient internal motion for producing a given holonomy? As a specific example, consider a satellite orbiting the Earth with a fixed orientation, so that its angular momentum about its center of mass is zero. It is desired to change its orientation using as little energy as possible. The obvious method of applying external torques (supplied by jets attached to satellite, for example) has the drawback that any uncompensated force or torque leaves the satellite in a state of translation or rotation. The alternative is to execute a sequence of internal motions (e.g., flywheels driven by motors); in the manner described above, these generate a change in orientation without altering the total linear or angular momentum.

The problem of finding the most efficient cycle with a given holonomy leads to a constrained variational problem in the internal degrees of freedom, which can be formulated in terms of control theory. The solution depends very much on how efficiency is measured. In certain circumstances, it may be advantageous to make some sizable internal motions initially in order to achieve a configuration for which the geometric phase curvature form (cf. Sec. 2.1.2) is large; then much smaller subsequent motions can produce relatively large effects. In other situations, it may be necessary to restrict to small motions about some equilibrium configuration; in this case, the variational problem may be analyzed in terms of infinitesimal circuits. The solutions often have a physical interpretation in terms of motion in a magnetic, or more generally a Yang–Mills, field. Shapere and Wilczek (1989d) find efficient swimming strokes through viscous media in two and three dimensions under various conditions. Marsden (1992) describes a variety of other examples.

4. OPTICS

Optics has provided fertile ground for studying the geometric phase. A comprehensive survey of experimental activity is given by Bhandari (1997). Most investigations have concentrated on polarization effects. The polarization of a beam of monochromatic, coherent light behaves like a quantum mechanical spin, and under cyclic evolutions (and noncyclic ones as well) acquires a geometric phase similar to that of a spinning particle in a magnetic field (cf. Sec. 1.3). There are various ways to change polarization. One is by varying the direction of propagation, as the polarization vector must remain transverse (Tomita and Chaio, 1986); in this case the polarization has a spin-1, or vectorial, character. Another is through optical activity induced by anisotropic media, in which case the polarization has a spin-$\frac{1}{2}$ character (Pancharatnam, 1956; Bhandari and Samuel, 1988; Bhandari, 1988).

A beam of light passing through a cycle of polarization states may be recombined with a second beam whose polarization has remained unchanged. Their total phase difference (dynamical + geometric) can be determined, for example, from their interference pattern. In certain cases, the dynamical phase shift can be made to vanish. In others, it can be explicitly computed and subtracted from the total phase. In either case, one obtains a measurement of the geometric phase.

4.1 Geometric Phase of Coiled Light

In a straight, single-mode optical fiber of circular cross section, there is no preferred state of polarization; whatever the polarization state of the source, it is preserved along the fiber. This is no longer so if the fiber is made to bend; then the polarization must change in order to remain transverse to the direction of propagation $\hat{\mathbf{t}}$. Provided the radius of curvature $R = \|d\hat{\mathbf{t}}/ds\|^{-1}$ is large compared to the wavelength λ (here s measures distance along the fiber), the polarization vector $\hat{\mathbf{d}}(s)$ of the electric displacement $\mathbf{D}(s,\rho) = \operatorname{Re} e^{i(2\pi s/\lambda - \omega t)} f(\rho)\hat{\mathbf{d}}(s)$ [here $f(\rho)$ is the radial modal profile] evolves along the fiber according to

$$\frac{d\hat{\mathbf{d}}}{ds} = -(\hat{\mathbf{t}}\cdot\hat{\mathbf{d}})\hat{\mathbf{t}}. \qquad (56)$$

The corrections to this approximate solution of Maxwell's equations are of order λ/R.

For a general elliptical polarization, $\hat{\mathbf{d}}$ is complex. Within the adiabatic approximation, both its real and imaginary parts $\hat{\mathbf{d}}_r$ and $\hat{\mathbf{d}}_i$ remain orthogonal to the direction of propagation $\hat{\mathbf{t}}$, and each satisfies (56) separately. As a function of s, $\hat{\mathbf{t}}(s)$ describes a curve C on the unit sphere, and the vectors $\hat{\mathbf{d}}_r(s)$ and $\hat{\mathbf{d}}_i(s)$ are tangent to the sphere at $\hat{\mathbf{t}}(s)$. Equation (56) is the condition for their parallel transport. (Infinitesimal parallel transport of a tangent vector $\hat{\mathbf{d}}$ from $\hat{\mathbf{t}}$ to $\hat{\mathbf{t}} + d\hat{\mathbf{t}}$ is accomplished by first rigidly transporting $\hat{\mathbf{d}}$ to $\hat{\mathbf{t}} + d\hat{\mathbf{t}}$ and then projecting the translated vector onto the plane tangent to $\hat{\mathbf{t}} + d\hat{\mathbf{t}}$.) If the curve C is made to close on itself, the vectors $\hat{\mathbf{d}}_r$ and $\hat{\mathbf{d}}_i$ return rotated through an angle θ_g equal to the solid angle subtended by C. θ_g is a geometric phase, depending only on the shape of C.

Tomita and Chiao (1986) observed this effect by introducing linearly polarized light from a He-Ne laser into a length of helically wound optical fiber whose initial and final directions coincided. The direction of linear polarization of the emergent beam was measured and found to have turned through an angle equal to the solid angle subtended by the cycle of directions. The experiment was performed with helices of both fixed and variable pitch, as well as for fibers constrained to lie in the xy plane. In this last case, the cycle of directions lies on the equator of the unit sphere, and the subtended solid angle is a multiple of 2π. As predicted, the direction of linear polarization remained unchanged.

The original analysis of the Tomita–Chiao experiment was based on quantum-mechanical considerations, treating a photon propagating in the fiber as a spin-1 particle whose helicity is constrained to be ± 1. (Classically, this corresponds to left- and right-circularly polarized light.) Just as a spin with nonzero magnetic moment tracks the direction of a slowly changing magnetic field (cf. Sec. 1.3), the helicity of the photon tracks the direction of propagation $\hat{\mathbf{t}}$ and acquires a geometric phase equal to the solid angle described by $\hat{\mathbf{t}}$. By decomposing a linear polarization into a superposition of left- and right-circular polarizations, the observed rotation of linear polarization may be recovered.

A systematic derivation requires a more detailed analysis, most easily carried out within the context of classical (rather than quantum) electromagnetic theory. Indeed, the essential features of such an analysis are contained in the work of Rytov (1938) and Vladimirsky (1941), who derived and interpreted the parallel-transport law (56) in the short wavelength, or geometrical optics, limit (see Berry, 1990a, for a discussion). Strictly speaking, geometrical optics is not appropriate for single-mode fibers, in which the transverse wavelength is comparable to the fiber diameter. Berry (1987a) has carried out a classical analysis using the full Maxwell equations, and it is the conclusions of this analysis that are described above.

Kitano *et al.* (1987) performed an experiment related to Tomita and Chiao's, in which the cyclic change in the direction of propagation was accomplished nonadiabatically through a series of discrete reflections from mirrors. These reflections reverse helicity instead of conserving it, and the calculation of the geometric phase must be appropriately modified.

4.2 Pancharatnam's Phase

When light passes through a homogeneous medium, its direction of propagation remains constant. However, if the medium is optically anisotropic, the polarization can change. Such changes in polarization are accompanied by a geometric phase, discovered by Pancharatnam in 1956. (See Berry, 1987b, for a contemporary discussion of Pancharatnam's work.) For definiteness, let us consider plane electromagnetic waves propagating in the z direction with fixed wave number k and frequency ω. The electric field $\mathbf{E}(\mathbf{r},t) = \mathrm{Re}\sqrt{I}e^{i(kz-\omega t)}|A\rangle$ is described by its intensity I_A and normalized polarization vector $|A\rangle = (A_x,A_y)$, whose complex components determine the phase and relative intensity along x and y. (Dirac notation is used for complex two-vectors to highlight an analogy with two-state systems, introduced below.)

Given two such waves, what is their relative phase? Unless their polarization states $|A\rangle$ and $|B\rangle$ happen to be proportional, it is not clear that the question is a sensible one. Pancharatnam found a natural and physically relevant prescription for their relative phase by considering the intensity I_{A+B} of the superposition, $\sqrt{I_A}|A\rangle + \sqrt{I_B}|B\rangle$. This intensity is given by

$$I_{A+B} = I_A + I_B + 2\sqrt{I_A I_B}\,\mathrm{Re}\langle A|B\rangle. \tag{57}$$

If the constituent intensities I_A and I_B are fixed, the superposed intensity depends only on the interference term and is maximized when $\langle A|B\rangle = 1$. This is Pancharatnam's criterion for the two polarization states $|A\rangle$ and $|B\rangle$ to be in phase. In general, their relative phase is defined to be $\arg\langle A|B\rangle$ (this is well defined unless $|A\rangle$ and $|B\rangle$ are orthogonal). It is the amount by which the phase of $|A\rangle$ must be retarded relative to the phase of $|B\rangle$ in order that the intensity of their superposition be a maximum.

Being in phase is not a transitive relation; if $|A\rangle$ is in phase with $|B\rangle$ and $|B\rangle$ is in phase with $|C\rangle$, then, in general, $|C\rangle$ is not in phase with $|A\rangle$. The relative phase $\arg\langle C|A\rangle$ has a simple geometrical interpretation, which we now describe. To every polarization state $|A\rangle$ may be associated a vector $\mathbf{e}_A$ on the unit sphere, namely, the unit vector $\langle A|\boldsymbol{\sigma}|A\rangle$ (here $\boldsymbol{\sigma}$ denotes the Pauli matrices) rotated through $\pi/2$ about the y axis. This is how polarization is represented, up to an overall phase factor, on the *Poincaré sphere.* The y rotation, a matter of convention, puts the left and right circular polarizations at the north and south poles, respectively, of the Poincaré sphere, and the linear polarizations at the equator. (In more mathematical language, the Poincaré sphere is the projective Hilbert space for two-state systems—cf. Sec. 2.3.)

One can show that the relative phase $\arg\langle C|A\rangle$ is equal to minus half the solid angle subtended by the spherical triangle $\mathbf{e}_A\mathbf{e}_B\mathbf{e}_C$ on the Poincaré sphere, which is constructed by joining $\mathbf{e}_A$, $\mathbf{e}_B$, and $\mathbf{e}_C$ with arcs of great circles. A direct demonstration (Pancharatnam's) uses formulas from spherical trigonometry. Another way is to realize that a sequence of polarization states $|\psi(t)\rangle$ parallel-transported according to (34) along great circles on the Poincaré sphere are, according to Pancharatnam's criterion, in phase with each other. Thus $\arg\langle C|A\rangle$ is precisely the geometric phase accumulated under parallel transport around $\mathbf{e}_A\mathbf{e}_B\mathbf{e}_C$ (for which the half-solid-angle formula is obtained in Sec. 1.3).

To establish a connection between these geometrical considerations and the actual physics, some analysis of the polarization dynamics is required. Pancharatnam considered systems of *ideal polarizers,* or *analyzers,* which completely transmit a polarization state $|A\rangle$ and absorb the state $|A_\perp\rangle$ orthogonal to it in such a way that the incident and transmitted states are always in phase. Ideal polarizers are very nearly approximated by very thin polarizing plates. (Mathematically, they are represented by the Hermitian projection operator $|A\rangle\langle A|$.) Therefore, under a polarization cycle generated by ideal polarizers, the initial and final polarizations differ by Pancharatnam's phase.

Polarization cycles can also be generated by *ideal retarders;* these are perfectly transparent devices that introduce a relative phase difference between two given orthogonal polarization states $|A\rangle$ and $|A_\perp\rangle$. A particular example is a quarter-wave plate, for which the orthogonal states are linearly polarized and the phase difference is $\pi/2$. [Mathematically, an ideal retarder is represented by $\exp(-i\pi\mathbf{e}_A\cdot\boldsymbol{\sigma}/4)$, a two-dimensional unitary matrix with determinant 1.] Polarization cycles generated by ideal retarders produce a dynamical phase in addition to Pancharatnam's phase. The dynamical phase is easily calculated, however.

Polarization cycles can also arise through optical activity in a birefringent gyrotropic medium. Such a medium induces a relative phase between orthogonal polarization states whose orientation is determined by the local dielectric tensor. When the variation in the medium is small over a wavelength, the polarization of a monochromatic beam tracks the eigenstates of the dielectric tensor. Berry (1987b) applied an adiabatic analysis to Maxwell's equations and calculated the phase change over a polarization cycle generated by a spatially periodic medium. The analysis is formally the same as for a spin-$\frac{1}{2}$ particle in a slowly changing magnetic field (Sec. 1.3), and there appears a dynamical phase and a geometric phase; the geometric phase in this case is just Pancharatnam's.

Observations of Pancharatnam's phase are based on two-beam interferometry. Such experiments were initiated by Pancharatnam himself, though current versions are greatly improved with the availability of laser sources. Schematically, a plane wave with polarization $|A\rangle$ is split into two coherent beams, which propagate along the arms of an interferometer. Beam 1 propagates freely, while beam 2 passes through a sequence of optical elements that induce a polarization cycle. The beams are then recombined, and their total relative phase is determined from their interference. Differences in dynamical phases are determined and subtracted, and the geometric phase subsequently is measured.

Bhandari (1988) used laser interferometry methods to measure changes in the geometric phase, rather than the geometric phase itself. These are readily generated (while keeping the relative dynamical phases fixed) by continuously rotating a half-wave plate in the polarization cycle.

Kwiat and Chiao (1991) observed Pancharatnam's phase in single-photon interference experiments using a source of entangled two-photon states. One photon, the idler, was passed through a narrow-band energy filter to a detector. Observation of this photon fixed the energy of its partner, which was made to pass through an interferometer. Detection rates varied in accordance with the intensity, which depends directly on Pancharatnam's phase. Various coincidence detectors were used to confirm that genuine single-photon interference was being observed.

Berry and Klein (1996) performed a modern version of Pancharatnam's experiment, determining the relative phase by direct measurement of photographed interference fringes. By increasing the number of optical components in the polarization cycle, they were also able to investigate the relation between discrete and continuous geometric phases.

5. MOLECULAR AND CONDENSED-MATTER PHYSICS

Several applications of the geometric phase to molecular spectroscopy (Sec. 5.1), nuclear magnetic resonance (Sec. 5.2), and the quantum Hall effect (Sec. 5.3) are discussed. Among a number of applications that have been omitted, we mention Λ-doubling of rotational levels in diatomic molecules (Moody *et al.*, 1986), and atomic and reactive molecular scattering (Mead and Truhlar, 1979; Zygelman, 1987; Mead, 1992; Kuppermann and Wu, 1993).

5.1 Pseudorotation in Triatomic Molecules

Ordinarily, the angular degrees of freedom of a spinless system have integer quantum numbers. This is because, ordinarily, the angular momentum L_ϕ conjugate to an angle ϕ is taken to be $-i\hbar\partial_\phi$; its eigenfunctions $\exp(i\nu\phi)$ are single-valued only if ν is an integer. The Aharonov–Bohm effect (cf. Sec. 1.2) provides an exception. In the presence of a magnetic flux line on the z axis, with flux $\alpha hc/e$, the azimuthal angular momentum of an electron is given by $-i\hbar\partial_\phi + \alpha$, the constant term α coming from the magnetic vector potential $\mathbf{A}^{(s)}(\rho,\phi,z) = \alpha/\rho\hat{\phi}$. Therefore, the eigenvalues of L_ϕ are no longer integral multiples of $\hbar$ but are given instead by $(m + \alpha)\hbar$, where m is an integer.

As discussed in Sec. 1.7, there emerges in the Born–Oppenheimer approximation a molecular analog of the Aharonov–Bohm effect. For a given electronic state $|n\rangle$, the nuclear configuration space is threaded by a magnetic flux concentrated at points where $|n\rangle$ is degenerate. This flux appears in the nuclear Hamiltonian as a geometric vector potential (4). As discussed by Mead (1992), a triatomic molecule X_3 composed of identical atoms (e.g., alkali metal trimers such as Na_3) provides a simple class of examples. A striking consequence of the molecular Aharonov–Bohm effect is the appearance of anomalous half-integer quantum numbers. Their existence has been confirmed experimentally (Delacrétez *et al.*, 1986). First anticipated by Longuet-Higgens *et al.* (1958), this phenomenon is most naturally understood in terms of the geometric phase.

The nuclear configuration space for a triatomic molecule has nine degrees of freedom. Six of these correspond to overall translational and rotational motion, which can be ignored for the purposes of this discussion. That leaves three internal degrees of freedom, which describe vibrations. The internal configuration space, which we denote by Q, may be parameterized by the distances R_{12}, R_{23}, and R_{13} between the nuclei. It may be thought of as the space of noncongruent triangles (the R_{ij}'s determine the lengths of the triangle's sides) whose vertices are distinguishable.

In the Born–Oppenheimer approximation, the electronic energy levels and eigenstates are regarded as functions of the internuclear distances R_{ij}. Assuming that the molecular Hamiltonian has time-reversal symmetry, we expect degeneracies of the electronic states to lie along one-dimensional curves in Q (cf. Sec. 1.5).

It turns out that some of these degeneracies can be determined by symmetry considerations alone. For equilateral configurations $R_{12} = R_{23} = R_{13} = a$, the nuclear configuration is invariant under the dihedral group D_3 of symmetries of the equilateral triangle. Therefore, the electronic eigenstates $|n(a,a,a)\rangle$ must transform according to an irreducible representation, or irrep, of D_3 (Tinkham, 1964). The group D_3 has two one-dimensional irreps, associated with states that are either invariant or else change sign under the symmetry operations, and a two-dimensional irrep, associated with a degenerate pair of states that transform into linear superpositions of each other under the symmetry operations. Therefore, if the state $|p(a,a,a)\rangle$ transforms according to the two-dimensional irrep, then the family of states $|p(R_{12},R_{23},R_{13})\rangle$ to which it belongs must be degenerate along the curve $R_{12} = R_{23} = R_{13} = a$ (with $a > 0$) in Q. Under parallel transport around this curve [cf. (2)], $|p(R_{12}, R_{23},R_{13})\rangle$ changes sign.

One might expect the energy $E_p(R_{12}, R_{23},R_{13})$ of this state to assume its minimum in an equilateral configuration. The Jahn–Teller effect (Jahn and Teller, 1937) shows this is not the case. It turns out to be energetically favorable for the molecule to assume an asymmetrical configuration, so that for the p-electronic state, the ground vibrational state of the molecule is distorted.

To analyze the vibrational motion, it is useful to introduce cylindrical-like coordinates, (ρ,ϕ,z), in Q. The vertical coordinate z is given by $R_{12}^2 + R_{23}^2 + R_{13}^2$ and determines the length scale; oscillations in z describe uniform dilations and contractions of the nuclei. The radial coordinate ρ is given by $\rho^2/4 = z^2 - 3(R_{23}^2R_{13}^2 + R_{12}^2R_{13}^2 + R_{12}^2R_{23}^2)$ and describes the degree of distortion. For collinear configurations, $\rho = z$; for equilateral configurations, $\rho = 0$. Thus, it is along the z axis (where $\rho = 0$) that the electronic state $|p(\rho,\phi,z)\rangle$ is degenerate. The angle ϕ is given by $\tan^{-1}[\sqrt{3}(R_{23}^2 - R_{13}^2)/(2R_{12}^2 - R_{23}^2 - R_{13}^2)]$ and describes the direction of the distortion. Displacements in ϕ are called *pseudorotations.* A 2π pseudorotation returns the nuclei to their original positions, while a $2\pi/3$ rotation induces a cyclic permutation among them.

A systematic calculation of the vibrational Hamiltonian H_{vib}, described in (Mead, 1992), requires an explicit expression for the electronic energy $E_p(\rho,\phi,z)$ along with a careful derivation of the kinetic energy in terms of the (ρ,ϕ,z) coordinates. However, for this discussion, an approximate model treatment will suffice. The potential is taken to be harmonic in z and ρ and independent of ϕ, and the kinetic energy to be of the standard form. Thus

$$H_{\text{vib}} = \frac{p_\rho^2}{2M} + \frac{L_\phi^2}{2M\rho^2} + \frac{p_z^2}{2M} + \tfrac{1}{2}M\omega_\rho^2(\rho - \rho_0)^2 + \tfrac{1}{2}M\omega_z^2(z - z_0)^2, \tag{58}$$

where (ρ_0,z_0) denotes the asymmetrical configuration that minimizes E_p. The vibrational energy levels are characterized by three quantum numbers j, m, and k, for the respective degrees of freedom ρ, ϕ, and z, and are given approximately by

$$E(j,m,k) = (j + \tfrac{1}{2})\hbar\omega_r + \frac{(m\hbar)^2}{2I} + (k + \tfrac{1}{2})\hbar\omega_z, \tag{59}$$

where the moment of inertia I about the z axis is taken to be $M\rho_0^2$. (The approximation consists of ignoring the dependence of I on the radial quantum number j).

The presence of the electronic degeneracy along the z axis introduces a geometric vector potential $\mathbf{A}_p = \alpha\hat{\boldsymbol{\phi}}/\rho$ into the nuclear Hamiltonian, which accounts for the sign change of the electronic eigenstate under parallel transport. (In the chosen coordinate system, $\alpha = \frac{3}{2}$.) Its effect is to replace the pseudoangular momentum operator $L_\phi = -i\hbar\partial_\phi$ by $-i\hbar\partial_\phi + \frac{3}{2}\hbar$, in analogy to what occurs in the magnetic Aharonov–Bohm Hamiltonian. Thus, the pseudorotational quantum number m in (59) is half-integral.

The half-integral quantization of pseudorotation was confirmed in a systematic spectral analysis of the vibrational spectrum of Na_3 by Delacrétez *et al.* (1986). A sequence of rovibrational levels corresponding to radial and pseudorotational motion were identified. It was found that the observed spectrum could be fitted by (59) only by assigning half-integer quantum numbers to the pseudoangular momentum. Such an assignment yields excellent agreement between observed and calculated energy levels.

5.2 Nuclear Magnetic Resonance

An rf magnetic field applied to polarized spins generates transitions between their stationary states. When the field is in resonance with the precession frequency of the spins, the transition probabilities can become large, even though the rf field may be weak. Transitions are manifested in oscillations of the spin magnetic moment, whose amplitude and frequency can be measured with great accuracy. This is the basis for nuclear spin-resonance experiments. In nuclear magnetic resonance (NMR), the nuclear spins are polarized by a static magnetic field. In nuclear quadrupole resonance (NQR), the spins are polarized by an electric field gradient (in the ambient crystalline potential, for example) that couples to the spin through the nuclear quadrupole moment.

Moody *et al.* (1986) and Cina (1986) pointed out that cyclic variations in the rf field would generate geometric phases in the nuclear spins, which could be detected as shifts in the frequency spectrum of the nuclear magnetic moment (this is an example of the third type of experiment described in

Sec. 1.6). Pursuing this suggestion, several groups have carried out NMR studies of the geometric phase, including its adiabatic (Tycko, 1987; Suter *et al.*, 1987), nonadiabatic (Suter *et al.*, 1988), and non-Abelian (Zwanziger *et al.*, 1990b) versions. These experiments not only have confirmed theoretical predictions but also have brought to light interesting new phenomena in NMR spectroscopy.

In an NMR experiment, the nuclear spins (let $s = \frac{1}{2}$, say) are initially polarized by a strong static magnetic field $B_z\hat{\mathbf{z}}$. The Hamiltonian H_0 is given by $\frac{1}{2}\hbar\gamma B_z\sigma_z$, where γ is the gyromagnetic ratio, and the eigenstates $|\pm\rangle$ have energies $\pm\hbar\omega_0/2$, where $\omega_0 = \gamma B_z$ is the Larmor frequency. For nonstationary states, the magnetic moment $\mathbf{M}(t) = \hbar\gamma\langle\psi(t)|\boldsymbol{\sigma}|\psi(t)\rangle/2$ precesses about $\hat{\mathbf{z}}$ at the Larmor frequency, so that its frequency spectrum has a single peak at ω_0.

A weak, circularly polarized rf field, $\mathbf{B}_{\text{rf}}(t) = B_x \cos\omega t\hat{\mathbf{x}} + B_y \sin\omega t\hat{\mathbf{y}}$, is then applied. (Weak means that $B_{\text{rf}} \ll B_z$.) The subsequent dynamics is most easily analyzed in a rotating frame turning about $\hat{\mathbf{z}}$ with angular frequency ω. There the effective magnetic field $\mathbf{B}_{\text{rot}}$ is static, and the Hamiltonian is given by

$$H_{\text{rot}} = \tfrac{1}{2}\gamma\hbar\mathbf{B}_{\text{rot}}\cdot\sigma,$$
$$\mathbf{B}_{\text{rot}} = B_x\hat{\mathbf{x}} + B_y\hat{\mathbf{y}} + (B_z - \omega/\gamma)\hat{\mathbf{z}}. \tag{60}$$

The spin eigenstates $|\pm\rangle_{\text{rot}}$ in the rotating frame are polarized along $\mathbf{B}_{\text{rot}}$ with energies $\pm\hbar\omega_{\text{rot}}/2$, and the magnetic moment $\mathbf{M}_{\text{rot}}(t)$ precesses about $\mathbf{B}_{\text{rot}}$ with frequency ω_{rot}, where $\omega_{\text{rot}} = \gamma B_{\text{rot}}$. Near resonance, where $\omega \approx \omega_0$, the axis of precession is nearly perpendicular to $\hat{\mathbf{z}}$ (even though $B_{\text{rf}} \ll B_z$).

The magnetic moment $\mathbf{M}(t)$ in the laboratory frame is given by $\mathbf{M}_{\text{rot}}(t)$ rotated back through an angle $-\omega t$ about $\hat{\mathbf{z}}$. Thus, the effect of the rf field is to superpose a slow longitudinal nutation (of frequency ω_{rot}) on the fast Larmor precession of $\mathbf{M}(t)$ about $\hat{\mathbf{z}}$ (of frequency ω_0). In consequence, the frequency spectrum of the magnetic moment has additional peaks at $\omega_0 \pm \omega_{\text{rot}}$.

The Hamiltonian H_{rot} of (60) depends parametrically on the components of the rf and static magnetic fields, B_x, B_y, and B_z, and vanishes for $B_x = B_y = 0$ and $B_z = \omega/\gamma$. If B_x, B_y, and B_z are slowly modulated through a cycle C, with a period T much greater than the precession period $2\pi/\omega_{\text{rot}}$ in the rotating frame, then the eigenstates $|\pm\rangle_{\text{rot}}$ of H_{rot} evolve adiabatically and acquire with each modulation cycle a geometric phase $\gamma_\pm(C)$ given by half the solid angle α described by C with respect to $(0,0,\omega/\gamma)$ (cf. Sec. 1.3). These geometric phases produce shifts $\mp\frac{1}{2}\hbar\alpha/T$ in the energies $\pm\frac{1}{2}\hbar\omega_{\text{rot}}$ of the unmodulated Hamiltonian H_{rot}, and in turn shift the precession frequency of the magnetic moment from ω_{rot} to $\omega_{\text{rot}} - \alpha/T$. (This shift is the magnetic analog of the daily precession of the Foucault pendulum discussed in Sec. 3.1.3.)

These frequency shifts were observed by Suter *et al.* (1987) in the NMR response of proton spins in a water/acetone sample. The adiabatic cycle C was produced by placing the magnetization detector in a frame rotating with angular frequency ω_{det} about $\hat{\mathbf{z}}$. In the detector frame, the effective magnetic field turns about $\hat{\mathbf{z}}$ with angular frequency $\delta = \omega - \omega_{\text{det}}$; for small enough δ, the spins adiabatically track the turning field. A variation of this experiment was subsequently performed by Suter *et al.* (1988), in which the geometric phase was observed as a rotation in the spin-echoed magnetic moment. This technique enabled observation of the individual geometric phases $\gamma_\pm$ rather than their difference $\gamma_+ - \gamma_-$. The spins were also taken through nonadiabatic cycles, thereby incorporating the Aharonov–Anandan phase (cf. Sec. 2.3).

In a nuclear quadrupole resonance experiment, the spin polarization is induced by an inhomogeneous electric field rather than a static magnetic field. Gradients in the electric field couple to spin through the nuclear electric quadrupole moment. The effective spin Hamiltonian is of the form $H_Q = \hbar\omega_Q(\mathbf{S}\cdot\hat{\mathbf{n}})^2$, where $\mathbf{S}$ denotes the dimensionless spin operators and $\hat{\mathbf{n}}$ is the symmetry axis of the electric-field-gradient tensor (assumed here to be axially symmetric). The eigenstates $|m(\hat{\mathbf{n}})\rangle$ are polarized along $\hat{\mathbf{n}}$ with energies $\hbar\omega_Q m^2$. Note that these are doubly degenerate for $m \neq 0$.

Geometric phase effects in the NQR spectrum of ^{35}Cl (for which $s = \frac{3}{2}$) were studied by Tycko (1987). In the experiment, a coherent superposition of eigenstates of H_Q was created at $t = 0$ by an rf pulse; the induced magnetic moment $\mathbf{M}(t)$ was then observed and spectrally analyzed. The spectrum of H_Q

consists of two degenerate doublets with energies $\frac{9}{4}\hbar\omega_Q$ and $\frac{1}{4}\hbar\omega_Q$ (corresponding to $m = \pm\frac{3}{2}$ and $m = \pm\frac{1}{2}$, respectively), so that the magnetic moment spectrum has a single peak at frequency $2\omega_Q$. Adiabatic cycling of H_Q was achieved by rotating a crystalline sample of $NaClO_3$ with angular frequency $\omega_R \ll \omega_Q$ about an axis inclined to the symmetry direction $\hat{\mathbf{n}}$. With each rotation, the spin eigenstates acquire geometric phases β_m (these may be computed explicitly), which shift their energies by $\hbar\beta_m\omega_R/2\pi$ and lift the double degeneracies. For the particular geometry realized in Tycko's experiment, theory predicts that the single peak in the magnetic moment spectrum is split into three peaks at frequencies $2\omega_Q$ and $2\omega_Q \pm \sqrt{3}\omega_R/\pi$. Precisely this splitting was observed in the experiment.

Since H_Q has degenerate energy levels, one might expect non-Abelian geometric phases (cf. Sec. 2.2) to appear. Tycko (1987) and Zee (1988) showed that they do not; the experiment can be analyzed completely in terms of the ordinary (Abelian) geometric phase. One can compute the non-Abelian vector potentials $\mathsf{A}_{\pm 3/2}$ and $\mathsf{A}_{\pm 1/2}$ of (25) explicitly (there is one for each degenerate doublet of H_Q); they are matrix-valued and are proportional to the matrix elements of the spin $\mathbf{S}$ taken between states in the degenerate doublets. For $m = \pm\frac{3}{2}$, the off-diagonal matrix elements vanish identically ($\mathbf{S}$ has nonzero matrix elements only between states $|m\rangle$ and $|m \pm 1\rangle$), and the diagonal matrix elements yield the ordinary geometric phases $\beta_{\pm 3/2}$. For $m = \pm\frac{1}{2}$, the off-diagonal elements $\langle \pm\frac{1}{2}|\mathbf{S}| \mp \frac{1}{2}\rangle$ do not vanish. However, for the adiabatic cycles used in the experiment, in which $\hat{\mathbf{n}}$ is turned about a fixed axis, a basis for the $m = \pm\frac{1}{2}$ doublet can be found that diagonalizes $\mathsf{A}_{\pm 1/2}$. During the cycle there are no transitions between these basis vectors and each acquires an ordinary geometric phase $\beta_{\pm 1/2}$.

Zee (1988) showed that more general adiabatic cycles of $\hat{\mathbf{n}}$ generate genuine non-Abelian geometric phases in the NQR spectrum. Zwanziger *et al.* (1990b) performed an experiment to observe these non-Abelian effects. The more complicated adiabatic cycles were generated by mounting the $NaClO_3$ crystal on a double rotor. Careful analysis predicts that the NQR resonance should be split into five peaks instead of three. This is precisely what was observed, with excellent quantitative agreement between theory and experiment.

5.3 The Quantum Hall Effect

Charged particles in crossed uniform electric and magnetic fields experience a net drift along the direction $\mathbf{E} \times \mathbf{B}$ normal to both—this is the basis for the *Hall effect*. The Hall effect concerns specifically the behavior of electrons in a planar conductor to which a perpendicular magnetic field $\mathbf{B} = B\hat{\mathbf{z}}$ and a tangential electric field $\mathbf{E} = E\hat{\mathbf{x}}$ are applied. The resulting current density has a transverse component $j_y = \sigma_H E$. σ_H is the *Hall conductance*. Using classical theory, one obtains for large magnetic fields that

$$\sigma_{\mathrm{H}} \approx nec/B, \tag{61}$$

where n is the two-dimensional electron density.

[Alternatively, one can consider conductors of finite transverse extent, e.g., long thin wires. Then the current density is necessarily longitudinal, whereas the electric field has a transverse component. In this case it is easier to compute the *Hall resistance* $\rho_{\mathrm{H}} = E_y/j$. Classical theory gives $\rho_{\mathrm{H}} = B/nec$ for all magnetic fields, not just large ones. The Hall conductance and resistance are the off-diagonal elements of the conductance and resistivity tensors σ and $\rho = \sigma^{-1}$, and the relation between them, $\sigma_{\mathrm{H}} = \rho_{\mathrm{H}}/(\rho_{\mathrm{O}}^2 + \rho_{\mathrm{H}}^2)$, depends on the longitudinal or Ohmic resistivity ρ_{O}.]

For large magnetic fields and at low temperatures, the classical prediction (61) fails; what is actually observed is a spectacular phenomenon, the quantum Hall effect. As B is increased, instead of falling off monotonically as $1/B$, the Hall conductance goes through a series of plateaus, where its value is constant, punctuated by intervals of monotonic decrease. The constant values assumed on the plateaus are sample independent and satisfy with extremely high accuracy (about one part in ten million) the quantization condition

$$\sigma_{\mathrm{H}} = re^2/hc. \tag{62}$$

As B increases, the coefficient r takes on integer values and decreases with B in unit steps until it reaches 1. This is the regime of the integer quantum Hall effect (von Klitzing *et al.*, 1980). As B is increased still further, one enters the regime of the fractional quantum Hall effect (Tsui *et al.*, 1982); r takes on rational values (less than 1) with odd denominators.

The theory of the quantum Hall effect begins with the quantum mechanics of two-dimensional electrons in a magnetic field. The one-electron stationary states are the Landau levels $E_N = \hbar\omega_c(N + \frac{1}{2})$, $N = 0, 1, 2, \ldots$, where $\omega_c = eB/mc$ is the classical cyclotron frequency. The Landau levels are highly degenerate; each can accommodate B/Φ_0 electrons per unit area ($\Phi_0 = hc/e$ is the quantum of magnetic flux). In real materials, the crystalline potential, impurities, and electron–electron interactions all serve to break this degeneracy. However, for sufficiently large magnetic fields, there is negligible mixing between the Landau levels, so that each Landau level is split by the perturbations into B/Φ_0 sublevels per unit area.

If the electron density in the sample is n, then the ground state has the first $\nu = n\Phi_0/B$ Landau levels filled. (Thus, the larger the field B, the fewer occupied Landau levels.) If ν has a fractional part, the uppermost level is only partially filled. The integer quantum Hall effect can now be explained by making two assumptions:

1. only a small proportion of sublevels in each Landau level can carry current, and
2. each filled Landau level contributes precisely e^2/hc to the Hall conductance.

Together, these assumptions imply that a nearly empty Landau level contributes nothing to the Hall conductance, as the occupied sublevels are unlikely to be the current-carrying ones, whereas, conversely, a nearly full Landau level contributes e^2/hc. From these qualitative considerations follows $\sigma_H = [\nu]e^2/hc$ ($[\nu]$ denotes the integer nearest ν). This is precisely the relation (62), with $r = [\nu]$.

The first assumption can be justified on the basis of localization theory—most of the sublevels are localized, whereas only extended states can carry current. For the second assumption, Thouless, Kohmoto, Nightingale, and den Nijs (TKN^2) found, in 1982, a topological explanation (Thouless *et al.*, 1982). In retrospect, their analysis can be seen as an application of the theory of the geometric phase. Indeed, this connection was drawn as early as 1983 by Simon (1983).

In outline, the analysis of TKN^2 is as follows. We consider an electron in two dimensions in a uniform magnetic field $B\hat{\mathbf{z}}$ and periodic crystalline potential $V(x,y)$, with periods a and b in x and y. Because the vector potential $\mathbf{A} = (-By/2, Bx/2)$ is not periodic, neither is the Hamiltonian $mv^2/2 + V(x,y)$, in which $\mathbf{v} = (\mathbf{p} + e\mathbf{A}/c)/m$ is the velocity. However, the Hamiltonian *is* invariant under the magnetic translation operators $T_x = \exp(-imv_x a/\hbar)$ and $T_y = \exp(-imv_y b/\hbar)$, which shift x and y by a and b while leaving the velocity (rather than the momentum) unchanged.

While the magnetic translation operators commute with the Hamiltonian, they do not necessarily commute with each other. In general, $T_xT_y = \exp(2\pi iBab/\Phi_0)T_yT_x$. However, if we take the flux Bab through a unit cell to be a rational multiple p/q of the magnetic flux quantum Φ_0, then $(T_x)^q$—a translation by q lattice spacings in x—and T_y do commute, and Bloch's theorem applies. In this case, the energy levels form a band structure, whose bands $\epsilon_n(\mathbf{k})$ are periodic over the first Brillouin zone $[0,2\pi/qa] \times [0,2\pi/b]$. The eigenfunctions $\psi_{n,\mathbf{k}}(\mathbf{r})$ are Bloch waves $\exp(i\mathbf{k}\cdot\mathbf{r})u_{n,\mathbf{k}}(\mathbf{r})$, where $u_{n,\mathbf{k}}(\mathbf{r})$ is an eigenfunction of the Hamiltonian

$$H(\mathbf{K}) = (1/2m)(-i\hbar\nabla + e\mathbf{A}/c + \hbar\mathbf{k})^2 + V(x,y), \tag{63}$$

with energy $\epsilon_n(\mathbf{k})$, which is invariant under the magnetic translations $(T_x)^q$ and T_y. For convenience, we sometimes denote the indices $n,\mathbf{k}$ by a single label α.

The Hall conductance can now be calculated perturbatively. An applied electric field $E\hat{\mathbf{x}}$ generates perturbed eigenstates $|u'_\alpha\rangle = |u_\alpha\rangle + |\delta u_\alpha\rangle$, which to lowest order are given by $\langle u_\beta|\delta u_\alpha\rangle = \langle u_\beta| - eEx|u_\alpha\rangle/(\epsilon_\alpha - \epsilon_\beta)$, $\beta \neq \alpha$. The electric field induces a transverse current density $\langle u'_\alpha|\, j_y|u'_\alpha\rangle$, where $\mathbf{j} = e(\mathbf{v} + \hbar\mathbf{k}/m)/A_0$ and A_0 is the area of the sample. From (63), the current may also be written as $\mathbf{j} = e\nabla_{\mathbf{k}}H/A_0$. The Hall conductance σ_H is given by the ratio of the total induced current density $\Sigma_\alpha\langle u'_\alpha|\, j_y|u'_\alpha\rangle$ to the electric-field strength E, where the sum is taken over the occupied levels; e.g., for the ground state, the levels below the Fermi energy ϵ_F. Making use of the identity $[x,H] = i\nabla_{k_x}H$, we obtain the following explicit expression:

$$\sigma_{\mathrm{H}} = \frac{e^2}{A_0\hbar c} \sum_{\epsilon(\alpha)<\epsilon_F} \sum_{\beta\neq\alpha} \mathrm{Im} \times \frac{\langle u_\alpha|\nabla_{\mathbf{k}}H|u_\beta\rangle \times \langle u_\beta|\nabla_{\mathbf{k}}H|u_\alpha\rangle}{(\epsilon_\alpha - \epsilon_\beta)^2}. \tag{64}$$

Equation (64) is the Kubo formula for the Hall conductance of the ground state.

Suppose we regard $H(\mathbf{k})$ as a family of Hamiltonians parametrized by the Bloch vector $\mathbf{k}$. Under parallel transport around a closed cycle C, the eigenstate $|u_{n,\mathbf{k}}\rangle$ acquires a geometric phase $\gamma_{n,\mathbf{k}}(C)$, which may be expressed (cf. Sec. 1.2) as the integral of the flux field $V_n(\mathbf{k}) = \mathrm{Im}\langle\nabla_{\mathbf{k}}u_{n,k}| \times |\nabla_{\mathbf{k}}u_{n,k}\rangle$ over the interior of C. Among the various expressions for $V_n(\mathbf{k})$ given in Sec. 1.2, we note that (10), which involves matrix elements of the gradient of the Hamiltonian with respect to the parameters $\mathbf{k}$, is contained precisely in the formula (64) for the Hall conductance. This allows us to rewrite (64) as $\sigma_{\mathrm{H}} = (e^2/A_0\hbar c)\Sigma_n\Sigma_k V_n(\mathbf{k})$. For samples large compared with the unit cell, the sum $\Sigma_{\mathbf{k}}$ over Bloch vectors may be replaced by an integral $(A_0/4\pi^2)\int d^2k$ over the first Brillouin zone T_k. Thus we obtain

$$\sigma_{\mathrm{H}} = \frac{e^2}{hc}\sum_n \sigma_n, \tag{65}$$

where

$$\sigma_n = \frac{1}{2\pi}\int_{T_k} V_n(\mathbf{k})d^2k \tag{66}$$

is the Hall conductance (in units of e^2/hc) of the nth band.

The central result of TKN^2 is that σ_n is an integer. The argument is as follows. Since the energy levels $\epsilon_n(\mathbf{k})$ are periodic over the Brillouin zone, the Bloch states $|\psi_{n,\mathbf{k}}\rangle$ are periodic up to an overall phase factor. In particular, the Bloch states on the corners of the first Brillouin zone, i.e., $\mathbf{k} = 0$, $\mathbf{A}$, $\mathbf{A}+\mathbf{B}$, and $\mathbf{B}$ [here $\mathbf{A} = (2\pi/qa,0)$ and $\mathbf{B} = (0,2\pi/b)$ denote the reciprocal lattice vectors], differ only by a phase. Thus $|\psi_{n,\mathbf{A}}\rangle = e^{i\alpha}|\psi_{n,0}\rangle$, $|\psi_{n,\mathbf{A}+\mathbf{B}}\rangle = e^{i\beta}|\psi_{n,\mathbf{A}}\rangle$, $|\psi_{n,\mathbf{B}}\rangle = e^{i\gamma}|\psi_{n,\mathbf{A}+\mathbf{B}}\rangle$, and $|\psi_{n,0}\rangle = e^{i\delta}|\psi_{n,\mathbf{B}}\rangle$. Together these relations imply that $|\psi_{n,0}\rangle = e^{i(\alpha+\beta+\gamma+\delta)}|\psi_{n,0}\rangle$, and it follows that $\alpha + \beta + \gamma + \delta$ is necessarily an integer multiple m of 2π. Applying Stokes's theorem to (66), we obtain $\sigma_n = (1/2\pi)\oint\mathrm{Im}\langle u_{n,\mathbf{k}}|\nabla_{\mathbf{k}}u_{n,\mathbf{k}}\rangle\cdot d\mathbf{k}$, where the integral is taken around the boundary of the first Brillouin zone. A little calculation shows that this integral gives precisely the accumulated phase change $(\alpha + \beta + \gamma + \delta)/2\pi$ around the first Brillouin zone T_k, i.e., the integer m. In the language of fiber bundles (cf. Sec. 2.1.4), the Bloch states $|\psi_{n,\mathbf{k}}\rangle$ constitute a complex line bundle over T_k with curvature $V_n(\mathbf{k})$, and σ_n is the first Chern number of this line bundle.

For large magnetic fields, the bands $\epsilon_n(\mathbf{k})$ coalesce into clusters of p nearly degenerate sublevels, each cluster associated with one of the Landau levels of the pure magnetic Hamiltonian. It can be shown (the argument is omitted here) that the sum of the conductances σ_n over states in a given Landau level is equal to 1. This completes the topological explanation for the quantization of Hall conductance. TKN^2 also calculate the individual σ_n in the limit of a weak periodic potential; these are found to satisfy certain Diaphantine equations in p and q.

TKN^2 was the first of a number of important applications of geometric-phase methods to the study of the quantum Hall effect. Several subsequent works address the fractional effect, where electron–electron interactions come into play. Niu *et al.* (1985) show how the results of TKN^2 can be generalized to accommodate them. Arovas *et al.* (1984) calculate properties of the elementary excitations of Laughlin's many-body fractional-quantum-Hall ground state (Laughlin, 1983) using geometric-phase arguments. Concerning the integer case, Arovas *et al.* (1988) establish a topological criterion for localization in terms of Chern numbers. Wilkinson (1984) incorporates the geometric phase into semiclassical calculations of the single-particle energy spectrum.

Finally, we mention studies by Avron and co-workers (Avron *et al.*, 1988; Avron, 1995) of electron transport in quantum systems. While not specifically concerned with the quantum Hall effect, they elucidate essentially similar topological mechanisms. One class of models consists of planar networks of one-dimensional wires whose closed loops C_i are threaded by magnetic fluxes ϕ_i normal to the plane. The physical properties of the network are Φ_0 periodic in the fluxes (fluxes differing by an integral number of flux quanta are related by a gauge transformation). Fixing all but two of the fluxes, the stationary states $|\psi_n(\phi_i,\phi_j)\rangle$ constitute a complex line bundle over the two-torus of fluxes (the analog of the first Brillouin zone). The associated Chern number, the integral of the curvature, has the following physical interpretation: it represents the average with respect to ϕ_i of the number of electrons transported around C_i as ϕ_j is increased adiabatically by one flux quantum.

GLOSSARY

Dynamical Phase: The time integral of the energy of an evolving quantum state divided by Planck's constant $\hbar$.

Geometric Phase: A phase factor accumulated by a cycled quantum eigenstate that depends only on the geometry of its evolution.

Geometric Magnetism: Effective Lorentz-type force that appears in the dynamics of a slow system coupled to a fast one after the fast degrees of freedom have been averaged away.

Hannay Angle: Displacement in the angle variables of adiabatically cycled integrable systems of purely geometric origin.

Holonomy: Change in phase induced by parallel transport of a quantum state around a closed curve.

Integrable System: A Hamiltonian system with as many constants of the motion in involution as there are degrees of freedom.

Parallel Transport: A prescription to determine the overall phase of an evolving quantum state.

Reduction: General theory of Hamiltonian dynamics in the presence of symmetry.

INTRODUCTION

Topology is the study of properties that are invariant under continuous deformation. If an object A can be continuously deformed into an object B, and B can be continuously deformed into A, then A and B are considered topologically equivalent. For example, a two-dimensional circular disk A is equivalent to a square B since each may be continuously deformed into each other. Such a disk is not, however, equivalent to the circle that is its boundary, since there is no way to deform a disk to a circle without introducing a discontinuity, i.e., a hole or tear, in the disk. Topology is sometimes called "rubber sheet geometry." It ignores metric aspects of a space such as distance, angle, and area, and concentrates on the aspects associated with the relative position of its points. The word "topology" comes from the Greek words "topos" and "logos" and means "analysis of place"; in some older literature, topology is called *analysis situs.*

"Cut-and-paste" techniques are common methods used to construct spaces in topology. For example, imagine a square sheet of completely flexible and stretchable material sitting in the plane with the corner points labeled A, B, C, and D starting with the upper left-hand corner and moving clockwise as in Fig. 1. Stretching the square out lengthwise and gluing the top edge AB to the bottom edge DC, with A attaching to D and B attaching to C, gives an orientable space that is a portion of a cylinder; it has two sides, and its boundary is equivalent to two circles. In Fig. 1 sets of arrows are placed on identified sides to indicate the orientation used in gluing. If the edge AB is given a 180° twist before the gluing so that A attaches to C and B attaches to D, then the resulting surface is the *Möbius strip,* which is nonorientable: it has only one side, and its boundary is equivalent to a single circle. Walking once around the central circle of a Möbius strip, a traveler returns to the same point but in an upside-down position. In the same way, the usual *torus T* is obtained from the above square by gluing the side AB to the side DC and the side BC to the side AD. The first gluing produces the cylinder as before, which is then stretched out and bent around for the second gluing. The torus is equivalent to the surface of a doughnut or the surface of a ball with a single hole drilled through it. The *Klein bottle K* is obtained by gluing AB to DC as before, but giving BC a 180° twist before gluing it to AD so that B attaches to D, and C attaches to A. The *real projective plane* $\mathbf{R}P^2$

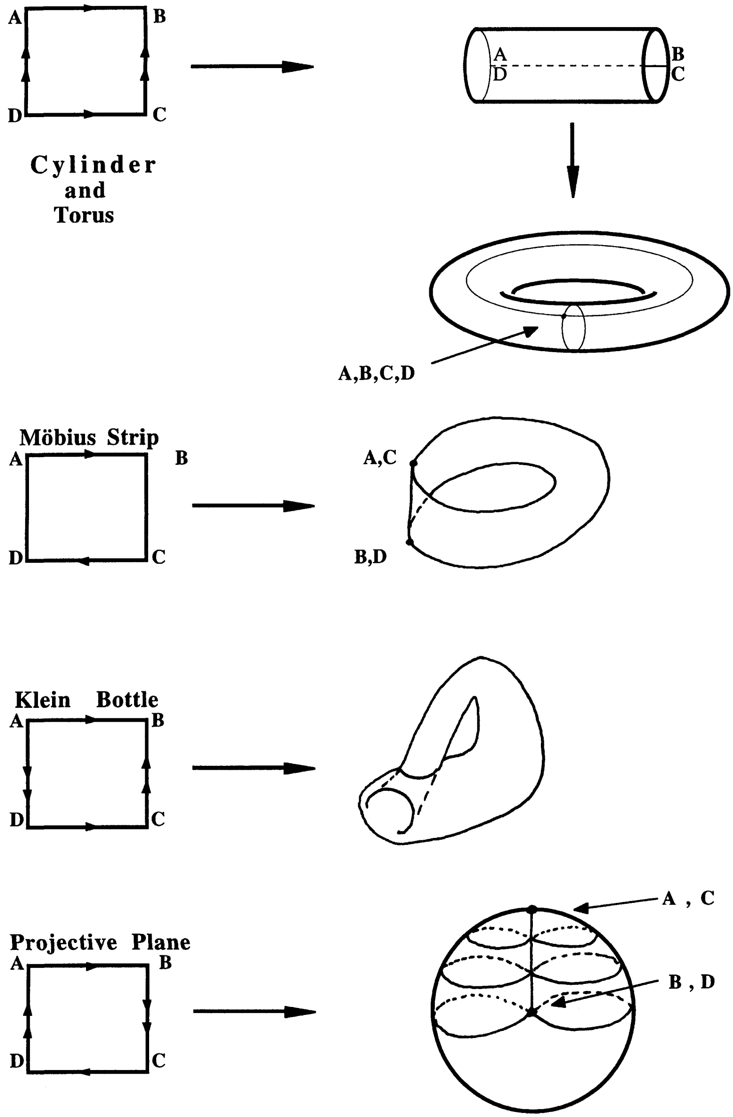

FIG. 1. Cut-and-paste methods for standard two-dimensional spaces.

results from twisting both AB and BC 180° before gluing, so that AB glues to CD and CB glues to AD with A attaching to C and B attaching to D. Of course, after the gluings for the torus, Klein bottle, and real projective plane, the points A, B, C, and D become a single point. The Klein bottle and real projective plane are nonorientable surfaces, and also both of these surfaces have self intersections when considered as subsets of $\mathbf{R}^3 = \{(x_1,x_2,x_3)|x_1,x_2,x_3 \in \mathbf{R}\}$. The above construction of $\mathbf{R}P^2$ can be viewed as taking a two-dimensional disk and gluing each point of its boundary to its antipodal point on the boundary. $\mathbf{R}P^2$ is the set of lines through the origin in $\mathbf{R}^3$. In general, *n-dimensional real projective space* $\mathbf{R}P^n$ is the set of all one-dimensional subspaces (i.e., lines through the origin) in $\mathbf{R}^{n+1}$, and the *n-dimensional complex projective space* $\mathbf{C}P^n$ is the set of all one-dimensional subspaces in $\mathbf{C}^{n+1}$. The dimensions in these projective spaces are taken with respect to the underlying scalars; thus $\mathbf{C}^3$ is three-dimensional as a complex manifold but six-dimensional as a real manifold. The ordinary sphere S^2 can also be obtained from the square ABCD by simply collapsing the boundary of the square to a point. If the

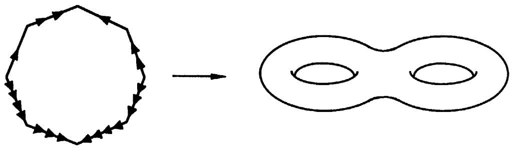

FIG. 2. Gluing the indicated sides produces the two-holed torus.

sides of a regular octagon are identified as in Fig. 2, the result is a two-holed torus.

After the spaces $\mathbf{R}^n$, the spheres are the most commonly encountered spaces in topology and are best considered simply as the set of points in $\mathbf{R}^{n+1}$ that are at unit distance from the origin; i.e., the *n-dimensional sphere* is $S^n = \{x \in \mathbf{R}^{n+1} \mid \|x\| = 1\}$. Each n-sphere S^n is the boundary of the unit $(n + 1)$*-dimensional ball* $B^{n+1} = \{x \in \mathbf{R}^{n+1} \mid \|x\| \leq 1\}$. Notice that the 0-sphere S^0 consists of two points and is therefore the only sphere that is not connected. The *g-holed torus* T_g is the two-dimensional space equivalent to the surface of a three-dimensional ball with g nonintersecting holes drilled through it. Using the above spaces, large numbers of examples can be constructed using additional operations such as Cartesian products and connected sums. Given spaces M and N, the *Cartesian product* $M \times N$ is defined to be $\{(p,q) | p \in M \ \&\ q \in N\}$. If M and N have the same dimension n, the *connected sum* $M \# N$ is constructed by removing an n-dimensional ball from each of M and N, and then gluing the resulting spaces together along the boundaries of the removed balls. Thus, the Cartesian product of two circles $S^1 \times S^1$ is the two-dimensional torus T, and the connected sum $T_g \# T_k$ of a g-holed torus and a k-holed torus is a $(g + k)$-holed torus.

Important isolated problems of a topological nature were treated by Descartes and Euler (the Descartes–Euler characteristic for polyhedra and the Königsberg bridge problem), and Riemann emphasized the importance of topological properties in his studies of complex analysis and algebraic functions. The key property of a Riemann surface is its genus, which counts the number of "holes" associated to the surface. Thus a two-dimensional sphere has genus 0, and a two-dimensional torus such as the surface of a doughnut has genus 1. With Cantor's development of set theory, mathematics entered a new era. More attention was paid to foundational questions, and a higher level of rigor was demanded. The real-number system had been carefully developed by Dedekind and Cantor in a constructive way, and mathematicians saw an opportunity to place all of mathematics on an axiomatic foundation similar to Euclid's *Elements*. The central areas in this new development were topology and abstract algebra. A very large part of twentieth century mathematics is associated with this program.

This development seems at first to be very remote from physics and the sciences. It is more like mathematical housecleaning: making more precise definitions, giving clearer statements and proofs of theorems, finding the weakest hypotheses that give a result, determining whether a property is metric or topological in nature, etc. However, it is important to note that most of the key questions arose from analysis of tools used in physical applications. Cantor's set theory came from his study of the convergence of Fourier series; Sophus Lie developed the theory of continuous groups to make the connection between symmetries and methods of solution of differential equations; Poincaré's deep study of the question of the "stability of the solar system" led him to realize that complicated systems were very difficult to treat quantitatively and that chaotic behavior was possible. In studying periodic orbits in celestial mechanics, Poincaré formulated a key difficulty as a topological conjecture, Poincaré's last geometric theorem, which was proved by G. D. Birkhoff. It was clear at this point that topology was essential to the qualitative analysis of dynamical systems. This was one of the major motivating forces behind the initial development of topology and remains so. Further, the development of general relativity and the associated area of differential geometry brought into focus the key relation between local and global aspects of spaces. To illustrate: Suppose that the given space is a two-dimensional sphere in three-space. Locally—for example, in the Northern hemisphere—there exist an infinite number of harmonic functions, i.e., solutions of the Laplace equation $\Delta f = 0$, even if the value of f is prescribed at the North Pole. However, globally only one such harmonic function exists; it must be a constant function. The topology of the sphere forces each function that is harmonic on the entire sphere to be a constant function. Similarly, it is possible to construct a unit-length tangent-vector field on the Northern hemisphere, but globally such a vector field is impossible. However, the two-dimensional torus does admit such a global unit-length tangent-vector field, and this torus is the only orientable surface without boundary with this property. This result follows from the famous Poincaré–Hopf index theorem discussed in Sec. 3.2. Topology plays an essential role in quantifying these global aspects of spaces and is therefore essential in global analysis and boundary-value problems. It is important to note that in applications, topology is usually combined with other areas of mathematics such as algebra and differential geometry.

This article discusses the three most prominent branches of topology: point-set topology, algebraic topology, and differential topology. These areas are considered to be closest to applications in physics.

1. POINT-SET TOPOLOGY

Point-set topology, also called general topology, provides the basic foundation for mathematical analysis, the portion of mathematics most directly connected with the calculus and the theory of differential and integral equations. The key concepts are continuity and convergence. The subject assumes only basic set theory. Point-set topology begins with topological spaces and continuous functions between such spaces. The basic properties of such spaces and functions are studied, and then gradually new concepts such as connectedness and compactness are added and examined. This step-by-step development leads to a clearer understanding of the role each hypothesis plays in a given result and often points the way to important extensions and generalizations. For example, the extreme-value theorem may be stated in a simple case as follows: A real-valued function that is continuous on a closed bounded interval $[a,b] \subset \mathbf{R}$ attains its maximum and minimum values at some points of the interval. Further analysis of this theorem shows that two basic ideas, continuity and compactness, are essential hypotheses for this theorem. The more general theorem is then this: a real-valued function that is continuous on a compact topological space attains its maximum and minimum values at some points of that space.

A very concise summary of essential definitions and results follows. This list is not comprehensive; it contains only the most commonly encountered definitions and results of point-set topology. These are particularly important for a clear understanding of functional analysis as used in physics. For example, point-set topology is basic to the theory of Fourier transforms, Sobolev spaces, finite-element methods, and the theory of distributions such as the Dirac delta function. The theory of distributions was a major motivation for the development of the theory of topological vector spaces.

Throughout this article, "iff" means "if and only if" and frequently indicates that a definition is being given.

1.1 Basic Concepts

A collection T of subsets of a set X is a *topology* on X iff

1. the empty set $\emptyset$ and the set X are in T;
2. T is closed under arbitrary unions; i.e., given any collection of subsets of X that are in T, their union is in T;
3. T is closed under finite intersections; i.e., given any finite collection of subsets of X that are in T, their intersection is in T.

A *topological space* (X,T) is a set X with a topology T on X. It is common to abbreviate (X,T) to X and *topological space* to *space*. If several topological spaces are involved, T may be replaced by T_X or another symbol such as S for clarity.

To illustrate, let $X = \{a,b,c\}$ be a set with three elements; then $T_1 = \{\emptyset,X\}$ and $T_2 = \{\emptyset,\{a\},\{b\},\{a,b\},X\}$ are topologies on X, but $T_3 = \{\emptyset,\{a\},\{b\},X\}$ is not since condition 2 is not satisfied. In general, for any set X, there are two standard topologies that can always be defined on X: the *discrete topology* consisting of the collection of all subsets of X, and the *indiscrete* or *trivial topology* that consists of only $\emptyset$ and X itself.

If (X,T) is a topological space, then the elements of T are called the *open sets* of the space. A subset A of a topological space (X,T) is *closed* iff its complement $X - A$ is open.

In the above example (X,T_2), $\{c\}$ is a closed set since its complement $\{a,b\}$ is open. Notice that open and closed are not opposites; a set can be both open and closed (e.g., X in T_1) or neither open nor closed (e.g., $\{a\}$ in T_1). The above topological spaces illustrate the definition clearly but are too artificial to be of much use in physics. A much more interesting example is given by $X = \mathbf{R}^n$, the n-dimensional vector space of all n-tuples of real numbers, with the *metric topology.* This is one of the most important topological spaces, and it is worth studying carefully. To define this topology some preliminary ideas are needed. For each pair of points a and b in $\mathbf{R}^n$, let $d(a,b)$ be the usual Euclidean distance from a to b. The *open ball* $B_r(p)$ centered at p and of radius $r > 0$ in $\mathbf{R}^n$ is defined to be $\{x \in \mathbf{R}^n | d(x,p) < r\}$, i.e., the set of all points strictly within distance r of p. Using these open balls the metric topology on $\mathbf{R}^n$ is defined as follows: A subset A is *open* in $\mathbf{R}^n$ iff for each $p \in A$, $B_r(p) \subset A$ for some $r > 0$. Intuitively, a subset A is open iff there is "space in all directions" in A around each of its points. This "space in all directions" is essential for the definition of key analytic concepts such as continuity and differentiation that require that the value of a function at a point be compared with values at all nearby points. Applying the definition is usually simple on an intuitive level. Thus, in the real line $\mathbf{R}$ the "open" interval $(0,1)$ is an open set, the "closed" interval $[-1,2]$ is a closed set since its complement, $(-\infty,-1) \cup (2,\infty)$, is an open set, and the half-open interval $(-3,5]$ is neither open nor closed.

In general, a metric topology may be defined on any set that has an appropriate notion of distance, i.e., a *metric,* defined on it. Often the metric is given by a more elaborate structure on the set such as an inner product or a norm. Inner products, norms, and metrics are formally defined as follows: Let V be a vector space over F where F is either the real or the complex number field, and let M be a set. Then $\langle , \rangle : V \times V \to F$ is an *inner product* on V iff

$\langle A,B \rangle = \overline{\langle B,A \rangle}$ for all $A, B, \in V$,
$\langle A, bB + cC \rangle = b\langle A,B \rangle + c\langle A,C \rangle$ for all $A, B, C \in V$ and $b, c \in F$, and
$A \in V$ and $A \neq 0$ imply that $\langle A,A \rangle > 0$.

An *inner product space* $(V,\langle , \rangle)$ is a vector space V together with an inner product $\langle , \rangle$ defined on it.

Next, $\|\cdot\|: V \to \mathbf{R}$ is a *norm* on V iff

$\|aA\| = |a|\|A\|$ for all $A \in V$ and $a \in F$,
$\|A + B\| \leq \|A\| + \|B\|$ for all $A, B \in V$, and
$A \in V$ and $A \neq 0$ imply that $\|A\| > 0$.

A *normed space* $(V,\|\cdot\|)$ is a vector space V together with a norm $\|\cdot\|$ defined on it.

Lastly, $d: M \times M \to \mathbf{R}$ is a *metric* on M iff

$d(x,y) = d(y,x)$ for all $x, y \in M$,
$d(x,z) \leq d(x,y) + d(y,z)$ for all $x, y, z \in M$, and
$d(x,y) \geq 0$ for all $x, y \in M$ and $d(x,y) = 0$ iff $x = y$.

A *metric space* (M,d) is a set M together with a metric d defined on it. Each of these structures gives the vector space V a natural metric topology since each inner product $\langle , \rangle$ induces a norm $\|\cdot\|$, which in turn induces a metric via the rules $\|A\| = \sqrt{\langle A,A \rangle}$ and $d(A,B) = \|A - B\|$.

If (X,T) is a topological space, and A is a subset of X, then A inherits a topology S from X as follows: B is *open in A* iff $B = A \cap U$ for some open set U in X. Briefly, this is written $B \in S$ iff $B = A \cap U$ for some $U \in T$. This topology is called the *relative topology* on A. It is also called the *induced* or *subspace topology* on A. Thus in the metric topology on $X = \mathbf{R}$ above, the interval $(1,2]$ is not open in X, but it is open in $A = [0,2]$ since $(1,2] = A \cap U$, with $U = (1,3)$ for example. A subset $N \subset X$ is a *neighborhood* of a point $p \in X$ iff $p \in U \subset N$ for some open set $U \in T$. If, in addition, N is an open set, then N is called an *open neighborhood* of p.

Let A be a subset of a topological space (X,T). $p \in X$ is an *interior point* of A iff $p \in U \subset A$ for some $U \in T$, i.e., A is a neighborhood of p. $p \in X$ is an *exterior point* of A iff p is an interior point of $X - A$. $p \in X$ is a *closure* or *limit point* of A iff each neighborhood of p contains at least one point of A. $p \in X$ is a *boundary point* of A iff p is a closure point of both A and $X - A$. $p \in X$ is an *accumulation point* of A iff each neighborhood of p contains at least one point of A other than p. $p \in A$ is an *isolated point* of A iff p is not an accumulation point of A. The *interior* of A is the set of all interior points of A and is denoted int$A$. It is also the union of all the open subsets of A and is the largest open set contained in A. The *closure* of A is the set of all closure points of A and is denoted cl$A$. It is also the intersection of all the closed subsets that contain A and is the smallest closed set containing A. The *boundary* of A is the set of all boundary points of A and is denoted bd$A$. It is equal to cl$A$ − int$A$. In many cases these concepts behave as the names indicate. Thus, for the metric topology on **R**, the set $A = [0,1)$ has the open interval $(0,1)$ as its interior, the closed interval $[0,1]$ as its closure, and the set $\{0,1\}$ consisting of the two "boundary points" as its boundary. However, these simple definitions contain some subtleties. For example, the subset of all rational numbers in $[0,1]$ has interior equal to the empty set, and both the closure and the boundary are equal to the closed interval $[0,1]$. The notations A°, $\bar{A}$, and ∂A are frequently used for int$A$, cl$A$, and bd$A$, respectively. A is *dense* in B iff $B \subset \mathrm{cl}A$. For example, the set **Q** of rational numbers is dense in the set **R** of real numbers, and the set of polynomials with rational coefficients is dense in the space $C^0([0,1],\mathbf{R})$ of all continuous real-valued functions on $[0,1]$ with the sup norm $\|f\| = \max\{|f(x)| \mid x \in [0,1]\}$. This notion of denseness is essential in approximation theory.

A topological space (X,T) is *Hausdorff* iff for each pair of points a and b there exist disjoint open sets U and V such that $a \in U$ and $b \in V$. Hausdorff spaces are also called T_2 spaces. Hausdorff is the most common of the several *separation* conditions that may be imposed on a topological space. All metric spaces are Hausdorff spaces.

The above definitions give the flavor of point-set topology. It is abstract and very set theoretic. It is important to keep in mind some of the primary examples that are discussed in the following such as surfaces in $\mathbf{R}^3$ with the induced metric topologies, topological and differentiable manifolds, and especially function spaces such as Hilbert and Banach spaces.

1.2 Continuity

The δ-ϵ definition for continuity given in calculus is as follows: a function $f{:}\mathbf{R} \to \mathbf{R}$ is *continuous at the point p* iff for each $\epsilon > 0$ there exists a $\delta_\epsilon > 0$ such that $|x - p| < \delta_\epsilon$ implies that $|f(x) - f(p)| < \epsilon$. The function is said to be *continuous on* $A \subset \mathbf{R}$ iff f is continuous at each point of A. Intuitively, continuous functions are allowed to stretch or contract portions of their domains, but no breaks or tears are permitted. The above definition is easily generalized to functions between metric spaces by simply replacing the absolute values by the appropriate distances, but it does not apply to more general topological spaces in which no such distance is given. The following definition generalizes the notion of continuity to topological spaces and is equivalent to the δ-ϵ definition above in the metric-space case. A function $f{:}(X,T_X) \to (Y,T_Y)$ is *continuous on X* iff $f^{-1}(U)$ is open for each $U \subset Y$; i.e., inverse images of open sets are open. Here the inverse image $f^{-1}(U)$ is defined to be $\{x \in X \mid f(x) \in U\}$; inverse images are defined for all functions, invertible or otherwise. The above function f is *continuous on* $A \subset X$ iff f restricted to A with the relative topology is continuous on A. It is common to abbreviate *continuous function* to *map*. Two topological spaces (X,T_X) and (Y,T_Y) are considered to be *topologically equivalent* or *homeomorphic* iff there exists a bijective function $f{:}(X,T_X) \to (Y,T_Y)$ that is continuous on X and that has an inverse f^{-1} that is continuous on Y. Such a function f is called a *homeomorphism*. For the purposes of topology, homeomorphic spaces are considered to be the same and must have identical topological properties.

1.3 Connectedness and Compactness

Compactness, connectedness, and path connectedness are among the most important topological properties and occur very frequently in topological analysis. Let A be a subset of a topological space (X,T_X). A collection of open subsets of X is an *open cover* of A iff A is contained in their union. A *finite subcover* of such an open cover is any finite subcollection that also contains A in its union. $A \subset X$ is *compact* iff each open cover of A has a finite subcover. For example, the open cover of the real line **R** given by $\{(n - 1, n + 1) \mid n \text{ is an integer}\}$ has no finite subcover; so **R** is not compact. Open covers are often denoted $\{U_i\}_{i \in I}$, where each U_i is an open set in the cover and I is an index set. $A \subset X$ is *connected* iff there do not exist open sets U and V in X with $A \subset U \cup V$, $A \cap U \neq \emptyset$, $A \cap V \neq \emptyset$, and $A \cap U \cap V = \emptyset$. Equivalently, $A \subset X$ is *connected* iff the only subsets of A that are both open and closed in the relative topology of A are $\emptyset$ and A. $A \subset X$ is *path connected* iff for each pair of points p and q in A there is a continuous function $\gamma:[0,1] \to A$ such that $\gamma(0) = p$ and $\gamma(1) = q$. Such a continuous γ is called a *path* in A from p to q. Path-connected spaces are necessarily connected, but not vice versa. If $f:(X,T_X) \to (Y,T_Y)$ is a function continuous on X and $A \subset X$ is compact, then the image $f(A)$ is also compact; similarly, if A is connected (resp. path connected), then $f(A)$ is also connected (resp. path connected). Two important theorems result from these concepts. Continuity plus compactness gives the extreme-value theorem: If $f:\mathrm{X} \to \mathbf{R}$ is continuous on X, and X is compact, then f must attain its maximum and minimum values at some points of X. Continuity plus connectedness gives the intermediate-value theorem: If $f:\mathrm{X} \to \mathbf{R}$ is continuous on X, and X is connected, and $f(a) < z < f(b)$ for some a and b in X and some real number z, then there is a $c \in X$ with $f(c) = z$. Two simple consequences of the intermediate-value theorem are the simple fixed-point theorem: Each continuous function $f:[0,1] \to [0,1]$ must have a fixed point, i.e., there is an $x \in [0,1]$ such that $f(x) = x$; and the heated-ring theorem: Given any continuous function $f:S^1 \to \mathbf{R}$, there exists at least one pair of antipodal points $x,x' = -x$ such that $f(x) = f(x')$. If S^1 is considered as the unit circle in the complex plane, and f is taken to be the temperature at each point, then this means that $f(x) = f(-x)$ for some $x \in S^1$; i.e., there are always at least two opposite points with the same temperature.

Continuity and compactness also combine to produce uniform continuity. A function $f:X \to \mathbf{R}$ is *uniformly continuous* on a metric space (X,d) iff for each $\epsilon > 0$ there is a $\delta_\epsilon > 0$ such that $x,y \in X$ and $d(x,y) < \delta_\epsilon$ imply $|f(x) - f(y)| < \epsilon$. The key point here is that δ_ϵ depends on ϵ but not on the points x and y involved. The important result is then that if $f:X \to \mathbf{R}$ is continuous on X, and X is compact, then f is uniformly continuous on X.

Compactness has several equivalent formulations, each appropriate to various applications. The Heine–Borel theorem says that $A \subset \mathbf{R}^n$ is compact iff A is closed and bounded. Here A is *bounded* iff A is contained in some sufficiently large open ball $B_r(p)$. This criterion is extremely easy to use, but it fails for most function spaces, which are usually infinite dimensional. For these more general cases, further conditions are usually required. As an illustration, consider the space $C^0([0,1],\mathbf{R})$ given in Sec. 1.1. The Arzela–Ascoli theorem says: $A \subset C^0([0,1],\mathbf{R})$ is compact iff A is closed, bounded, and equicontinuous. Here A is *equicontinuous* iff for each $\epsilon > 0$ there is a $\delta_\epsilon > 0$ such that $x,y \in [0,1]$ and $|x - y| < \delta_\epsilon$ imply $|f(x) - f(y)| < \epsilon$ for all $f \in A$. The essential part of this definition is that the same δ_ϵ works for all $f \in A$. Equicontinuity extends the notion of uniform continuity and is therefore sometimes called *uniform uniform continuity.*

A sequence $x_1, x_2, x_3, \cdots$ of points in a topological space X *converges* to $p \in X$ iff for each neighborhood U of p there exists an integer N_U such that $x_k \in U$ for all $k \geq N_U$. To make this definition useful, it is necessary to require that the space X be Hausdorff; otherwise a sequence may converge to two distinct points. For example, in the space $X = \{a,b\}$ with the indiscrete topology $\{\emptyset,X\}$, the sequence $a, b, a, b, a, b, a, \cdots$ converges to both a and b. This pathological behavior does not occur in Hausdorff spaces. A sequence $x_1, x_2, x_3, \cdots$ in a metric space M is a *Cauchy sequence* iff for each $\epsilon > 0$ there exists an integer N_ϵ such that $d(x_m,x_n) < \epsilon$ for all $m,n \geq N_\epsilon$. A metric space M is *complete* iff each Cauchy sequence in M converges to a point of M. A metric space M is *totally bounded* iff for each $\epsilon > 0$ there exists a finite collection of open balls of radius ϵ that contains M in their union; i.e., they form a finite open cover of M. A complete normed space is called a *Banach space.* A complete inner-product space is called a *Hilbert space.*

Four equivalent criteria for compactness are given as follows: A is compact iff

1. each open cover of A has a finite subcover (topological version);
2. each sequence in A has a subsequence that converges to a point of A (*sequential compactness* version);
3. A is complete and totally bounded (metric-space version); or
4. each infinite subset of A has an accumulation point in A (*Bolzano–Weierstrass property*).

The following properties are used frequently. Each closed subset of a compact topological space is compact. Each compact subset of a Hausdorff topological space is closed. The Tychonoff theorem states that the Cartesian product of an arbitrary number of compact topological spaces is compact.

An essential tool in the piecing together of local objects to form a global object is a *partition of unity.* Some definitions are needed first. A topological space X is *paracompact* iff X is Hausdorff and each open cover of X has a locally finite refinement. A *locally finite refinement* of an open cover $\{U_i\}_{i\in I}$ is an open cover $\{V_j\}_{j\in J}$ such that each V_j is contained in some U_{i_j} and each point of X is in at most a finite number of the V_j's. Given an open cover $\{U_i\}_{i\in I}$ of the space X, a family of continuous functions $\varphi_i{:}X \to [0,1]$ is a *partition of unity* subordinate to the cover $\{U_i\}_{i\in I}$ iff $\mathrm{supp}(\varphi_i) \subset U_i$ for each $i \in I$, and for each $p \in X$, $\varphi_i(p) = 0$ for all but a finite number of indices i and $\Sigma_{i\in I}\varphi_i(p) = 1$. Here $\mathrm{supp}(\varphi)$ denotes the *support* of $\varphi{:}X \to \mathbf{R}$ and is defined to be the closure of the subset of X on which φ is nonzero, i.e., $\mathrm{cl}\{p \in X|\varphi(p) \neq 0\}$. The basic theorem in this regard is this: Each paracompact topological space admits a partition of unity. This result is important for the theory of manifolds (see Sec. 3.1). It implies that each paracompact manifold can be given a Riemannian metric (see GEOMETRICAL METHODS, Sec. 2.3). Essentially, the coordinate charts on the manifold give induced metrics on parts of the manifold, which are then pieced together via an associated partition of unity.

2. ALGEBRAIC TOPOLOGY

The key idea in algebraic topology is to assign algebraic invariants to topological spaces in such a way that homeomorphic spaces have the same algebraic invariants. It is hoped that the algebraic information given by groups, rings, vector spaces, and homomorphisms is then easier to analyze. For example, if two spaces have different invariants, then they cannot be equivalent. This gives a method for distinguishing many spaces.

Physically, the most direct motivation for algebraic topology comes from potential theory. The fundamental problem of electrostatics is to find the equilibrium charge-density distribution on the surface of a charged conductor. This difficult problem is replaced by the simpler and in many cases more relevant problem of the determination of the electric field $\mathbf{E}$ produced by such a charge distribution. This field problem is in turn reduced to a function problem via the introduction of a potential function φ. The equation div $\mathbf{E} = 0$ then becomes the Laplace equation, $\Delta\varphi = 0$, with solution given by the line integral $\varphi(X) = \int_\gamma \mathbf{E}\cdot d\mathbf{l}$, where γ is any smooth path from a fixed point A to the variable point X. The path γ is also required to lie inside the region exterior to the conductor. The point A is usually taken to be a point at infinity or some point assumed to have zero potential. If the field $\mathbf{E}$ is given by $\mathbf{E} = (P,Q,R)$, and the line element $d\mathbf{l}$ is denoted by (dx,dy,dz), then $\varphi(X) = \int_\gamma Pdx + Qdy + Rdz$ expresses the potential as the integral of the differential one-form $\alpha = Pdx + Qdy + Rdz$ over a path from A to X. Further, the condition curl $\mathbf{E} = 0$ implies that the one-form α is closed (i.e., $d\alpha = 0$), and therefore the Stokes theorem implies that the line integral above will give the same value on any smooth path γ' connecting A to X that can be continuously deformed into γ without crossing the surface of the conductor. In such a case the paths γ and γ' are said to be *homotopic* to each other within the region exterior to the conductor. Two examples are useful here. If the conductor is a solid ball, then each pair of paths from arbitrary points A and X and lying in the region exterior to the ball are homotopic to each other in that region. Such a region is called *simply connected.* An equivalent form of this condition is that each closed path (*loop*) beginning and ending at a given point A should be continuously deformable within the region to the point A. For a nonsimply connected example, consider a solid torus (doughnut-shaped) conductor; then a loop at A that passes once through the hole in the torus is not deformable to the point A. This results, in general, in multivalued potential functions.

2.1 Some Basic Tools

Helmholtz's theorem also requires simply connected regions. A vector field $\mathbf{V}$ with curl $\mathbf{V} = 0$ in a simply connected region can be expressed as a gradient of appropriate potential functions, and a vector field $\mathbf{V}$ with div $\mathbf{V} = 0$ in a simply connected region can be expressed as a curl of appropriate vector potentials. These basic results are simplified and generalized by the theory of differential forms. For simplicity consider the case of $\mathbf{R}^3$ with the usual Cartesian coordinate system. A *0-form* f is simply a smooth real-valued function on $\mathbf{R}^3$, such as $f(x,y,z) = x^2y + \sin(xyz^2)$. A *1-form* α has the form $\alpha = Pdx + Qdy + Rdz$, and a *2-form* β has the form $\beta = Pdy \wedge dz + Qdz \wedge dx + Rdx \wedge dy$, where P, Q, and R are 0-forms. Finally, a *3-form* γ has the form $\gamma = fdx \wedge dy \wedge dz$, where f is a 0-form. The *wedge product* symbol $\wedge$ is used to emphasize that this multiplication is skew commutative; i.e., $dy \wedge dx = -dx \wedge dy$ and, in particular, $dx \wedge dx = 0$; $dy \wedge dz \wedge dy = 0$, etc. As a consequence, all differential forms of degree higher than the dimension of the underlying space are zero. The properties of these forms are based on those of determinants where interchanging any two distinct rows reverses the sign of the determinant. Determinants measure signed lengths, areas, volumes, and hypervolumes; differential forms measure infinitesimal signed lengths, areas, volumes, and hypervolumes and, therefore, appear as integrands in integrals giving such quantities. The wedge product generalizes the cross product to spaces of arbitrary dimension. The key operator in differential forms is the exterior derivative d. Letting E^p denote the real vector space of all p-forms on $\mathbf{R}^3$, this derivative maps each p-form α to a $(p + 1)$-form $d\alpha$, i.e., $d{:}E^p \to E^{p+1}$. Thus, for each 0-form f, $df = f_xdx + f_ydy + f_zdz$, where the subscripts denote partial derivatives; for each 1-form $\alpha = Pdx + Qdy + Rdz$, $d\alpha = (R_y - Q_z)dy \wedge dz + (P_z - R_x)dz \wedge dx + (Q_x - P_y)dx \wedge dy$; for each 2-form $\beta = Pdy \wedge dz + Qdz \wedge dx + Rdx \wedge dy$, $d\beta = (P_x + Q_y + R_z)dx \wedge dy \wedge dz$; and $d\gamma = 0$ for each 3-form γ. A key property of this derivative is $d^2 = 0$; i.e., $d(d\alpha) = 0$ for each p-form α. A p-form α is *closed* iff $d\alpha = 0$, and α is *exact* iff $\alpha = d\varphi$ for some $(p - 1)$-form φ. The $d^2 = 0$ property implies that each exact form is also a closed form. If a vector field $\mathbf{X} = (P,Q,R)$ is identified with the 1-form α above, then curl $\mathbf{X}$ corresponds to $d\alpha$; and if $\mathbf{X}$ is identified with the 2-form β above, then div $\mathbf{X}$ corresponds to $d\beta$. The basic vector analysis identities curl $\nabla\mathbf{X} = 0$ and div curl $\mathbf{X} = 0$ are special cases of $d^2 = 0$. In physics, the vector fields corresponding to 1-forms are called "polar" vector fields, and the vector fields corresponding to 2-forms are called "axial" vector fields. Using this formalism, classic formulas such as

the fundamental theorem of calculus:

$$\int_a^b f'(x)dx = f(b) - f(a),$$

Green's theorem:

$$\iint_G (Q_x - P_y)dx \wedge dy = \int_{\partial G} Pdx + Qdy,$$

the Stokes theorem:

$$\iint_S (\text{curl}\,\mathbf{X}\cdot\mathbf{n}dS) = \int_{\partial S} \mathbf{X}\cdot d\mathbf{s}, \text{ and}$$

the divergence theorem:

$$\iiint_D \text{div}\,\mathbf{X}dV = \iint_{\partial D} \mathbf{X}\cdot\mathbf{n}dS$$

are special cases of the "generalized Stokes theorem," which has the form

$$\iint \cdots \int_M d\alpha = \int \cdots \int_{\partial M} \alpha$$

for each n-dimensional orientable manifold M with boundary ∂M and $(n - 1)$-form α on M. Thus, integration of the right sort of n-form, namely, an exterior derivative, over a given region reduces to an integral over the boundary of the region. In a sense this results from the fact that whatever enters or leaves a region must cross the boundary. The differential-forms formalism and the above theorems are very directly connected to basic techniques of potential theory and are therefore relevant to electromagnetism and in particular to Maxwell's equations.

The constructions in algebraic topology are designed to measure the topological complexity of a given space relative to the above considerations. For example, if T is a cylindrical tube with boundary ∂T given by two circles C_1 and C_2 with proper orientations, and α is a given closed 1-form on M, then $\int_{C_1}\alpha = \int_{C_2}\alpha$. Thus, C_2 is equivalent to C_1 in these circumstances. Two such spaces that form the boundary of a third space of one higher dimension are said to be *homologous* and are considered to be equivalent in *homology*. For example, any two disjoint circles on the two-dimensional sphere S^2 form the boundary of an annular region on S^2, and so the homology group (as defined in Sec. 2.3) $H_1(S^2)$ of S^2 is 0. The *de Rham cohomology* of M (see Sec. 3.3) is defined directly in terms of the differential-forms structure as the quotient of the vector space of closed p-forms on M by the vector space of exact p-forms on M for each p and therefore measures the extent to which each closed form can be represented as an exact form. In the more general case, cohomology is defined by taking the appropriate notion of a *dual* of the homology of the space.

Some of the most famous theorems provable via algebraic topological methods are the following (let n be a positive integer, B^n be the unit ball in $\mathbf{R}^n$, and S^n be the unit sphere in $\mathbf{R}^{n+1}$):

Jordan–Brouwer separation theorem: Each compact connected hypersurface X in $\mathbf{R}^n$ divides $\mathbf{R}^n$ into two open sets: the "inside" of X and the "outside" of X. The special case with X a simple closed curve in $\mathbf{R}^2$ is called the Jordan curve theorem. A *hypersurface* in $\mathbf{R}^n$ is an $(n - 1)$-dimensional submanifold of $\mathbf{R}^n$.

No-retraction theorem: There is no continuous map from B^n to its boundary S^{n-1}.

Brouwer fixed-point theorem: If $f:B^n \to B^n$ is continuous, then f has a fixed point; i.e., there exists a point $p \in B^n$ such that $f(p) = p$.

Borsuk–Ulam theorem: If $f:S^n \to \mathbf{R}^n$ is continuous, then $f(x) = f(-x)$ for some $x \in S^n$; i.e., f takes the same value on at least one pair of antipodal points.

Ham-sandwich theorem: Let A, B, C be three bounded subsets of $\mathbf{R}^3$ each of which has a volume; then there exists a plane that bisects each of the three sets. (This theorem generalizes to the case of n bounded sets with hypervolume and guarantees the existence of a hyperplane in $\mathbf{R}^n$ that bisects each of them.)

To illustrate via a physical example: Imagine a fluid flowing inside a torus-shaped container in such a way that each point of the fluid is moving counterclockwise around the torus as in Fig. 3; then the Brouwer fixed-point theorem implies that this flow must have a closed (periodic) orbit. Here the B^n involved is a disk placed perpendicular to the central circle of the torus, and the map f associates to each point on this disk the return point obtained by flowing once around the torus. This application is close to one of Poincaré's original motivations for topology. He wanted to prove the existence of periodic orbits in phase-space flows associated with celestial mechanics. The intercepting space is called a *Poincaré section.*

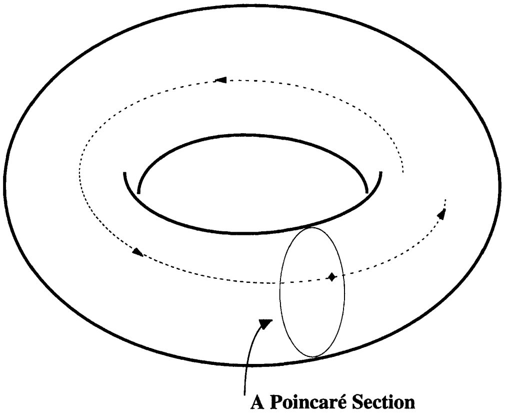

FIG. 3. Placing a Poincaré section in a fluid flow in a torus.

2.2 Homotopy

Intuitively, two paths from point P to point Q and lying in a region R are *homotopic* iff each can be continuously deformed into the other without leaving the region. This notion clearly depends on the region involved. For example, consider the paths γ_1 = the upper semicircle and γ_2 = the lower semicircle connecting the points $P = (-1,0)$ and $Q = (1,0)$ in the plane $\mathbf{R}^2$. These are homotopic in the region $\mathbf{R}^2$, but they are not homotopic in the punctured plane, $\mathbf{R}^2 - \{(0,0)\}$. Thus, if the one-form α has no singularities on or inside the unit circle, then $\int_{\gamma_1}\alpha = \int_{\gamma_2}\alpha$; but for the one-form

$$\alpha = \frac{-ydx + xdy}{x^2 + y^2},$$

which has a singular point at the origin, these two line integrals have distinct values. The *fundamental group* measures the complexity of a space in this regard. In Fig. 4 the underlying space is a torus, and the paths γ_1 and γ_2 are homotopic, but neither path is homotopic to the path γ_3.

Let I be the unit interval [0,1]. A *path*

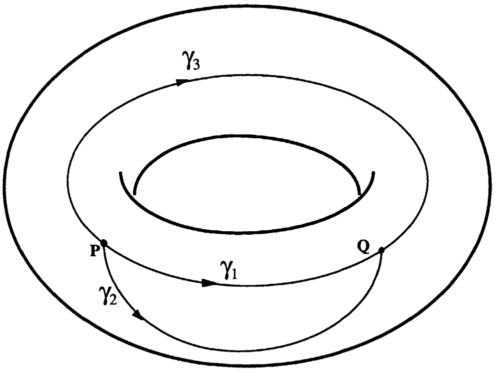

FIG. 4. Path γ_1 is homotopic to γ_2, but not to γ_3.

from P to Q in a topological space M is a continuous function $f{:}I \rightarrow M$ with $f(0) = P$ and $f(1) = Q$. Two paths f and g from P to Q in M are *homotopic* iff there exists a continuous function $F{:}I \times I \rightarrow M$ such that $F(0,t) = P$, $F(1,t) = Q$, $F(s,0) = f(s)$, and $F(s,1) = g(s)$ for all s and t in I. Thus F maps the unit square $I \times I$ into M so that all points on the left edge go to P, all points on the right edge go to Q, the bottom edge is mapped to the path f, and the top edge is mapped to the path g. This is illustrated in Fig. 5. This definition makes precise the notion of "continuous deformation" of f to g in M. Notice that all paths are reparametrized if necessary so as to have domain I. To define the fundamental group of M, a single point x_0 in M is fixed, and only *loops*, i.e., paths with initial and terminal points at x_0, are considered. Two loops are considered *equivalent* iff each can be deformed into the other within M. In particular, a loop is *trivial* iff it can be deformed to the basepoint x_0; i.e., it is homotopic to the constant path at x_0. The *fundamental group* of M with *basepoint* x_0 is defined to be the set of equivalence classes of such loops at x_0. If M is path connected, then the fundamental group is independent of the choice of basepoint. The group product operation $*$ in the fundamental group is defined as follows: Given two equivalence classes $[f]$ and $[g]$ of loops at x_0, pick representative loops, f and g, from each class; reparametrize f to have domain $[0,1/2]$ and g to have domain $[1/2,1]$, and define a new loop, denoted $f \cdot g$, which is just f followed by g; then the product is defined by $[f] * [g] = [f \cdot g]$. This operation is independent of the choices made and gives the set of equivalence classes a group structure. If M is path connected and the fundamental group of M is 0, i.e., the group has only one element, then M is said to be *simply connected*. The fundamental group of M is also called the *Poincaré group* or *first homotopy group* of M and is denoted $\pi_1(M,x_0)$ or just $\pi_1(M)$ if M is path connected. Simple examples are $\pi_1(\mathbf{R}^n) = 0$ for all n, $\pi_1(S^1) = \mathbf{Z}$ for the circle S^1, and $\pi_1(S^n) = 0$ for all spheres S^n with $n \geq 2$. The real projective plane has fundamental group $\mathbf{Z}_2$ as does the rotation group $R(3) = \mathrm{SO}(3)$. To see this, consider $R(3)$ as a solid ball of radius π in $\mathbf{R}^3$ with each point on its boundary identified to its antipodal point; i.e., each rotation in $\mathbf{R}^3$ with an axis corresponds to a point in the ball along that axis at a distance given by the angle of rotation about that axis. The identity rotation corresponds to the center of the ball, and each

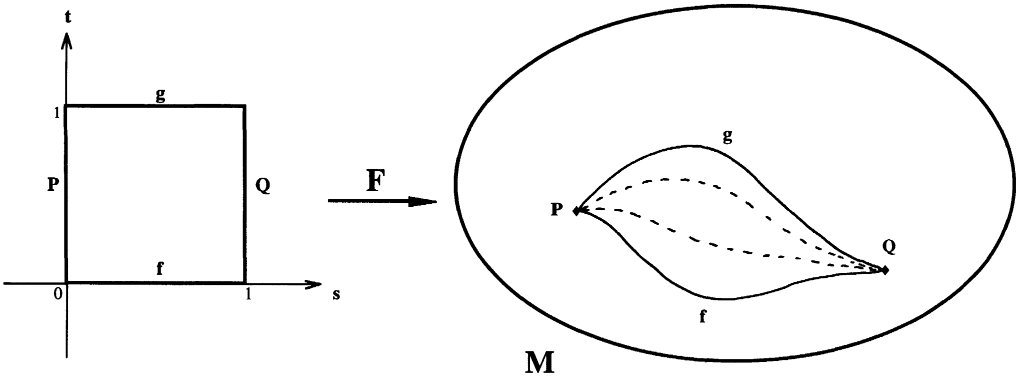

FIG. 5. A homotopy F between paths f and g.

point on the boundary is a rotation through π radians and corresponds to a rotation through $-\pi$ radians, which is the antipodal point. The loop starting at the origin, going upward to the North pole, which is identified with the South pole, and then continuing upward to the origin is not homotopic to a point; yet the same loop traversed twice is deformable to a point. This is the topological property of $R(3)$ that is associated to "spin" and "spinor" representations in quantum mechanics.

Each loop with basepoint x_0 can be considered as a map of the unit circle $S^1 \subset \mathbf{R}^2$ into M that sends (1,0) to the point x_0. $\pi_1(M)$ is then the set of equivalence classes of such maps. In an analogous fashion, higher homotopy groups $\pi_n(M)$ are defined to be the sets of equivalence classes of maps of n-spheres S^n into M, which map a chosen fixed point of S^n to the basepoint x_0. These groups detect higher-dimensional "holes" in the given space M. For example, let M be a solid ball of radius 3 with a concentric inner ball of radius 1 removed. M is simply connected, and so $\pi_1(M) = 0$. However, $\pi_2(M) \neq 0$ since no two-sphere that encloses the inner hole can be collapsed to a point inside of M. In general, $\pi_1(M)$ is non-Abelian. However, the higher-dimensional counterparts $\pi_n(M)$ are Abelian groups for $n \geq 2$.

One of the most important unsolved problems in topology is the Poincaré conjecture. Poincaré asked if a compact three-dimensional space with trivial fundamental group had to be homeomorphic to the three-sphere. Higher-dimensional versions of this conjecture have been proved to be true by Smale for all dimensions greater than 4 and by Freedman in dimension 4, yet the original case remains unresolved. This problem continues to play a very important role in the development of topology.

2.3 Homology

There are several ways to define homology groups for a given topological space M. Examples include combinatorial, simplicial, cellular, and singular homology. Each method has some advantages, and for the majority of cases the resulting groups are identical. Simplicial homology was very popular in the early development of algebraic topology in part because it is easy to visualize spaces as constructed step by step with standard pieces such as points, line segments, triangles, and tetrahedra that are called simplices and are more precisely defined later. Thus, any triangulated surface could be approximated by its associated simplicial complex. For example, a two-sphere is homeomorphic to a (hollow) tetrahedron. Using such simplicial approximations, the homology groups can be computed via linear algebra. Unfortunately, the computations are unwieldy for complexes with large numbers of simplices. Singular homology is more frequently encountered and is the only case treated here. Let $\mathbf{Z}$ be the integers, $\mathbf{R}$ be the real numbers, and $\mathbf{C}$ be the complex numbers.

The *standard p-simplex* Δ_p is defined by

$$\Delta_p = \{(t_0,t_1,\cdots,t_p) \in \mathbf{R}^{p+1} | t_0 + t_1 + \cdots + t_p = 1 \text{ and each } t_i \geq 0\}.$$

See Fig. 6. The *vertices* of Δ_p are $e_0 = (1,0,0,\cdots,0)$, $e_1 = (0,1,0,\cdots,0)$, $\cdots$, $e_p = (0,0,0,\cdots,1)$, which form the standard or-

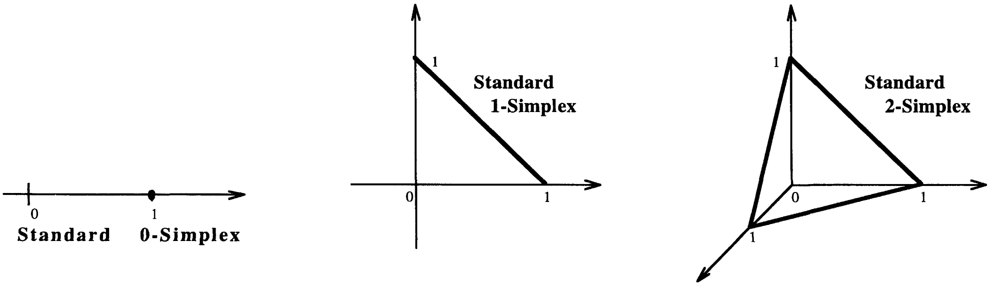

FIG. 6. Standard zero-, one-, and two-dimensional simplices.

thonormal basis in $\mathbf{R}^{p+1}$. Thus Δ_1 is the one-dimensional line segment from (1,0) to (0,1) in $\mathbf{R}^2$, and Δ_2 is the two-dimensional triangle with vertices at (1,0,0), (0,1,0), and (0,0,1) in $\mathbf{R}^3$. $[e_0,e_1,\cdots,e_p]$ is a convenient notation for Δ_p. A p-simplex with its vertices listed in such an order is called an *oriented p-simplex.* Two oriented p-simplices are *equivalent* iff one can be obtained from the other by an even permutation of the vertices, e.g., $[e_2,e_0,e_1]$ and $[e_0,e_1,e_2]$ are equivalent oriented standard 2-simplices.

A *singular p-simplex* in a topological space X is simply a continuous function $f:\Delta_p \rightarrow X$. Thus the points of X may be thought of as the images of singular 0-simplices, and paths in X correspond to the images of singular 1-simplices. The word *singular* is used to indicate that the dimension of the image may be less than the dimension p of the domain Δ_p. So points can in fact be the images of 1-simplices, 2-simplices, etc., and the image of any p-simplex can be regarded as the image of a q-simplex if q is larger than p. The boundary elements of each p-simplex break up into lower-dimensional simplices called *faces,* e.g., the triangle Δ_2 has three one-dimensional faces given by its edges and three zero-dimensional faces given by its vertices. For each $0 \leq i \leq p$, the ith *face* of the singular p-simplex f is the singular $(p-1)$-simplex $F_i(f):\Delta_{p-1} \rightarrow X$ defined by $F_i(f)(t_0,t_1,\cdots,t_{p-1}) = f(t_0,t_1,\cdots,t_{i-1},0,t_i,\cdots,t_{p-1})$. The *boundary operator* ∂_p is defined on each singular p-simplex f by $\partial_p f = F_0(f) - F_1(f) + \cdots + (-1)^p F_p(f)$. This agrees with the notion of boundary used in the Stokes theorem. To illustrate, let $f:\Delta_2 \rightarrow X$ be a singular 2-simplex, so that f maps the triangle $[e_0,e_1,e_2]$ in $\mathbf{R}^3$ to X. The boundary $\partial_2 f$ is then given by the combination of three 1-simplices: $\partial_2 f = F_0(f) - F_1(f) + F_2(f)$, where $F_0(f)$ corresponds to the map f restricted to side $[e_1,e_2]$, $F_1(f)$ corresponds to the map f restricted to side $[e_0,e_2]$, and $F_2(f)$ corresponds to the map f restricted to side $[e_0,e_1]$. The negative sign attached to $F_1(f)$ indicates that the orientation is reversed, so that $\partial_2 f$ simply traverses the boundary of f in the expected manner. See Fig. 7.

As seen above, the boundary operators give sums of simplices. The notion of a *p-chain* is introduced to define these correctly as well as to discuss more complicated subsets of X and to develop the algebraic structure of the theory. The pth *singular chain group* $C_p(X)$ of X is defined to be the free Abelian group generated by the set of all singular p-simplices in X; i.e., c is a *singular p-chain* in X iff $c = n_1 f_1 + n_2 f_2 + \cdots + n_k f_k$ for some integers $n_1, n_2, \cdots, n_k$ and singular p-simplices $f_1, f_2, \cdots, f_k$. So a singular p-chain is simply a finite integer-weighted sum of singular p-simplices. Intuitively, imagine such a sum as a collection of parametrized regions over which an integration is performed. An integer weight k indicates that the value of the integral over that region is counted k times; a negative weight indicates that the integral is taken with the opposite

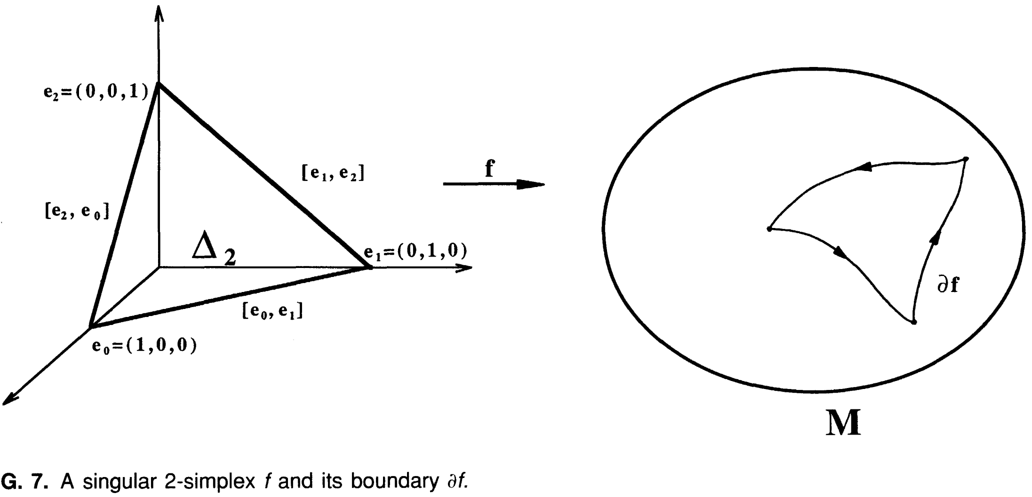

FIG. 7. A singular 2-simplex f and its boundary ∂f.

orientation, and therefore the sign of the value is reversed. The boundary operator extends to such singular p-chains by $\partial_p c = n_1\partial_p f_1 + n_2\partial_p f_2 + \cdots + n_k\partial_p f_k$. This gives a sequence of boundary operators $\partial_p: C_p(X) \to C_{p-1}(X)$ defined for each $p \geq 1$. ∂_0 is defined by $\partial_0 c = 0$ for each singular 0-chain c. These operators satisfy $\partial_p \circ \partial_{p+1} = 0$ for all $p \geq 0$; i.e., the boundary of a boundary is always 0 where by convention 0 represents the special degenerate singular chain whose image is the empty set. This important condition is usually abbreviated to $\partial^2 = 0$.

A singular p-chain $z \in C_p(X)$ is called a *p-cycle* in X iff $\partial_p z = 0$. $b \in C_p(X)$ is called a *p-boundary* in X iff $b = \partial_p c$ for some $c \in C_{p-1}(X)$. The group of p-cycles in X is denoted by $Z_p(X)$, and the group of p-boundaries in X is denoted by $B_p(X)$. By convention, $Z_0(X)$ is equal to $C_0(X)$. The condition $\partial^2 = 0$ implies that each p-boundary is also a p-cycle, and so $B_p(X) \subset Z_p(X)$ for each p. For each $p \geq 0$ the pth *singular homology group with integer coefficients* of the topological space X is defined to be the factor group $H_p(X,\mathbf{Z}) = Z_p(X)/B_p(X)$. Thus a sequence of Abelian groups is assigned to each space X. "Integer coefficients" refers to the integer weights in the chain groups; other coefficient groups may also be used.

Here are a few famous examples. Assume $n \geq 1$.

For n-dimensional real spaces $\mathbf{R}^n$,

$H_p(\mathbf{R}^n,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$, and 0 otherwise.

For the n-dimensional spheres S^n,

$H_p(S^n,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$ or n, and 0 otherwise.

For the real projective plane, $\mathbf{R}P^2$:

$H_p(\mathbf{R}P^2,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$, $\mathbf{Z}_2$ if $p = 1$, and 0 otherwise.

Here $\mathbf{Z}_2$ is the Abelian group with exactly two elements. In general, $\mathbf{Z}_n$ denotes the cyclic group with exactly n elements. For the two-dimensional Klein bottle K:

$H_p(K,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$, $\mathbf{Z} \oplus \mathbf{Z}_2$ if $p = 1$, and 0 otherwise.

For the two-dimensional torus $T = S^1 \times S^1$:

$H_p(T,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$ or 2, $\mathbf{Z}^2 = \mathbf{Z} \oplus \mathbf{Z}$ if $p = 1$, and 0 otherwise.

For the two-dimensional g-holed torus T_g:

$H_p(T_g,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$ or 2, $\mathbf{Z}^{2g}$ if $p = 1$, and 0 otherwise.

Here $\mathbf{Z}^{2g}$ denotes the direct sum of $2g$ copies of $\mathbf{Z}$. The nonnegative integer g is called the *genus* of T_g. For the n-dimensional tori $T^n = S^1 \times \cdots \times S^1$:

$H_p(T^n,\mathbf{Z}) = Z^{C(n,p)}$ for all $0 \leq p \leq n$, and 0 otherwise, where $C(n,p)$ is the binomial coefficient.

For the n-dimensional real projective spaces, $\mathbf{R}P^n$:

$H_p(\mathbf{R}P^n,\mathbf{Z}) = \mathbf{Z}$ if $p = 0$ or n with n odd, $\mathbf{Z}_2$ if p is odd and $0 < p < n$, and 0 otherwise.

For the $2n$-dimensional complex projective spaces, $\mathbf{C}P^n$:

$H_p(\mathbf{C}P^n,\mathbf{Z}) = \mathbf{Z}$ if $p = 0, 2, 4, \cdots, 2n$, and 0 otherwise.

In most cases of interest such as compact manifolds, the above homology groups are *finitely generated Abelian groups;* i.e., they can be put into the *cyclic normal form*

$$\mathbf{Z}^m \oplus \mathbf{Z}_{t_1} \oplus \mathbf{Z}_{t_2} \oplus \cdots \oplus \mathbf{Z}_{t_k}$$

for some integer $m \geq 0$ and integers $t_1, t_2, \cdots, t_k$ such that each $t_i > 1$ and t_i divides t_{i+1} for each $1 \leq i < k$. Here $\mathbf{Z}^m$ denotes the direct sum of m copies of $\mathbf{Z}$, and $\mathbf{Z}_n$ denotes the cyclic group of order n.

For $H_p(X,\mathbf{Z})$ in the above form, the integer m is called the pth *Betti number*, β_p, of X, and $t_1, t_2, \cdots, t_k$ are called the pth *torsion coefficients* of X, and the number k of such torsion coefficients is denoted τ_p. The *Euler–Poincaré characteristic* $\chi(X)$ is given by the alternating sum of the Betti numbers of X:

$$\chi(M) = \sum_{p \geq 0} (-1)^p \beta_p.$$

The homology groups, Betti numbers, torsion coefficients, and Euler–Poincaré characteristic are topological invariants of the space X; i.e., these invariants are the same for homeomorphic spaces. However, these invariants may also be the same for some nonhomeomorphic spaces such as $\mathbf{R}$ and $\mathbf{R}^2$. So these invariants are generally more useful in proving spaces are not homeomorphic than in proving them homeomorphic. If M and N are compact manifolds of dimension m and n, respectively, then $\chi(M \times N) = \chi(M) \times \chi(N)$, and if $m = n$, then $\chi(M \# N) = \chi(M) + \chi(N) - [1 + (-1)^n]$, where $M \times N$ is the Cartesian product and $M \# N$ is the connected sum of M and N.

In the 1920s Lefschetz defined the *relative homology* groups of a *pair* (X,A) of topological spaces with $A \subset X$. Intuitively, this corresponds to the homology of the space obtained from X by collapsing A to a point. Formally, the group of *relative p-cycles mod A* is $Z_p(X,A) = \{c \in C_p(X) | \partial_p c \in C_{p-1}(A)\}$, and the group of *relative p-boundaries mod A* is $B_p(X,A) = \{c \in C_p(X) | c - c' \in B_p(X)$ for some $c' \in C_p(A)\}$. The pth *relative singular homology group of the pair* (X,A) is then defined to be the factor group $H_p(X,A) = Z_p(X,A)/B_p(X,A)$ for each $p \geq 0$. One very important consequence of relative homology is the *long exact sequence in homology.* For each pair (X,A) two inclusion maps of pairs are naturally defined: $i{:}(A,\emptyset) \to (X,\emptyset)$ and $j{:}(X,\emptyset) \to (X,A)$. These induce natural maps i_* and j_* in homology, and combining these with appropriate induced boundary operators ∂_* yields the long exact homology sequence:

$$\cdots \to H_{p+1}(X,A) \xrightarrow{\partial_*} H_p(A) \xrightarrow{i_*} H_p(X)$$
$$\xrightarrow{j_*} H_p(X,A) \xrightarrow{\partial_*} H_{p-1}(A) \to \cdots$$

Such a sequence $\cdots \to G \xrightarrow{f} H \xrightarrow{g} K \to \cdots$ of groups connected by group homomorphisms is *exact* at the group H iff the image of f equals the kernel of g; i.e., $f(G) = \{a \in H | g(a) = e_K\}$, where e_K is the identity element in the group K. Thus, the long exact sequence in homology is exact at each group in the sequence. Further, each continuous map $f{:}(X,A) \to (Y,B)$ between pairs induces natural homomorphisms between their associated long exact sequences. This structure is very important in the theoretical development and application of algebraic topology in general. Similar long exact sequences also exist for homotopy and cohomology. To illustrate briefly a typical use of the structure of exact sequences, consider such a sequence

$$\cdots \to F \xrightarrow{f} G \xrightarrow{g} H \xrightarrow{h} K \to \cdots.$$

If the group F is the zero group, then the map g must be injective; if the group K is the zero group, then the map g must be surjective; thus if both F and K are zero groups, then the map g is an isomorphism, and the groups G and H are isomorphic.

2.4 Cohomology

Cohomology groups are additional algebraic structures associated to a given space. Like homology, there are various methods for defining and computing cohomology such as simplicial, cellular, singular, Čech, and de Rham. Singular cohomology proceeds by constructing dual objects called cochain groups and their associated coboundary operators and performing quotient group operation as in homology. As usual, for the spaces typically found in physics, such as manifolds, all of these methods produce essentially the same results. The cohomology groups of a space are dual to the homology groups in a sense similar to that of the duality between Dirac's bra and ket vectors, or between contravariant and covariant tensors. The most commonly encountered cohomology in physics is the de Rham cohomology associated with the differential forms on a manifold, and this is discussed in Sec. 3.

3. DIFFERENTIAL TOPOLOGY

Differential topology is the area of topology most directly associated with physics. The basic objects are smooth manifolds, and the functions of interest are smooth maps between such manifolds. Vector fields, differential forms, differential operators, and integration are naturally the key tools. The subject is very closely tied to differential geometry and global analysis, and these subjects usually appear together in applications. This section has much in common with the article GEOMETRICAL METHODS. This section treats manifolds, bundles, vector fields and differential forms, de Rham cohomology, and Morse theory. Manifolds are the natural answer to the question: What sort of spaces should be the domains and ranges of functions? It is clear that higher-dimensional spaces are needed for problems involving several variables such as dynamical systems. Also spaces with curvature are necessary to treat surfaces in Euclidean spaces as well as general relativity. Coordinate systems are required in order to apply the techniques of calculus and analysis. These allow problems in the space to be transferred to subsets of $\mathbf{R}^n$, analyzed, and then mapped back to the original space. Manifolds are spaces designed with these objectives in mind. Bundles, more precisely called fiber bundles, are structures built on manifolds. They answer the question: Where are objects such as vector fields, differential forms, and general tensor fields located? Perhaps the most familiar example in physics is phase space. Here the underlying "base" manifold is configuration space: the set of allowable positions or generalized positions for the system. A simple planar pendulum, for example, has the circle S^1 as its configuration space and phase space given by an infinite cylinder. This infinite cylinder is the "cotangent" bundle of S^1. The double planar pendulum has configuration space given by a two-dimensional torus T, and its phase space is the cotangent bundle of T, which is four-dimensional. Two of these dimensions give the position of the pendulum bobs, and the remaining two give their momenta. If the generalized momenta are replaced by generalized velocities, then the appropriate bundle is the tangent bundle of the configuration space M. Velocities are given by vector fields on M and are therefore located in the tangent bundle, whereas momenta are given by 1-forms on M and so are located in the cotangent bundle.

The topology of a manifold M places restrictions on the behavior of the functions, vector fields, and differential forms defined on M. For example, each smooth tangent vector field on a 2-sphere must be zero at some point. Intuitively, at each point in time there must be some point on the Earth at which the (horizontal component of the) wind velocity is zero. The Poincaré–Hopf index theorem makes this relation precise. Similarly, the theorems of de Rham and Hodge use de Rham cohomology to quantify the topological restrictions on the differential forms on manifolds. One of most beautiful areas of differential topology is Morse theory, which Marston Morse developed in connection with his study of geodesics on manifolds. The original motivation for this work came from the work of Poincaré and Birkhoff in dynamical systems where the motion of the system is described by geodesics. Morse theory quantifies the topological restrictions on the critical points of smooth nondegenerate functions. For example, the theory guarantees that each smooth nondegenerate function on a g-holed torus must have at least $2g + 2$ critical points.

Characteristic classes are specific cohomology classes assigned to bundles. They were designed to answer two questions: (1) When is a bundle trivial, i.e., a simple Cartesian product of the base manifold and the fiber? and (2) When are two bundles equivalent? An important area of application is the Atiyah–Singer index theorem that quantifies the number of solutions of certain operators on manifolds. Although mentioned briefly in this article, these topics require more extensive machinery than is reasonable in this discussion. See Sec. 4 for appropriate references.

3.1 Manifolds and Bundles

The notion of a manifold is a generalization of that of a surface in $\mathbf{R}^3$ such as a two-dimensional sphere. It is not possible to cover the sphere with a single coordinate system; at least two are needed. If each coordinate system is viewed as an observer, then in the regions in which their coordinate systems overlap, they should be able to compare data, i.e., effectively transform each coordinate system into that of any overlapping system. Since not only positions but also velocities and accelerations should be transformable, the changes of coordinates are required to be *smooth;* i.e., the functions and all their derivatives of all orders are required to be continuous. Typical examples are the configuration and phase spaces used in classical mechanics. These are usually higher-dimensional manifolds.

An *n-dimensional differentiable manifold M* is a locally Euclidean topological space.

More precisely, M has a covering by *coordinate charts,* which are homeomorphisms $\varphi_i{:}U_i \to \varphi_i(U) \subset \mathbf{R}^n$ for each $i \in I$ such that each U_i is an open subset of M, $M \subset U_{i\in I}U_i$, and on the overlap between the images of each pair of charts, the function $\varphi_j \circ \varphi_i^{-1}$: $\varphi_i(U_i \cap U_j) \to \varphi_j(U_i \cap U_j)$ is a smooth function. See Fig. 8. Coordinate charts are also called coordinate systems, local charts, or just charts. On a manifold, calculus is done by transferring the process back to $\mathbf{R}^n$ via the coordinate charts, performing the appropriate calculus operations, and then transferring the result back to the manifold. For example, a function $f{:}M \to N$ between manifolds M of dimension m and N of dimension n is smooth iff $\psi \circ f \circ \varphi^{-1}$ is smooth as a map from an open set of $\mathbf{R}^m$ to an open set of $\mathbf{R}^n$ for each pair of charts φ on M and ψ on N. A smooth function $\varphi{:}M \to N$ with a smooth inverse is called a *diffeomorphism.* A manifold M is *orientable* iff a covering by coordinate charts $\{\varphi_i\}_{i\in I}$ can be chosen for M in such a way that the determinants of the Jacobian matrices of the overlap maps $\varphi_j \circ \varphi_i^{-1}$ are positive for each $i,j \in I$. Manifolds for which such a covering does not exist are called *nonorientable.* Among two-dimensional surfaces, the sphere and g-holed tori are orientable, whereas the Klein bottle and real projective plane are nonorientable. Very frequently, manifolds are assumed to be Hausdorff or even paracompact topological spaces, and this is the case for almost all cases typically encountered. If, in the above definition of differentiable manifold, $\mathbf{R}^n$ is replaced by $\mathbf{C}^n$ and the overlap maps $\varphi_j \circ \varphi_i^{-1}$ are required to be complex analytic, then the space M is called an *n-dimensional complex manifold,* and the tools of complex analysis are appropriate. *Manifolds with boundary* are defined by allowing two kinds of coordinate charts: the usual manifold style charts as given originally, plus special charts adapted for boundary points as follows. Let $\mathbf{R}^n_+ = \{(x_1,x_2, \cdots,x_n)|x_n \geq 0\}$ be the standard *upper half-space* in $\mathbf{R}^n$ with the induced topology. Then each point of a *manifold with boundary* is required to be homeomorphic to an open subset of either $\mathbf{R}^n$ or $\mathbf{R}^n_+$, and where charts overlap, their transition functions must be

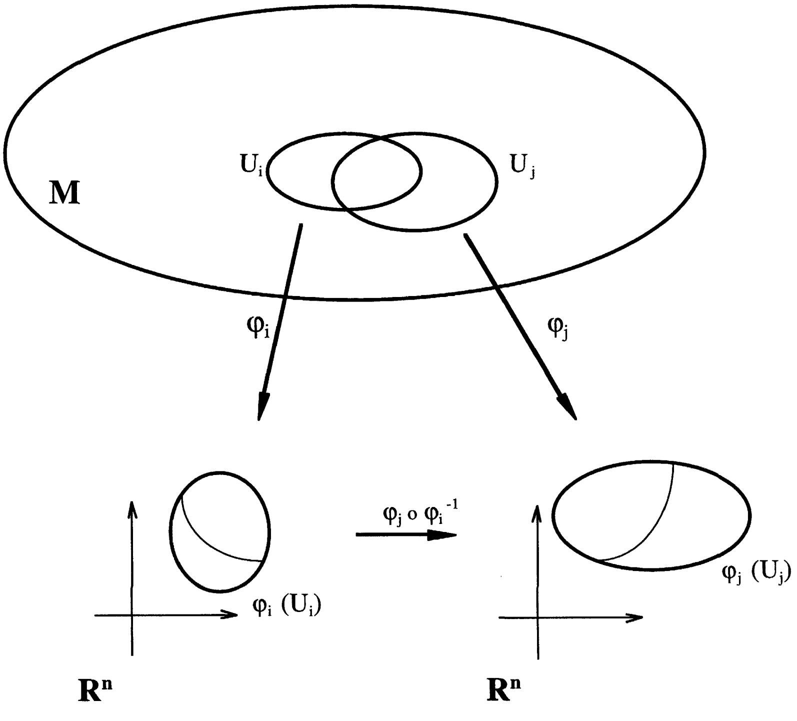

FIG. 8. Manifold charts ϕ_i and ϕ_j must have smooth transition functions $\phi_j \circ \phi_i^{-1}$ on overlaps $\phi_i(U_i \cap U_j)$.

smooth. In Fig. 9 the manifold with boundary is a torus with a disk removed at the top. Each point such as P on the boundary requires a half-space chart as illustrated by ψ. The points such as Q in the interior of M have usual manifold-style charts. The boundary of M is denoted ∂M. Typical examples are the Möbius strip and the upper hemisphere of the 2-sphere, each of which has boundary homeomorphic to the circle S^1, and the closed ball in $\mathbf{R}^n$ with boundary given by the $(n - 1)$-sphere S^{n-1}. In discussions involving manifolds both with and without boundary, manifolds without boundary are often called *closed manifolds.*

Although the initial motivation for manifolds came from spaces such as surfaces sitting in Euclidean spaces, the definition of a manifold does not assume this, and so it is an interesting question whether such abstractly given manifolds can be considered as embedded in $\mathbf{R}^n$ for n sufficiently large. The Whitney embedding theorem guarantees that this is the case, i.e., each paracompact manifold of dimension $n \geq 1$ has an embedding into $\mathbf{R}^{2n}$. Thus the Klein bottle always intersects itself when considered as a subset of $\mathbf{R}^3$, but it can be placed in $\mathbf{R}^4$ without such a self intersection.

Manifolds are the natural choice for the complicated geometrical structures that occur in physics. In addition to the configuration and phase spaces mentioned above, Minkowski spacetime, the universe of general relativity if singularities are ignored, and all Lie groups such as the rotation groups, Lorentz groups, unitary groups, and Poincaré groups are manifolds. However, structures such as vector fields, differential forms, and other tensors defined on such spaces require more general constructions, namely, bundles built on such manifolds. Bundles (see GEOMETRICAL METHODS) are special manifolds that are generalizations of Cartesian products. $\mathbf{R}^2$ is the Cartesian product of $\mathbf{R}$ and $\mathbf{R}$ and so has a global product structure. In a bundle only a local product structure is required. The most commonly used bundles on a manifold M are the tangent bundle TM, the cotangent bundle T^*M, the exterior product bundles $\Lambda^p M$, and more generally the tensor bundles $T^r_s M$. These are vector bundles; i.e., the fibers are vector spaces and the sections of these bundles give the vector fields, differential forms, and tensors on M. A *section* of a bundle is simply a smooth map that assigns to each point of the base manifold an element of the fiber over that point. Thus, a section of the tangent bundle of M is a (tangent) vector field on M. The two basic formulations of classical mechanics, Lagrangian and Hamiltonian, are associated to the bundles TM and T^*M, respectively. For example, if M is the configuration space of the system, then the phase space is the cotangent bundle T^*M, and the Hamiltonian is a map $H:T^*M \to \mathbf{R}$. In gauge theories vector bundles are replaced by the

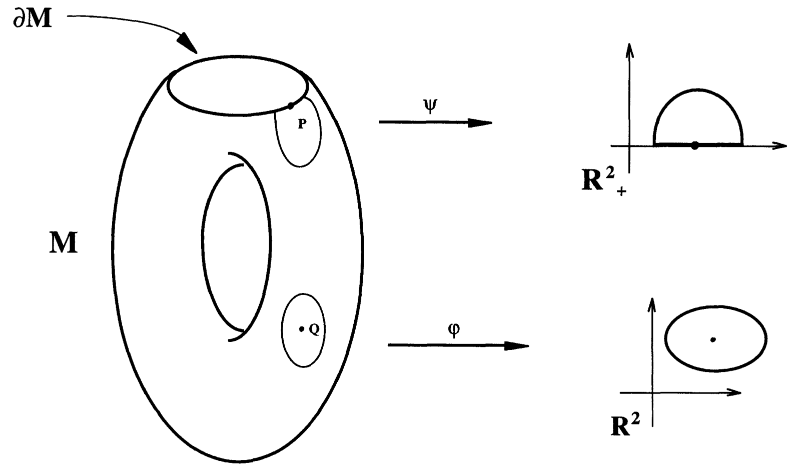

FIG. 9. Manifolds with boundary require "half-space charts" ψ for boundary points such as P.

more general principal fiber bundles in which each fiber is a Lie group appropriate to the symmetries of the fields involved. Characteristic classes are special cohomology classes giving topological information about bundles. These can be used, for example, to determine whether a given bundle has a global product structure, or to distinguish various bundles since bundles with different characteristic classes must be different. The Euler class, Stiefel–Whitney classes, Pontryagin classes, and Chern classes are standard characteristic classes. Secondary characteristic classes such as the Chern–Simons classes also play a role in gauge theories and mechanics.

3.2 Vector Fields and the Poincaré–Hopf Index Theorem

Viewed in terms of the above considerations, a (tangent) vector field on a manifold M is a section of the tangent bundle of M. Each point of M at which a vector field X is zero is called a *zero* of X, and the set of such zeros is denoted Z_X. If a zero p of X is isolated, i.e., p is the only zero of X in some neighborhood of p, then an integer *index* $i_X(p)$ can be assigned to p. Consider first the vector field X in $\mathbf{R}^2$ defined by $X(x,y) = (x^2 - y^2, 2xy)$. X has the origin, $p = (0,0)$, as its only zero. Let C be the circle of radius 1 centered at p, and consider the normalized unit vector field $U = X/\|X\|$ restricted to C. As C is traversed once counterclockwise, the tip of U performs exactly two counterclockwise rotations about its origin; therefore the index of X is 2. This X is not the field of a dipole, but it does have the same flow lines. Similarly, $X(x,y) = (x^3 - 3xy^2, 3x^2y - y^3)$ has the same flow lines as a quadrupole and index 3. The vector field $X(x,y) = (x,-y)$ has the flow lines of a saddle and index -1. For the case of a general planar vector field $X(x,y) = (P(x,y),Q(x,y))$ with an isolated zero at the origin p, the index may be computed by the formula

$$i_X(p) = \frac{1}{2\pi}\int_C \frac{PdQ - QdP}{P^2 + Q^2},$$

where C is a circle centered at p with radius small enough so that p is the only zero of X inside C, and C is traversed counterclockwise. In the n-dimensional case, the index is defined to be the degree of the map of a small $(n - 1)$-dimensional sphere S^{n-1}, centered at p and containing no other zero of X, to itself produced by appropriately normalizing X restricted to this S^{n-1}. This index is always an integer and is independent of the choice of radius of the sphere provided p is the only zero of X interior to that sphere.

The Poincaré–Hopf index theorem states that if X is a vector field having only isolated zeros on a compact orientable manifold M of dimension n, then

$$\sum_{p\in Z_X} i_X(p) = \chi(M).$$

Thus, among the orientable surfaces, the sum of the indices of the zeros of such a vector field must be 2 for the sphere and $2 - 2g$ for the g-holed torus. In particular, only the usual torus can admit a nonzero (tangent) vector field.

3.3 Differential Forms and de Rham Cohomology

It is hard to overemphasize the importance of differential forms in differential geometry and topology. Although they are just completely alternating covariant tensor fields on manifolds and are therefore part of the general theory of tensors, the simplicity of their structure and operations plus the direct connection with the underlying geometry of the space have given them a very special place in these subjects. Examples of forms in $\mathbf{R}^3$ were given in Sec. 2.1 above. See GEOMETRICAL METHODS for the more general case as well as definitions of the exterior derivative operator d, the Hodge star operator $*$, and the codifferential operator δ, which is the adjoint of d with respect to the inner product $(,)$ defined by $(\alpha,\beta) = \int_M \alpha \wedge *\beta$ for each pair of p-forms α and β on M. Here E^pM denotes the vector space of all p-forms on M. A Riemannian or pseudo-Riemannian metric is required for the definition of both $*$ and δ. If M has dimension n, then $d{:}E^pM \to E^{p+1}M$, $*{:}E^pM \to E^{n-p}M$, and $\delta{:}E^pM \to E^{p-1}M$ for each p. The $d^2 = 0$ condition again holds, i.e., $d(d\alpha) = 0$ for all $\alpha \in E^pM$, as well as $\delta^2 = 0$. The Laplace–Beltrami operator $\Delta{:}E^pM \to E^pM$ is then defined by $\Delta = d\delta + \delta d$. This generalizes the usual Laplace operator $\Delta = \nabla^2$, which is the divergence of the gradient on functions. The Laplace operator certainly has a claim to being the most important and the most studied operator in mathematical physics. It occurs in the Laplace equation, Poisson equation, heat equation, wave equation, wave-equation forms of Maxwell equations, and Schrödinger equation among others. The underlying reason is that it measures the deviation from equilibrium. So it is very natural to seek a generalization of this operator. However, it is important to be careful about the sign of the operator. The usual conventions for the Hodge star operator give the negative of the divergence of the gradient. This agrees with Maxwell's convention; he called this Δf the *concentration* of f. As a result of this convention the spectrum (set of eigenvalues) of Δ on a compact manifold is nonnegative. Δ is then a nonnegative, elliptic, self-adjoint, second-order operator on each E^pM. Also, Δ acting on one-forms corresponds to the negative of the usual Laplacian, $\nabla \operatorname{div} X - \operatorname{curl} \operatorname{curl} X$, on vector fields X as used in vector analysis. It is important to notice that since a metric is needed to define the Hodge star operator $*$, and therefore also the codifferential operator δ, the Laplace–Beltrami operator involves the geometry of the manifold as well as its topology.

Again, $\alpha \in E^pM$ is *closed* iff $d\alpha = 0$, and $\alpha \in E^pM$ is *exact* iff $\alpha = d\varphi$ for some $\varphi \in E^{p-1}M$. Setting $Z^p(M)$ equal to the set of closed p-forms, and $B^p(M)$ equal to the set of exact p-forms, $d^2 = 0$ implies that $B^p(M) \subset Z^p(M)$, and the *de Rham cohomology* vector spaces are defined by $H^p_{\mathrm{dR}}(M,\mathbf{R}) = Z^p(M)/B^p(M)$ for each p. The *Poincaré lemma* says that each p-form that is closed in a neighborhood equivalent to an open ball is exact in that neighborhood; the de Rham cohomology measures the extent to which this holds globally on the manifold M. The de Rham theorem says that this cohomology agrees with that derived via the more topological methods such as singular and Ĉech. Further, on each compact orientable manifold M of dimension n, the Hodge star operator induces an isomorphism called *Poincaré duality* between $H^p_{dR}(M,\mathbf{R})$ and $H^{n-p}_{dR}(M,\mathbf{R})$ for each p. The Hodge theorem gives an orthogonal decomposition $E^pM = \mathcal{H}^pM \oplus dE^{p-1}M \oplus \delta E^{p+1}M$, where $\mathcal{H}^pM$ denotes the set $\{\alpha \in E^pM | \Delta\alpha = 0\}$ of *harmonic* p-forms, $dE^{p-1}M$ is the set of *exact* p-forms, and $\delta E^{p+1}M$ is the set of *coexact* p-forms on M. Further, the dimension of the space of harmonic p-forms is $\beta_p(M)$, the pth Betti number of M. The Hodge theorem is a generalization of Helmholtz's theorem that represents vector fields in $\mathbf{R}^3$ as sums of curls and gradients. More sophisticated global theorems such as the Hirzebruch–Riemann–Roch theorem and the general Atiyah–Singer index theorem utilize the theory of characteristic classes.

3.4 Morse Theory

Morse theory relates the critical-point structure of a smooth function on a manifold to the topology of the manifold. Given a smooth function $f:A \to \mathbf{R}$ where A is an open subset of $\mathbf{R}^n$, a point $p \in A$ is a *critical point* of f iff

$$\frac{\partial f}{\partial x_i}(p) = 0$$

for each $i = 1, 2, \cdots n$; i.e., the gradient of f is 0 at p. Such a critical point of f is *nondegenerate* iff the determinant of the Hessian matrix $Hf(p)$ is nonzero. The *Hessian* $Hf(p)$ is the symmetric matrix of second derivatives of f evaluated at p; i.e.

$$(Hf(p))_{ij} = \frac{\partial^2 f}{\partial x_i \partial x_j}(p).$$

The *index* k of a critical point p is the number of negative eigenvalues of $Hf(p)$. For example, $f(x) = 3x^5 - 5x^3 + 1$ has a degenerate critical point at 0, and nondegenerate critical points at -1 and 1 with indices 1 and 0, respectively. The Rosenholtz function $f(x,y) = 4x^2e^y - 2x^4 - e^{4y}$ has exactly two critical points, located at $(-1,0)$ and $(1,0)$, both nondegenerate and of index 2. This remarkable function has two local maxima and no other critical points; its graph has two mountains but no saddle points. Index-0 critical points correspond to local minima, and critical points of maximal index (equal to the dimension of the domain of the function) correspond to local maxima; the critical points of intermediate index behave like saddle points.

The Morse lemma states that for each nondegenerate critical point p of index k of f

there is a neighborhood U of p and a set of coordinates $\{t_1,t_2,\cdots,t_n\}$ in U such that f can be expressed as $f(t_1,t_2,\cdots,t_n) = f(p) - t_1^2 - t_2^2 - \cdots - t_k^2 + t_{k+1}^2 + \cdots + t_n^2$ in U. So f has a *normal form* in some neighborhood of each of its nondegenerate critical points. This implies that each nondegenerate critical point is isolated. These local notions easily extend to smooth real-valued maps on manifolds, although it is worth noting that in general a Riemannian metric is needed to define the Hessian at noncritical points. A standard example is the height function f defined on a two-dimensional torus M placed on end on the x-y plane in $\mathbf{R}^3$ as in Fig. 10. The value $f(p)$ is just the height (the z coordinate) of the point p above the $z = 0$ plane. This function has four critical points located at a, b, c, and d, all nondegenerate: the bottom point a with index 0, the two saddle points b and c each of index 1, and the top point d with index 2. For the torus laid flat on the plane, the height function has two circles of critical points at top and bottom, and each of these critical points is degenerate; however, the slightest tilting of the torus from this position is sufficient to give a height function with all nondegenerate critical points. A smooth function $f{:}M \to \mathbf{R}$ is a *Morse function* on M iff each critical point of f is nondegenerate. The Morse functions are dense in the set of smooth functions on M in the following sense: Given any smooth function $f{:}M \to \mathbf{R}$, there exist arbitrarily nearby Morse functions.

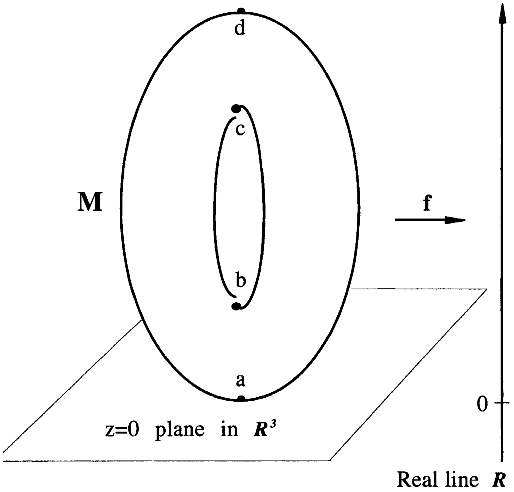

FIG. 10. The height function f has critical points at a, b, c, and d. The minimum at a has index 0, the saddle points at b and c have index 1, and the maximum at d has index 2.

Morse, following the lead of his advisor G. D. Birkhoff, found a sequence of inequalities giving topological restrictions on the number c_k of critical points of index k for a general Morse function f on a compact manifold M of dimension n. Letting β_p denote the pth Betti number of M, the *Morse inequalities* are

$$\begin{aligned} c_0 &\geq \beta_0 \\ c_1 - c_0 &\geq \beta_1 - \beta_0 \\ c_2 - c_1 + c_0 &\geq \beta_2 - \beta_1 + \beta_0 \\ &\vdots \\ \sum_{0\leq i\leq p} (-1)^{p-i} c_i &\geq \sum_{0\leq i\leq p} (-1)^{p-i}\beta_i \\ &\vdots \\ \sum_{0\leq i\leq n} (-1)^{n-i} c_i &= \sum_{0\leq i\leq n} (-1)^{n-i}\beta_i. \end{aligned}$$

Notice that the last relation is in fact always an equality. Thus the alternating sum of the *critical numbers* c_p of f equals the Euler–Poincaré characteristic $\chi(M)$. These relations immediately imply $c_p \geq \beta_p$ for each p. These inequalities were extended by Pitcher to include the influence of the torsion coefficients of M as follows: For each p,

$$c_p \geq \beta_p + \tau_p + \tau_{p-1},$$

where τ_p denotes the number of torsion coefficients in the cyclic normal form of the pth homology group $H_p(M,\mathbf{Z})$, as discussed in Sec. 2.3. As a simple application, consider a surface M sitting in $\mathbf{R}^3$. For almost all points p not on M, the distance function from p to each of the points of M is a Morse function on M (the other points are called *focal points*), and the critical points of this function correspond to lines from p to M that are perpendicular to M. Thus the Morse inequalities imply that the number of normals to M from any nonfocal point p is greater than or equal to the sum of the Betti numbers of M.

4. A BRIEF GUIDE TO FURTHER READING

Topology has a vast literature with texts ranging from very elementary to very specialized. This section is designed to select a relatively small number of readily available books in each of the areas covered in this article. These books are usually intended to be used in courses and therefore are rather condensed. More physics-oriented texts such as Felsager (1983), Nash and Sen (1983), von Westenholz (1981), Eguchi *et al.* (1980), Nash (1991), Göckeler and Schücker (1987), and Nakahara (1990) are demanding texts, but they usually keep physical applications in the forefront. Browsing through these texts for an initial orientation is strongly recommended.

4.1 Point-Set Topology

Many of the classic texts on point-set topology were designed to provide a foundation for analysis. Good examples are Simmons (1963), Wilansky (1970), and Kelley (1955). Texts by Munkres (1975), Sieradski (1992), Jänich (1984), Dugundgi (1966), and Hocking and Young (1961) also include discussion of algebraic-topological topics such as homotopy and homology. Most algebraic-topology texts include brief discussions of point-set topology topics. Armstrong (1983) and Kinsey (1993) are good examples at an undergraduate level. Most functional-analysis texts also contain relevant material; see, for example, Naylor and Sell (1982), Kreyszig (1978), Reed and Simon (1980), and Lang (1993).

4.2 Algebraic Topology

Seifert and Threlfall (1980), Veblen (1931), Cairns (1961), and Wallace (1968) are older texts that treat simplicial homology. Armstrong (1983), Kinsey (1993), and Jänich (1984) are good undergraduate-level introductions. Munkres (1984), Greenberg and Harper (1981), Rotman (1988), Massey (1991), Dold (1980), and Spanier (1981) are popular graduate-level texts. Hilton and Wiley (1960), Mac Lane (1963), and Vick (1994) treat homology theory, and Hu (1959) is a basic early reference for homotopy theory.

4.3 Differential Topology

Guillemin and Pollack (1974), Milnor (1965), Dodson and Poston (1991), and Wallace (1968) are good introductions. Bröcker and Jänich (1982), Hirsch (1976), Kosinski (1993), Lang (1995), and Warner (1983) are popular graduate-level texts. Springer (1981) and Weyl (1955) are classic introductions to Riemann surface theory. Steenrod (1951), Chern (1979), Kobayashi and Nomizu (1963, 1969), Gilkey (1995), Bott and Tu (1982), Milnor and Stasheff (1974), Hirzebruch (1966), and Husemoller (1994) are standard references for bundles and characteristic classes. Milnor (1963), Hirsch (1976), Bott (1994), and Kosinski (1993) discuss Morse theory. Eguchi *et al.* (1980), Gilkey (1995), Nash (1991), and Nakahara (1990) are good references for the Atiyah–Singer index theorem. Choquet-Bruhat *et al.* (1982, 1989) is a good general reference that covers a wide range of topics in differential topology and geometry particularly relevant for physics. Chern (1979), Wells (1980), and Hübsch (1992) treat complex manifolds.

4.4 Physical Applications

Flanders (1963) is the classic reference for differential forms. Schutz (1980) and von Westenholz (1981) are recommended for more advanced applications. Felsager (1983), Nash and Sen (1983), Eguchi *et al.* (1980), Nash (1991), Göckeler and Schücker (1987), and Nakahara (1990) are highly recommended for physicists. Birkhoff (1927) is a classic text in dynamical systems; more recent mathematically oriented texts are Arnol'd (1989), Abraham and Marsden (1978), and Abraham *et al.* (1988) for classical mechanics and dynamical systems, and Atiyah (1990), Green *et al.* (1987), and Hübsch (1992) for relations to string theories.

GLOSSARY

INTRODUCTION

Measurement involves the transfer of information about a process and, as a by-product, the transfer of energy from a process (Stein, 1992). Measurements are made by transducers. A transducer is a component in a measurement system that converts a physical quantity such as displacement, force, pressure, or acceleration into a proportional electrical quantity. A transducer can be modeled as having two input ports and one output port (Stein, 1992). At each input port, two direct, temporal, or spatial functions of energy exist. Their product possesses units of energy, energy rate, energy flux, etc. One input is desired while the second is undesired. For example, the inputs to a force transducer are force and the resultant displacement of the force collecting element. It would be desired to measure force using an infinitely stiff transducer. Since infinitely stiff force transducers do not physically exist, the transducer's input stiffness or impedance (force/displacement) should be as high as possible compatible with producing an adequate electrical signal output. Any deflection of the force transducer modifies the process being measured by absorbing energy (force times displacement) from the process. Similarly, the inputs to a pressure transducer are pressure and the accompanying volumetric change of the pressure collector. The volumetric change of the pressure collector modifies the pressure being measured through a similar energy (pressure times volume) absorption process. A pressure transducer's input impedance (pressure/volume) should be as high as possible.

A measurand is the physical or chemical process to be measured. A measurement system is a chain of components that link the measurand to the recorded data in a proportional manner. The transducer is the first component in the system. At subsequent component interfaces, it is desired to maintain the output impedance of the preceding component as small as possible and the input impedance of the next component as high as possible. For electrical components, a high input impedance (voltage/current) minimizes the current drain and thus the energy transfer from the preceding component. In addition to high input impedances and low output impedances required in all measurement system components, supplemental requirements exist for components used to measure time-varying phenomena. These requirements include a linear component input/output relationship to the measurand as well as flat amplitude and linear phase-frequency response characteristics.

Aside from the transducer, any measure-

ment system can be considered to be comprised of three additional subsystems.

Transmitting system—The transmitting system typically consists of some or all of the following components: cable, amplifier, subcarrier oscillator, filter, analog-to-digital (A/D) converter, transmitter, and antenna.

Receiving system—The receiving system typically consists of some or all of the following devices: antenna, preamplifier, multicoupler, receiver, tape recorder, discriminator, decommutator, digital-to-analog (D/A) converter, and output filter.

Data output and display system—The data output and display system typically consists of some or all of the following devices: oscilloscope, analog meter, digital meter, graphic display, and digital printer. Either these devices may be connected directly to the output of the receiving system or a computer may process the data from the receiving system before display.

The field of mechanical measurements encompasses or is synergistic with topics such as vacuum, temperature, acoustic, and flow measurements; telecommunications; calibration techniques; electrical instrumentation; and error analysis. These topics are described in other articles in the *Encyclopedia of Applied Physics*.

1. MECHANICAL DISPLACEMENT MEASUREMENT

The measurement of the basic quantity of linear displacement allows derived quantities such as length, width, thickness, position, level, erosion, wear, surface quality, strain, or vibration to be determined. Similarly, the measurement of angular displacement allows derived quantities such as attitude, angle of incidence, angle of turn, angle of flow, or angular vibration to be determined. Sensing techniques used to measure mechanical displacement include variable resistance, variable inductance, variable capacitance, and piezoelectric effect.

1.1 Variable Resistance

Common resistance-based transducers used to measure displacement include potentiometers and strain gages. The simplest displacement-measuring transducer is a linear or rotary potentiometer excited by a dc voltage source. It may be configured to produce an output voltage directly proportional to displacement. The resistance element is either a wire-wound or film potentiometer. The potentiometer's wiper arm is attached through a linkage to respond to motion.

Potentiometers are used for large displacements, typically operating over a range of 2–250 mm. The resolution of the wire element ranges from 0.05 to 0.5% of full scale. Linearity is typically 1.0% of full scale. Resistance values range from 100 to 1000 Ω and output impedance varies with wiper position. A potentiometric displacement transducer usually requires no signal conditioning because of its ability to produce a large output voltage. This output voltage is limited only by the supply voltage applied and the power dissipation capabilities of the potentiometer. Potentiometers are susceptible to shock and vibration. Their sliding wiper arm can become contaminated by dirt or corrosion. Wear due to friction associated with this wiper arm typically limits their life to 10^6 to 10^7 cycles.

Resistance strain gages are most commonly available in either foil or semiconductor form. Foil strain gages are essentially small printed circuits. A 0.003- to 0.005-mm-thick foil grid is manufactured from a process that includes a master gage pattern, photographic reduction of the pattern, application of a light-sensitive emulsion to the foil, exposure to the photographic plate, a development process, and chemical etching. The grid is then bonded to a backing. Alternately, semiconductor strain gages begin their fabrication process with a single high-purity silicon crystal. The crystal is sliced into wafers, and atoms such as phosphorus (*n* type) or boron (*p* type) are doped into the material at high temperature (>1000 °C) to lower its resistivity. Each wafer is then masked and etched to produce a suitable grid pattern that is bonded to a backing. The strain-induced change in resistance of either the foil or the semiconductor grid results in an electrical signal output when the strain gage is configured into a Wheatstone bridge circuit (Walter, 1990).

Strain gages can withstand only relatively small deflections. A strain-gage–based displacement transducer would consist of an

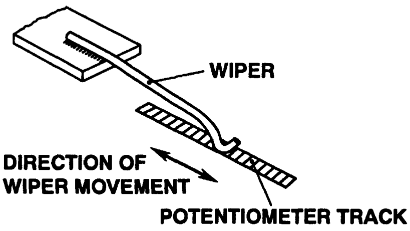

FIG. 1. Potentiometer.

elastic element with one to four attached strain gages. Walter (1990) provides additional description of resistance strain gages, their associated circuity, and their application in various transducers. Strain-gage transducers possess typical outputs from 30 to 500 mV and linearities from fractional percentage to 2% of full scale. Figures 1 and 2 show a potentiometer and a resistance strain gage, respectively.

1.2 Variable Inductance

A change in displacement can be electrically related to a change in inductance through a change in coil geometry, change in reluctance of a magnetic path by a varying air gap, change of permeability of a core material (magnetostrictive material), change in mutual coupling between two coils, or change in coupling between a primary and a secondary coil as in a transformer. A linear variable differential transformer (LVDT) illustrates the use of this last inductive coupling effect to measure displacement.

In an LVDT, three coils of conductive wire are wrapped along a hollow insulated form. A ferromagnetic core can move within the form along the common axis of the coils in either a positive or a negative direction. An ac voltage applied to the primary (center) coil induces voltages of the same frequency in each secondary coil. If the core is centered along the length of the three coils, and the two secondary coils are connected together in series opposition, the net voltage output from the LVDT is zero. A demodulator (ac signal-conditioning component producing a phase-sensitive dc output) can be interfaced to the series-connected output of the secondary coils to produce a proportional positive or negative output voltage as the core is displaced along the center line of the coils. LVDTs are typically used for displacements of 2 to 150 mm. The upper frequency displacement limit is a function of the demodulator but typically extends to tens or hundreds of hertz. LVDTs exhibit no wear, friction, or hysteresis, produce a continuous output, and are relatively insensitive to cross-axis motion. Dependent on their demodulator circuitry, they typically provide 1 to 10 V full-scale output. Their input–output is electrically isolated, and their operating temperature range can extend from −270 to 600 °C. Figure 3 provides a schematic of an LVDT. Herceg (1976) provides detailed information on LVDT design, selection, and application.

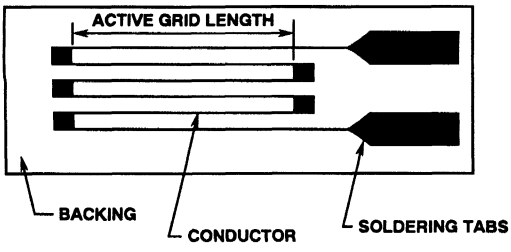

FIG. 2. Foil resistance strain gage.

1.3 Variable Capacitance

A capacitance displacement transducer can be designed by measuring the capacitance variation due to a change in distance

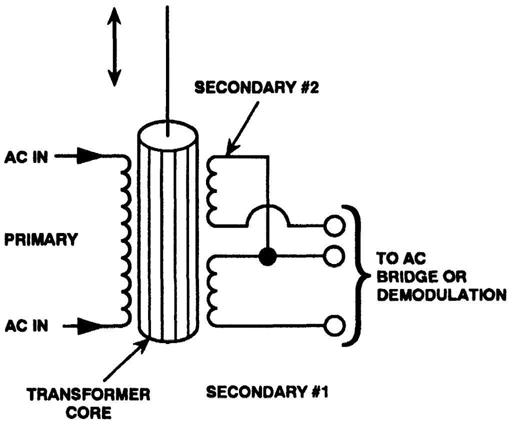

FIG. 3. Linear variable differential transformer (LVDT).

between its electrodes, keeping the electrodes fixed and measuring the change in capacitance due to a dielectric of varying permittivity being displaced between the electrodes, or changing the area of the electrodes in a manner that is related to displacement (e.g., by a rolling action of one electrode). Capacitive transducers known as Inductosyns are also used to measure linear or angular position. In an inductosyn, one capacitor plate moves over a second, which is configured in a grid or comb-type pattern, resulting in a pulse-type output. The pulse count can be a measure of position if grid spacing is known. Accuracies of 0.0025 mm can be obtained for linear displacements.

The simplest capacitance transducer takes advantage of a relative displacement between its electrodes. One capacitor plate of fixed area senses motion of either a metallic target plate or, if the target is an insulator, a metallic coated surface. The sensitivity is inversely proportional to the distance to be measured. Because of this relationship, capacitance transducers are well suited to measure small displacements. Typical displacement ranges extend from 3 to 6 mm. Variable-capacitance transducers, like variable-inductance transducers, are typically used in ac-powered bridge circuits with accompanying demodulated outputs ranging from 1 to 10 V. Figure 4 provides an illustration of a capacitance displacement transducer.

1.4 Piezoelectricity

Piezoelectric displacement transducers take advantage of the ability of a material to generate an electrical charge as a result of a mechanical stress that changes its shape. The basis for a piezoelectric material is absence of a center of charge symmetry. Thirty-two crystal forms occur in nature, of which 20 are piezoelectric. Quartz is a naturally occurring piezoelectric. Ceramics composed of ferroelectric crystals can be pressed, fired, electroded, and subjected to a high dc voltage to produce a material that will behave roughly like a single-domain piezoelectric crystal. Lead zirconate titanate is such a ceramic. The output impedance of any piezoelectric device is almost purely capacitive, and therefore, piezoelectric transducers will not produce a dc response to a static displacement. Their static response decays according to the circuit *RC* time constant. This time constant is determined by the transducer capacitance and the input impedance of its subsequent signal-conditioning component.

Piezoelectric transducers are extremely stiff and rugged, operate over a wide (10 000:1) dynamic range, and provide exceptionally high-frequency response. They can be made small in size and can operate over temperature ranges of −250 to +760 °C. As noted, they can perform only dynamic measurements. They require special cables and electronics and their high output impedance is susceptible to contamination.

2. FLEXURAL DEVICES

Force, pressure, and acceleration transducers can be constructed by having a displacement transducer sense the motion of a flexural element. This motion must be proportional to the quantity being measured.

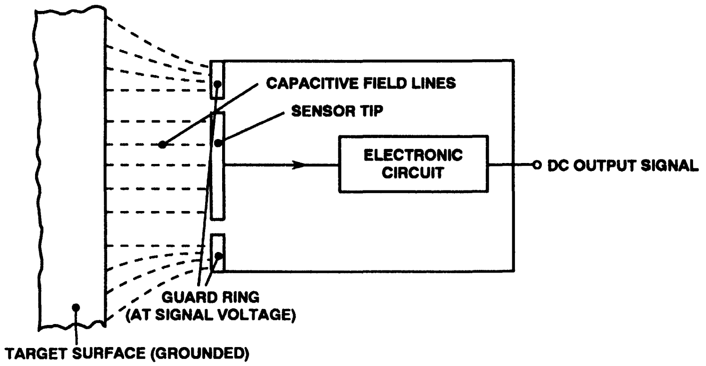

FIG. 4. Capacitance displacement transducer.

Potentiometric, inductive, and capacitive displacement transducers can directly measure this motion. The same is true for piezoelectric transducers if the motion is dynamic. Resistance strain gages take advantage of the strain pattern on the surface of the flexure. Among the gamut of flexural elements are Bourdon tubes, cantilever beams, and clamped diaphragms.

2.1 Bourdon Tubes

Bourdon tubes are one of the most widely used flexures for sensing pressure. The original patent for this device was granted to Eugene Bourdon in 1852. Bourdon tubes are hollow tubes that are twisted or curved along their length. The application of pressure deforms the tube wall that, depending on tube shape, causes it to untwist or unwind. Motion of the tube is measured and related to its internal pressure. Bourdon tubes can be integrated into transducers to achieve extremely high accuracies and have been manufactured from perfectly elastic materials such as quartz. Transducers employing Bourdon tubes tend to be physically large and easily damaged by environmental inputs such as acceleration. In addition, the tubes themselves afford poor frequency response to time-varying pressure.

2.2 Cantilever Beams

Cantilever beams are routinely used as the flexural element in transducers used to measure force, pressure, and acceleration. Strain near the clamped end of the beam can be measured, as can displacement of the free end, to correlate to force or torque applied to the free beam end, dynamic pressure associated with fluid flow acting over the beam surface, acceleration of the base to which the beam is mounted, etc. The compliance of a cantilever beam is defined as

$$y/F = L^3/3EI, \tag{1}$$

where y is the deflection of the free beam end, F is the force applied to this end, L is the beam length, E is the modulus of elasticity of the beam material, and I is the beam area moment of inertia. A compliant fixture will result in a transducer with a large electrical signal output. The above equation indicates that a compliant fixture can be achieved by a long, thin, narrow beam of low-modulus material. The penalty attached to such a design in application could be a transducer that is bulky, displays undesirable response to physical inputs orthogonal to its sensing direction, and has poor dynamic response.

2.3 Clamped Diaphragms

Clamped diaphragms are flexures used to transform strain or displacement into a measurement proportional to applied pressure. A small, flat, circular diaphragm can be made simply and can be placed flush against surfaces whose flow dynamics are being studied. This type of diaphragm is typically made to deflect in accord with theory associated with clamped circular plates. Corrugated diaphragms provide extensibility over a greater linear operating range than do flat diaphragms. A catenary diaphragm consists of a flexurally weak seal diaphragm bearing against a thin cylinder whose motion is measured. The compliance of a flat, circular diaphragm is defined as

$$y/P = 3R^4(1 - \nu^2)/16t^3E, \tag{2}$$

where y is the deflection of the center of the diaphragm, P is the applied pressure, R is the diaphragm radius, ν is Poisson's ratio, t is the diaphragm thickness, and E is the modulus of elasticity of the diaphragm material. Somewhat analogous to the cantilever beam, a compliant diaphragm would have a large radius, be thin, and be made of a low-modulus material. Equation (2) holds for deflections no greater than t.

3. DYNAMIC MODEL FOR FLEXURAL TRANSDUCERS

Flexural transducers can be dynamically modeled through their first resonant frequency as in Fig. 5. This single-degree-of-freedom system is characterized by a linear second-order differential equation with constant mass (m), viscous damping (c), and stiffness (k) coefficients. The governing equation for the system in Fig. 5 is

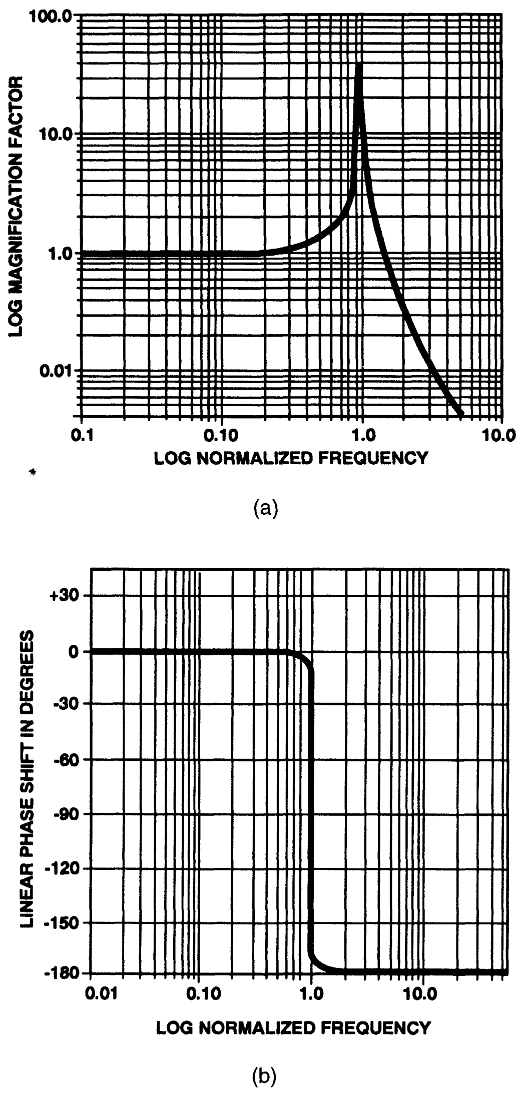

FIG. 5. Dynamic model for flexural transducers: (a) amplitude-frequency response; (b) phase-frequency response.

$$mx'' + cx' + kx = f(t), \qquad (3)$$

where the prime denotes a time derivative of the dependent variable x and $f(t)$ is the time-varying forcing function. Figure 5 represents a system viscously damped to 0.01 of critical, typical for transducers that are not intentionally damped. The maximum gain in Fig. 5(a) is 50:1, and the response is constant (flat) within 4% of the 0-Hz value to one-fifth of the maximum gain or resonant frequency. The phase in Fig. 5(b) is linear over this same range of frequencies. Thus, the criteria for measuring time-varying phenomena presented in the Introduction of this article are satisfied.

3.1 Force, Pressure, Acceleration Transducers

Force transducers measuring impact forces satisfy the model of Fig. 5 where the transducer's reciprocal compliance is the stiffness in Eq. (3), and the mass is the resultant summation of the effective mass of the transducer and the mass of the impacting object. Flush-diaphragm pressure transducers also satisfy the model of Fig. 5 where the reciprocal compliance of the diaphragm is the stiffness in Eq. (3) and its effective mass the mass term. Recess mounting of the transducer's diaphragm degrades transducer dynamic performance. Rigidly mounted accelerometers containing beam or other flexural elements satisfy the model of Fig. 5 in an analogous fashion as does the pressure transducer diaphragm. The significant difference in Eq. (3) when applied to force and pressure transducers versus accelerometers is that for force and pressure transducers x represents the absolute displacement of the mass while for accelerometers x represents the relative displacement between the mass and the accelerometer base. As mentioned in Sec. 2, this displacement can be measured with displacement transducers and related to the measurands of force, pressure, or acceleration as in Fig. 5.

3.2 Applications

Force transducers can be used in weighing or pressing applications where only their static response is important. Their dynamic response becomes important in applications such as dynamic force control, impact studies, and machine dynamics. Static pressure measurements are important in applications such as proof testing, monitoring of stationary flow processes, and liquid-level determination. Dynamic pressures are encountered in applications that include ballistics, explosions, cold-gas shock tubes, and combustion processes. Representative static accelerations can be found associated with centrifuges, rocket motor burns, and powered aircraft flights. Time-varying or dynamic accelerations are represented in vibration testing, mechanical shock testing, crash environments, and setback accelerations in cannons.

4. MEASUREMENT PLANNING CHECKLIST

Optimizing the mechanical measurement of displacement, either directly or as it relates to force, pressure, or acceleration stimuli, requires a knowledge of the physics of both the transducer and the process being measured. In adverse environments, it also requires an experienced measurements practioner. For the less experienced practioner, a checklist can provide guidance to assist in instrumentation system design. Consideration should be given to the following items:

1. Transducer type
2. Transducer interface to the measurand
   A. Special fixturing
3. Number of data channels
   A. Multiplexing desirability
   B. Location of signal conditioning
      1. Cable type
4. Signal conditioning type
5. Data filtering
6. Recording technique
   A. Time correlation requirements
7. Grounding and shielding
8. Calibration techniques
   A. Transducer calibration
   B. Measurement system checkout
   C. Field calibration
9. Data validation technique(s)
10. Data reduction technique(s)
11. Data presentation format(s)
12. Measurement system documentation

The included list of Further Reading contains detailed information about the various elements of this checklist to allow the successful design of measurement systems.

GLOSSARY

Measurand: The physical or chemical process to be measured.

Measurement: The transfer of information about a process and, as a by-product, the transfer of information from a process.

Transducer: A component in the measurement system that converts a measurand into a proportional electrical quantity.

INTRODUCTION

This article provides a conceptual overview of the physical principles underlying the operation of the common sensors for temperature, pressure, and flow. The article is not intended as a measurement engineering text and consequently does not address implementation issues. Important topics for measurement system application such as time and frequency response, cross-sensitivity, nonlinearity, response drift, measured-system disturbance, signal transmission, and noise are only adumbrated. For more information on measurement system design and application, the reader is referred to any of the several recent, excellent texts on the subject (see Further Reading). This article is neither mathematically rigorous nor exhaustive in scope, seeking instead to provide insight into the operational principles of sensors that are commonly employed.

The terms sensor, sensor element, transducer, and measurement are key to any description of the operation of measurement systems, yet these common terms are frequently confused. For the purpose of this article, the terms are defined as follows:

- transducer—an object that converts one form of energy into another;
- sensor element—the set of transducers used to convert energy from the measured form to a form usable to transfer information;
- sensor—an object that converts energy from a measured form into a form usable to transfer information; and
- measurement—the process of quantifying a physical process or event or the result of such a process.

A diaphragm-deflection–based pressure measurement system is illustrative of these terms. In this system the diaphragm whose front surface is exposed to the pressure being measured is the transducer. The transducer converts energy due to applied pressure into strain energy in the diaphragm. The strain energy in the diaphragm is in turn converted into an electrical signal by means of a strain gage attached to the diaphragm and a voltage source. The diaphragm and strain gauge together constitute the sensor element. The electrical signal is the form of energy used to transfer information about the quantity of pressure. The sensor comprises the sensor element and the voltage source.

1. TEMPERATURE TRANSDUCERS

1.1 Physics of Temperature

Temperature is a physical state parameter that represents the mean translational kinetic energy of the constituent elements (atoms, molecules, and electrons) of a thermal system. Temperature and heat are intimately related quantities. Temperature represents the potential for heat flow, while heat is the form of energy transferred when two systems at different temperatures are brought into thermal contact. Heat transfer occurs by one or more of the following methods:

- *conduction,* the diffusion of heat (without bulk atomic motion) from regions of higher to lower temperature;
- *convection,* the increased transfer of heat in the presence of a temperature gradient, due to bulk atomic motion; and
- *radiation,* the emission of heat in the form of electromagnetic energy due to accelera-

tion of the constituent elements of a thermal system in turn resulting from the interaction of the constituent elements because of their kinetic energy.

Many monographs exist on temperature and thermometry. The interested reader is directed to Quinn (1990), Kerlin and Shepard (1982), and Ricolfi and Scholz (1990) for more in-depth coverage.

1.2 Temperature Scales

Although in principle a temperature scale can be developed on the basis of statistical mechanics, relating temperature to mean kinetic energies (which are dependent only on mass, length, and time standards for their description), elemental kinetic energies are not generally measurable at present. The SI unit for temperature is the kelvin, which is defined as 1/273.16 of the temperature interval between absolute zero and the triple point of water. Two practical temperature scales, which remain in common use, were developed before the understanding of the thermodynamic basis of temperature. The Celsius temperature scale assigns 0 °C to the ice point (the water–ice equilibrium temperature at one atmosphere pressure) and 100 °C to water's boiling point at one atmosphere pressure. A one-degree Celsius change is equal to a one-kelvin change, and 0 °C is equal to 273.15 K. The Fahrenheit temperature scale originally assigned 0 °F to the lowest temperature that could be achieved by a mixture of ice, water, and sel-ammoniac and 96 °F to the blood temperature of a healthy man (Fraden, 1997, p. 99). The Fahrenheit scale was later amended, assigning 32 °F to the ice point and 212 °F to the boiling point of water.

1.3 Thermocouples

The operation of a thermocouple can be qualitatively understood using a simple free-electron–gas model of the conduction process. A more rigorous description of thermoelectricity is provided in Pollock (1985) and Blatt *et al.* (1976). Park (1993) provides detailed information on the application of thermocouples to temperature measurement. For a conductor in a thermal gradient, the electrons at the hot end have more kinetic energy than those at the cold end. The increased motion of the electrons results in a net diffusion of electrons from hot to cold. The skewed distribution of electrons produces an electric potential gradient opposing the thermal diffusion. The detailed mechanics of the diffusion are intimately involved with how the electrons scatter both among themselves and with the lattice atoms. The relation of the mean free path of electrons in a conductor and their kinetic energy is quite complex. The effect of point defects in the lattice structure (grain boundaries, interstitial impurities, etc.) has a strong influence on the quantitative value of the local diffusion parameters. The dependence of electron diffusion on lattice parameters results in thermally induced electric potentials being substantially different for different materials. It is these differences that are exploited to create thermocouple temperature sensors.

A thermocouple consists of two electrical conductors with different thermoelectric coefficients that are electrically connected at one end, isolated along their length, and connected to an electrical potential measurement circuit at the other end (see Fig. 1). Note that since all conductors exhibit thermoelectric potential (including those in the measurement circuit), the measurement ends of both thermoelements should be at the same temperature.

The change in electric potential in a material with temperature is quantified as the Seebeck coefficient, $S(T)$. The voltage developed along a thermocouple circuit (ΔV) can be expressed as the integral of $S(T)$ along the circuit:

$$\Delta V = \int S(T)dl, \tag{1}$$

where dl represents differential length along the thermoelements and the integral is performed from one end to the other of the thermocouple circuit.

Almost any set of conductors can be used as a thermocouple. However, eight sets of thermoelements with advantageous properties (large voltage response, lattice stability, durability, etc.) have received *letter designation* (type J, K, S, R, B, E, N, and T) and are commonly available commercially (ASTM, 1993).

Thermocouples are among the most du-

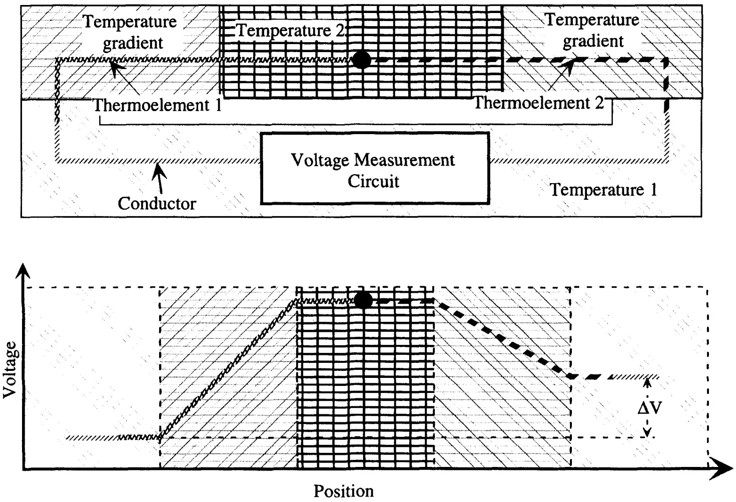

FIG. 1. Thermocouple voltage development.

rable and widely used temperature sensors available. Although accuracies of 0.25% or better are achievable using standards-laboratory practices, thermocouples, as commonly used in industrial practice, typically have inaccuracies of ~0.75% of reading. Anything that effects the mean free path of the electrons in the thermoelement lattice (impurity diffusion, work hardening, phase changes, etc.) affects the thermoelectric potential buildup. At higher temperatures, electrical shunting between the elements also becomes a concern.

A key concept in understanding thermocouple operation is that thermocouple voltage is developed over regions with temperature gradients and *not* across the thermoelement junction. Since thermocouple voltage builds up over a temperature gradient and degradation in thermocouple response also is highly dependent on the temperature gradient, thermocouple drift cannot be calibrated out without locating the thermocouple in the same temperature gradient where it is to be used.

1.4 Resistance Thermometers

Resistance thermometers function by measuring the change in electrical resistance of a transducer with temperature. Both metals and semiconductors are commonly used as resistance thermometer elements. The conventional conceptual models for electrical conduction in metallic conductors and semiconductors are substantially different. For a formal introduction to electrical conduction in solids, the reader is referred to introductory solid-state theory texts such as Kittel (1986). Quinn (1990, p. 208 *et seq.*) also provides a well-reasoned overview of conductivity variation with temperature.

1.4.1 Qualitative Sketch of Electrical-Conductivity Variance with Temperature in Metals The basic conceptual model for electrical conductivity in metals is that of free-electron waves propagating through a periodic lattice. Conductivity is determined by how frequently the electrons collide, the energetics of those collisions, and how rapidly the electrons accelerate back to drift velocity following collisions. The electron collisions can be separated into collisions with lattice phonons, with point defects in the lattice, and with other electrons. Collisions with lattice imperfections are largely independent of temperature.

At room temperatures, the mean free path for electron–electron collisions is at least an order of magnitude more than that of electron–phonon collisions, and so electron–phonon collisions are the dominant source of electrical resistance temperature variation in metals near room temperature. Near room temperature the concentration of thermal lattice phonons is proportional to temperature. Hence metal electrical resistivity is roughly proportional to temperature near room temperature.

At very low temperatures (liquid helium

range) thermal phonon scattering in metals competes with electron–electron scattering, and lattice imperfection scattering. Bloch obtained an analytic result for electron–phonon scattering at low temperatures in metal that resistivity varies as T^5 (T is absolute temperature). At these temperatures, electron–electron collision mean free paths can be several centimeters (inter-conduction-electron spacing is ~2 Å). These large free paths [due mostly to the low thermal energy of the conduction electrons and the Pauli requirement to have unfilled orbitals with energies suitable for in-scattering (Kittel, 1986, p. 280)] result in much greater conductivity for pure metals at low temperatures as compared to room temperature (conductivity ratios of 10^5 are common). For transition metals (those with partially filled *d* orbitals such as platinum and nickel), the situation is further complicated by large-angle electron–electron scattering. This effect becomes dominant below about 10 K in transition metals, producing a T^2 dependence in electrical resistivity.

Transition metals, because of their partially filled band structure, have significant variations in the density of electron states that are thermally populable. This is generally expressed as a further T^2 modification (which can be positive or negative) in the simple T dependence of the electrical resistance of metals near room temperature.

Above room temperature, the electrical resistance is modified by an additional T^2 term due to the thermal expansion of the lattice. The expansion causes the interatomic spacing to increase, the stiffness of the interatomic bonding therefore to decrease, and the amplitude of atomic vibration to increase, which, in turn, causes atomic nuclei to become more effective electron-scattering centers.

At still higher temperatures, lattice vacancies begin to increase as thermal vibrations become comparable to lattice bonding energies, resulting in an exponential increase in electrical resistivity with the exponent value given by the ratio of the energy required to form a vacancy (~1.5 eV for platinum) and kT (k is Boltzmann's constant).

1.4.2 Qualitative Sketch of Electrical-Conductivity Variance with Temperature in Semiconductors The distinction between semiconductors and conductors is that the allowed electron energy bands of semiconductors exhibit a gap, which can be thermally bridged at temperatures below lattice atom migration temperatures. The semiconductor upper energy band (unpopulated at low temperatures) is called the conduction band while the lower energy band (completely filled at low temperatures) is the valence band. In semiconductors, the electron energy level that has a 50% occupancy probability (the Fermi level) resides within the energy band gap at low temperatures (see Fig. 2). In contrast, conductor Fermi levels lie within an energy band at all temperatures. For more complete introduction to semiconductor solids and their thermoelectrical properties see, for example, Streetman (1980) or Kittel (1986).

Electrical conduction in semiconductors takes place by a combination of migration of electrons in the conduction band and countermigration of electron vacancies, termed holes, in the valence band. Electrical resistivity of semiconductors is strongly dependent on the electron population of the conduction band and the hole population of the valence band.

The semiconductors used in temperature measurements are doped. That is, they have impurity atoms substitutionally included within the lattice. These impurity atoms either have an additional valence electron as compared to the bulk lattice, which is available to donate to the conduction process, or have one fewer valence electron and can serve as a sink for lattice electrons in the valence band. Conceptually these dopants either raise (in the case of donor atoms) or lower (in the case of acceptor atoms) the lattice Fermi level such that much lower temperatures are required to place electrons in the conduction band or holes in the valence band.

Four major conduction temperature regimes can be identified in semiconductors. In the highest temperature regime, the conductivity is dominated by electrons thermally excited from the valence band to the conduction band. Here the resistance falls off roughly exponentially with increasing temperature. In the next lower temperature region, all of the donor and acceptor atoms have been ionized, but valence- to conduction-band thermal excitation occurs rarely. In this region, the conductivity depends on

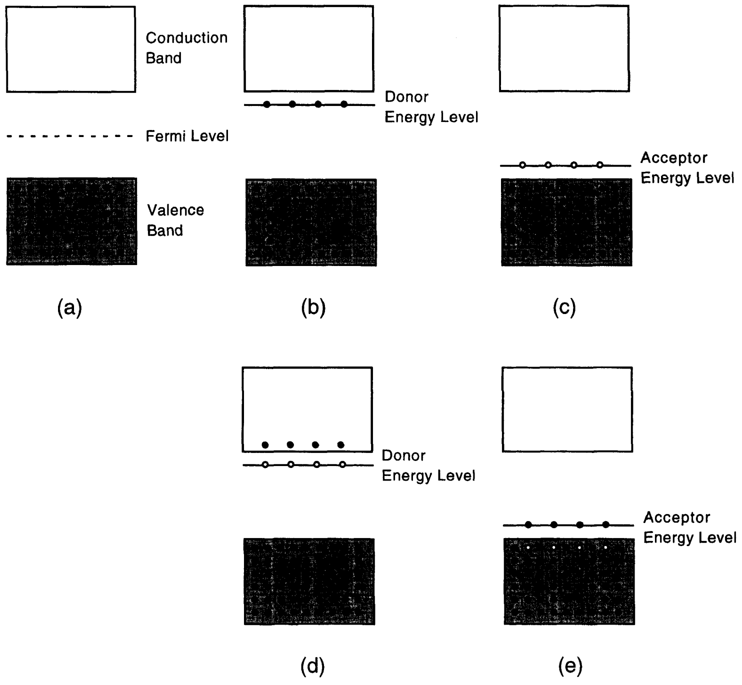

FIG. 2. Semiconductor band population diagram. (a) Semiconductor band structure, (b) donor energy-level population at 0 K, (c) acceptor energy-level population at 0 K, (d) donor energy-level population at 50 K, and (e) acceptor energy-level population at 50 K.

temperature only through the mobility of the electrons and holes, which decreases (because of increased scattering) with increasing temperature. Hence the resistivity has a positive temperature coefficient. In the next lower temperature region, ionization of the donor and acceptor atoms is only partial and conductivity is dominated by the ionization fraction of the dopant atoms. In this region, the resistivity of the semiconductor falls roughly exponentially with increasing temperature as the dopant atoms are thermally ionized. In the lowest temperature region, conduction takes place by electrons jumping from one dopant atom to the next. This is known as impurity conduction, and in this temperature region conductivity exponentially increases with increasing temperature.

1.4.3 Resistance Temperature Detectors Platinum resistance temperature detectors (RTDs) are among the most common of all general-purpose temperature sensors. Platinum resistance elements are commonly used from ~0.5 K (alloyed with cobalt) to ~1400 K. Several different versions of platinum RTDs are available for different applications. One limitation of metal RTDs is that the thermal expansion coefficient of metals is significantly greater than that of available insulation support structures. Therefore, for the most accurate implementations, to avoid strain-induced resistance changes minimally supported platinum wires are used. For industrial-grade applications, both thick films and thin films of platinum deposited on insulator substrates are commonly employed. Wire-wound platinum elements fully supported by powdered insulation are also commonly used industrially (see Fig. 3). Capsule-type platinum RTDs are used to make highly accurate temperature measurements from ~10 to ~500 K. Long-stem platinum RTDs are used for temperatures from ~50 to ~1400 K. Platinum RTDs are available with ice-point resistance ranging from ~0.25 Ω to ~5 kΩ with the dominant fraction having ice-point resistances of either 25 or 100 Ω.

1.4.4 Thermistors Thermistors (literally temperature-sensitive resistors) are the semiconductor form of resistance temperature detectors. One type of thermistor is the doped monocrystalline germanium resistor, which is used for accurate temperature measurements from ~1 to 30 K. A large class of thermistors are composed of mixed oxides of transition metals such as titanium, iron,

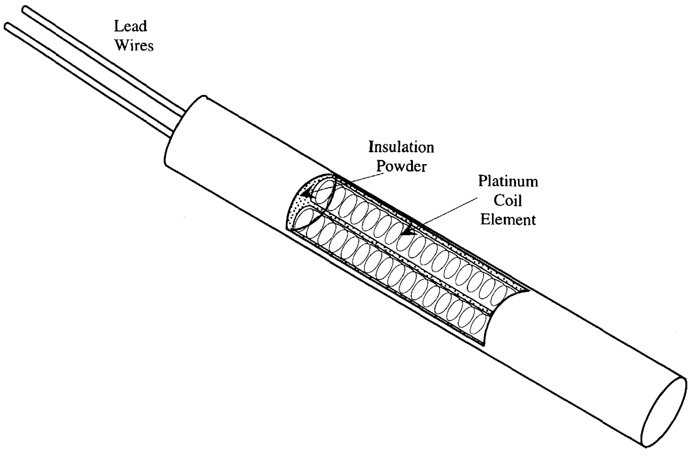

FIG. 3. Ceramic-insulated wire-wound industrial platinum resistance thermometer element, cutaway view.

nickel, copper, and cobalt. This composition of thermistor is referred to as a negative–temperature-coefficient (NTC) thermistor because of its resistivity decrease with increasing temperature. NTC thermistors are most commonly formed by mixing powdered oxide with a liquid binder to form a slurry that is applied to parallel wire strands. The assembly is then dried and the oxide sintered in a controlled atmosphere. The resultant beads are then overcoated with glass or epoxy for environmental protection. Chip-type thermistors (fabricated using a tape-casting process) are becoming more common as thermistors are implemented in surface-mount form for circuit-board temperature monitoring.

Positive–temperature-coefficient thermistors are most commonly made from perovskite-type oxides of barium and strontium titanate. Above the Curie point of the composite material, the resistance of the sensor rapidly rises with temperature over a few-degree temperature range (typically more than 100%/°C). The anomalous resistance-to-temperature relationship of these materials has been explained (Sachse, 1975) on the basis of the sensitivity of the activation energy (amount of energy required to cause a dopant atom to release its charge carrier) of impurity centers in the semiconductor to the material relative dielectric constant. The relative dielectric constant of most semiconductor materials is roughly constant with temperature. However, in ferroelectric materials, such as $BaTiO_3$, the relative dielectric constant varies strongly with temperature near their Curie temperature. An additional feature of this conductivity–temperature relationship is that the steep increase in resistivity with temperature is not a bulk material property but is caused by barrier layers developed at the grain boundaries. The electric barrier results from surface states acting as trapping locations for the conduction electrons released by dissociating dopant atoms.

The basic characteristics of thermistors is that they are very small and vibration resistant, and have a very large resistance change over a small temperature window. Mixed-oxide type thermistors are commonly used for high-precision temperature measurement over a limited temperature range such as in medical applications, while the positive–temperature-coefficient thermistors are most commonly used as temperature limit switches. Mixed-oxide thermistors are most commonly used with resistances between 1 MΩ and 100 Ω. On account of variations in the manufacturing process, mixed-oxide form thermistors often exhibit a significant resistance offset and are not yet as easily interchangeable as RTD elements.

1.5 Radiation Thermometers

1.5.1 Emission Physics Radiation thermometers function by measuring some fraction of the radiant energy emitted by a body as a consequence of its temperature. The amount and wavelength of radiation emitted (spectral radiance) by a blackbody (an ideal object that absorbs all incident radiation) was first derived by Planck from quantum mechanics (Liboff, 1980):

$$L_b(\lambda,T) = \frac{2hc^2}{\lambda^5[\exp(hc/\lambda kT) - 1]}, \tag{2}$$

where h is Planck's constant, k is Boltzmann's constant, T is absolute temperature, c is the speed of light in a vacuum, λ represents wavelength, and the subscript b on L denotes blackbody conditions. Several key points about thermal radiation are provided by Planck's law. For all wavelengths, the amount of radiation emitted increases with temperature. As temperature increases, relatively more radiation is emitted at progressively shorter wavelengths. Integrating Planck's law over wavelength and all possible directions yields the total *exitance* (M),

$$M_b = \frac{2k^4\pi^5}{15c^2h^3}T^4 = \sigma T^4. \tag{3}$$

This formula is known as the Stefan–Boltzmann law, and it underlies all of radiation thermometry. Planck's and Stefan–Boltzmann's laws apply without modification only to ideal blackbodies.

The surface radiative property *emissivity* (ϵ) is defined as the ratio of the radiation emitted by the surface to the radiation emitted by a blackbody at the same wavelength in the same direction. In general, the emissivity depends on wavelength, temperature, surface conditions (roughness, fouling, oxidation), angle of emission, and state of polarization. The largest uncertainty in most radiation thermometry applications is due to uncertainty in the value for the emissivity. For a detailed description of the theory and practice of radiation thermometry, the interested reader is referred to DeWitt and Nutter (1988).

1.5.2 Types of Radiation Thermometers Total-radiation thermometers measure radiant energy over as wide as possible a wave band. These devices are typically used in general-purpose, low-temperature instruments. Single–wave-band thermometers measure the incident radiation in a single narrow wave band. The wave band measured is selected so that the rate of change of radiant energy with temperature is as high as possible (2–3%/°C) in the designed operating range (655 nm is a common wavelength choice). Ratio thermometers work on the principle of comparing the energy in multiple wave bands. Their advantage is that their response is independent of target size, optical path, and emissivity (provided that the optical absorption and emissivity are wavelength independent).

1.5.3 Radiation Detectors Radiation detectors are classified as thermal or photon detectors. Silicon and germanium photodiodes are examples of photon-sensitive detectors. They directly convert incident photons within their response wave bands to electrical signals. Thermal detectors are designed to collect all incident radiation and respond uniformly to all incident wavelengths. A thermal detector's sensor temperature is designed to rise until an equilibrium is achieved with heat losses to the surroundings. The sensor temperature is then measured with a thermopile, resistance thermometer, or pyroelectric detector. A thermopile is a series connection of thermocouples with their sensing junctions receiving the incoming radiation while the cold junctions are shielded.

Pyroelectric detectors are composed of ferroelectric ceramics. Each grain in the crystal behaves as a miniature electric dipole. The dipoles are oriented in the sensor, giving the crystal a residual polarization (and surface charge). The degree of polarization (and the surface charge) decreases with increasing temperature as increased thermal energy randomizes the atomic oscillations. This decreased surface charge results in a decrease in the potential developed in a capacitor placed along the polarization direction of the crystal. Connection to any measurement circuit allows a flow of charge that ultimately neutralizes the polarization effect. Thus pyroelectric detectors cannot directly measure steady radiation. Beam choppers, which periodically block the incident radiation, are employed to overcome this limitation (upper frequency limit typically <1 MHz) and allow the measurement of the rate of temperature rise in a pyroelectric detector.

1.6 Special-Application Thermometers

1.6.1 Semiconductor-Junction (Diode) Thermometers Semiconductor-junction–based temperature sensors function on the basis of the temperature sensitivity of the voltage–current characteristics of *pn* semiconductor junctions. This type of sensor can be monolithically integrated with other electronic components and has consequently won widespread acceptance in the area of instrument temperature monitoring. Silicon-based diode temperature sensors function from about 1 to 525 K. Forward-biased diode characteristics are such that practically no current flows below the voltage necessary for charge carriers to overcome the junction potential. Above this voltage, the current increases approximately exponentially with increasing voltage-to-temperature ratios. Diode-based temperature sensors are often implemented using a constant-current source connected in series with the diode, since in this configuration the forward voltage varies approximately linearly (~ -2 mV/K) with increasing temperature ($T > \sim 20$ K).

1.6.2 Liquid-in-Glass Thermometers Liquid-in-glass thermometers function on the basis of the differential thermal expansion of the liquid and glass container material (see Fig. 4) and are typically optimized to measure the temperature of a fluid. Different styles of liquid-in-glass thermometers are available based upon the immersion depth into the fluid. *Partial immersion* thermometers are inserted to a fixed point marked on the stem. This is the least accurate implementation, since the liquid and glass temperatures above the surface may be significantly different from that of the immersed portion. This affects their differential thermal expansion and consequently directly affects the measured value. *Total immersion* thermometers are designed to be immersed until the liquid in the column is totally immersed in the fluid. *Complete immersion* thermometers are designed for use completely submerged in the fluid.

The dominant cause of shifts in thermometer response are variations in the glass bulb volume due to glass structural changes. The major requirement for good thermometric glass is that its shape and rigidity remain stable on heating and with thermal cycling. Since glass is not a crystal structure, plastic flow can occur with heating. For accurate temperature measurement, the effects of pressure on liquid volume must also be accounted for. The volume of the glass bulb is equivalent to several thousand degrees temperature shift in the stem; thus even small changes in the bulb volume affects the temperature reading (0.1 °C per atmosphere is a typical correction factor).

1.6.3 Resonant-Frequency Thermometers Quartz crystals form the sensing elements of most resonant-frequency thermometers. Ricolfi and Scholtz (1990, p. 270 *et seq.*) give a thorough review of the operation of quartz resonator temperature sensors. Quartz crystals are piezoelectric—mechanical deformations in the crystal cause a change in the electric polarization. As the crystal polarization changes, the surface charge density changes—this allows for easy excitation and detection of its vibrations. Different crystal resonant frequencies are produced depending on the orientation of the crystallographic axes and the vibration. Along some of the crystallographic axes, the variation in resonance frequency with temperature is very small (for temperatures less than 250 °C). Along other axes, the resonant frequency varies strongly with temperature (up to 90 ppm/K). Quartz thermometers are often realized by beating the resonant-frequency signals obtained along different crystallographic axes and monitoring the resultant heterodyne signal.

1.6.4 Acoustic Thermometers Acoustic thermometers function by measuring the propagation time of sound waves through a

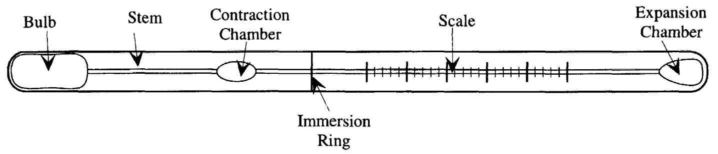

FIG. 4. Liquid-in-glass thermometer principle features. The immersion line is provided only on partial-immersion thermometers. The expansion chamber is provided to prevent excess pressure from being developed in gas-filled thermometers when the thermometer is used near the top of its range.

medium. Lynnworth (1989) provides more details about the operation of acoustic thermometers. Two classes of acoustic thermometers are conventionally specified—those in which the sound is transmitted through a separate element in the monitored environment and those in which the environment itself propagates the sound. Acoustic thermometers are available that are designed to function with gaseous, liquid, and solid media. The velocity of sound in a medium is commonly measured by one of three techniques. The velocity can be determined through simple geometry by measuring the times of arrival of sound emitted from a single source at two different receivers at known locations. Alternatively, a fixed-frequency wave can be launched from a single source. The phase relationship of the source signal and that recorded at the sensor can be used to determine wave velocity. The resonant frequencies of acoustic resonators (e.g., a flute) also depend on gas temperature. A typical application of media-as-sensor implementation is in measuring the flame temperature in power-plant type fireboxes. In these systems a series of acoustic transmitter/receivers rings the fireball. Each individual sound path gives an average temperature along the line. Using multiple lines through the fireball, a temperature profile can be constructed.

Foreign-medium–based acoustic thermometers function by measuring the time delay between the arrival of a reflected pulse received from a discontinuity in a thin wire waveguide and another discontinuity (see Fig. 5). The time of flight is determined by the length of the sensor between the discontinuities and the velocity of sound in the sensor material (thermal-expansion length changes are typically negligible).

1.6.5 Noise Thermometers Johnson noise is a fundamental representation of temperature—it is the vibration of the electronic field surrounding atoms as they thermally vibrate. Johnson-noise thermometry technology has recently been reviewed (White *et al.*, 1996). As an absolute measurement, Johnson-noise thermometry is inherently drift free. Moreover, Johnson-noise is insensitive to the material condition of the sensor and consequently is immune to contamination and thermomechanical response shifts.

The mean squared noise voltage, in a frequency interval df, appearing across the ends of any resistor is given by (Ricolfi and Scholz, 1990, p. 228)

$$d\overline{V^2} = \frac{4hf\,\mathrm{Re}(Z(f))df}{e^{hf/kT} - 1}, \tag{4}$$

where h is Planck's constant, k is Boltzmann's constant, Re(Z) is the real part of the complex impedance Z, and f is the frequency. An important consequence of this relationship is that Johnson noise provides a means of equating temperature to fundamental physical variables (length, time, and mass) through a voltage and an impedance measurement.

A wide variety of measurement circuits have been devised to minimize the effects of electronic noise and to avoid needing to measure the sensor resistance. Simultaneous measurement of the noise current, which is inversely proportional to Re(Z), and noise voltage allows cancellation of the resistance in the determination of noise power, which is a fundamental representation of temperature.

The major limitation of Johnson-noise thermometry lies in the very low levels of signals produced and the difficulty in acquir-

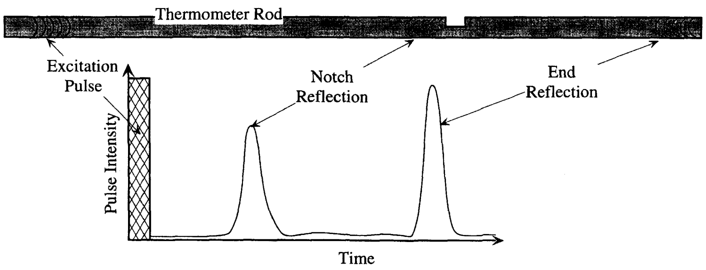

FIG. 5. Acoustic notch thermometer.

ing and processing them. Both radiatively coupled electronic noise and vibrationally induced noise degrade thermally produced noise's relative signal level. For a 300-K measurement using a 100-Ω resistor and a 100-kHz frequency band, the root of the mean squared noise voltage is approximately 4×10^{-7} V.

1.6.6 Fiber-Optic–Coupled Phosphor Thermometers The sensing element in a major class of phosphor thermometers is composed of rare-earth atoms substitutionally included in a refractory lattice (Y_2O_3:Eu or LaF_3:Gd, for example). A more detailed description of phosphor thermometry is given in Grattan and Zhang (1995). The sequence of events underlying rare-earth phosphor thermometry is as follows. First, electrons in the rare-earth atom are excited out of their ground state. Since rare-earth atoms have incomplete, widely spaced inner-electron shells, some of the ground-state energy inner electrons can be pumped into an excited state ($4f \rightarrow 5d$ transition) using UV/deep blue light. Following this, the electrons deexcite either radiatively or nonradiatively. The radiative transition probability is governed by the quantum-mechanical selection rules for inner-electron transitions and as such is essentially independent of temperature. In contrast, nonradiative transitions are mediated by phonons. As such they are governed by the phonon density (a fundamental temperature indication) and the allowed optical-phonon modes (function of the short-range lattice order). Since only radiative transitions can be easily monitored, the effect of the increasing probability of nonradiative transitions with increasing phonon population (temperature) is to create an apparent radiative decay-time variation with temperature.

The variation in fluorescence decay time can be exploited to determine temperature by monitoring the time relationship between the exciting energy and the emitted fluorescence. This is typically done either by exciting the phosphor with a pulsed laser and monitoring the exponential phosphor decay lifetime, or by sinusoidally exciting the phosphor and monitoring the phase lag of the resultant fluorescence.

1.6.7 Bimetallic Thermometers A bimetallic temperature sensor takes advantage of the differential coefficients of thermal expansion between different metals. When two metal strips are bonded together and heated, the differential expansion with temperature will cause the joined strips to bend. The most common implementation of this effect is in household thermostat temperature indicators. In these devices, a bimetallic strip is wound into a spiral, one end of which is fixed and the other attached to a temperature-control switch and an indicator needle that points to a temperature scale.

1.6.8 Vapor-Pressure Thermometers Constant-volume vapor-pressure thermometry relies upon the change in vapor pressure of a gas with temperature as the basis for measurement. The ideal-gas law relates temperature, pressure, and volume for ideal gases. Corrections to the ideal-gas law are required for use with nonideal gases at common temperatures and pressures. Constant-volume vapor-pressure thermometers can be used as absolute thermometers at low pressures. Since gas performance only becomes truly ideal at zero pressure, a set of measurements is typically made while reducing gas pressure to allow extrapolation to zero pressure. Constant-volume gas thermometers used in this fashion have been used in defining the thermodynamic temperature scale.

1.6.9 Fizeau-Cavity Thermometers Fizeau-cavity–based thermometers are another optically based temperature measurement scheme (Fig. 6). Fizeau cavities are a low-finesse (sensitivity) implementation of Fabry-Pérot etalons, which are described in Sec. 2.8. The transmittance and reflectance of Fizeau cavities are sensitive to the spacing of the reflectors and the wavelength of the incident light. Thus, thermal expansion of the material between the reflectors yields an optical signal that is a function of temperature (the "expansion" is typically dominated by an optical expansion due to change in index of refraction as opposed to a change in physical size). To avoid signal variation due to nonthermal effects, multiple-wavelength ratiometric techniques are incorporated into the signal detection and processing.

1.6.10 Distributed Fiber-Optic Thermometers One form of distributed fiber-optic temperature measurement relies on temperature-dependent change in the relative amounts of Stokes and anti-Stokes scattering

from an incident light pulse (Udd, 1991). Stokes and anti-Stokes scattering are forms of Raman scattering in which the incident photon interacts with a phonon of the material lattice in which the photon is propagating (Fig. 7). In Stokes scattering, the propagating photon interacts with the material lattice, emitting a phonon and downshifting in energy. In anti-Stokes scattering the photon absorbs a phonon and is thereby upshifted in energy. The number of phonons in the material (and hence the ratio of Stokes to anti-Stokes scattering) is a function of temperature. This form of sensing is implemented by injecting a narrow–wavelength-band optical pulse into a fiber at a known time and measuring the subsequent Stokes and anti-Stokes light scattered back down the fiber. Since both the time of injection of the optical pulse and the index of refraction

of the optical fiber are known, the time at which the backscattered light arrives at the fiber end is a measure of the location of the scattering. Correspondingly, the intensity ratio of the Stokes to anti-Stokes component of the backscattering is a measure of the temperature. The technique of obtaining spatial information about reflections from the time interval between pulse injection and reflection return is referred to as *optical time-domain reflectometry* (OTDR).

Other forms of OTDR-based distributed fiber-optic temperature have also been demonstrated. In one system a conventional fiber-optic core is coated with a polymer cladding containing scattering centers. The polymer cladding has a temperature-dependent refractive index. Therefore, both the optical power present in the cladding and the amount of backscattered light vary with temperature. This sensor has been reported to be able to pick out hot spots of <10 cm in length and to have an accuracy of ±2 °C from 0 to 60 °C and ±5 °C from 60 to 150 °C (Boiarski and McGinniss, 1993).

2. GENERAL CONCEPTS OF PRESSURE AND PRESSURE INSTRUMENTATION

2.1 Physical Nature of Pressure

Pressure is the force exerted normal to a unit surface area,

$$P = \frac{dF}{dA}. \tag{5}$$

At a given position, pressure is directionally independent and is also unaffected by the geometries of the surfaces upon which it acts. For gases, pressure may be evaluated as a measure of the total kinetic energy of the molecules, as presented from the ideal-gas law (Fraden, 1997)

$$P = 2U/3V = NRT, \tag{6}$$

where U is the kinetic energy of the gas, and P, V, N, R, and T are pressure, volume, number of molecules per unit volume, specific gas constant, and absolute temperature, respectively.

Pressure measurement is referred to as either absolute, gauge, or differential. Absolute pressure indicates pressure referenced to total vacuum, as opposed to gauge, which references to ambient pressure conditions. Differential pressure is, as the name implies, a differential measurement of pressure, often used to quantify upstream and downstream flow conditions, or a pressure difference between control volumes. Common pressure units include the N/m^2, or pascal (Pa), pounds per square inch (PSI), bar (10^6 dyn/cm^2), and various gravimetric bases: mm mercury (Torr), inches mercury, and inches of water column.

2.2 Manometers

Manometers indicate pressure through the balancing of forces on a fluid column within a fixed cavity. The most common manometer is the mercury barometer, consisting of a column of mercury contained in a tube, sealed at one end and open to an exposed reservoir at the other. The ambient pressure P upon the open reservoir imparts a distributed force that displaces the mercury column to a height h at which the weight of the column balances the pressure on the reservoir:

$$P = \rho g h. \tag{7}$$

The measurement is dependent upon the density of the mercury, ρ, and upon the local gravity constant g. The sealed end of the mercury barometer creates a vacuum reference condition making the barometer an absolute pressure measurement. Gauge pressures may be measured in the same manner, with the top of the liquid column connected to a constant reference pressure. Under this condition, the force balance upon the liquid column is the summation of the reference pressure at the top of the liquid column and the weight of the column against the process pressure at the reservoir. Multitube manometers perform the same balance, but with multiple process-pressure tubes connected in parallel to a reference pressure reservoir. Other manometer configurations include spring and inverted-bell manometers, in which the process-pressure force and weight of displaced liquid balance with spring loading and the weight of the bell housing, respectively.

The performance of a liquid-column manometer is influenced primarily by the density of the reservoir fluid. Range of use may be extended by using fluids of higher density, at the cost of resolution of the liquid-column displacement measurement. To improve resolution, the column may be inclined rather than vertical, such that a large horizontal component may be used to relate to the smaller vertical displacement of the fluid.

2.3 Elastic-Member Pressure Transducers

Elastic-member pressure transducers indicate pressure through elastic deformation of a transducer subjected to pressure-induced force. The resultant mechanical deformation may be used to measure pressure through mechanical amplification or may be converted into an electrical signal.

The C-Bourdon tube is a "C"- or horseshoe-shaped tube of elliptical cross section, sealed at one end, and open to process pressures at the other (Fig. 8). The pressure acting within the tube generates a uniform force distributed across the inner surface of the tube. Because of the longer length of and resultant additional force upon the convex outer tube wall, the internal pressure acts to straighten the entire assembly. A force balance results where the internal pressure forces equal the spring force of the elastically deformed C. A mechanical coupling to the closed end of the Bourdon tube may be used to indicate the internal process pressure. The nonlinearity of the system, resulting from the spring force of the C tube and its displacement, may also be addressed by implementing an additional force-balancing component onto the structure. Typically, a variable force member is coupled to the sealed end of the tube, restricting the motion of the C and reducing the nonlinear spring force of the system.

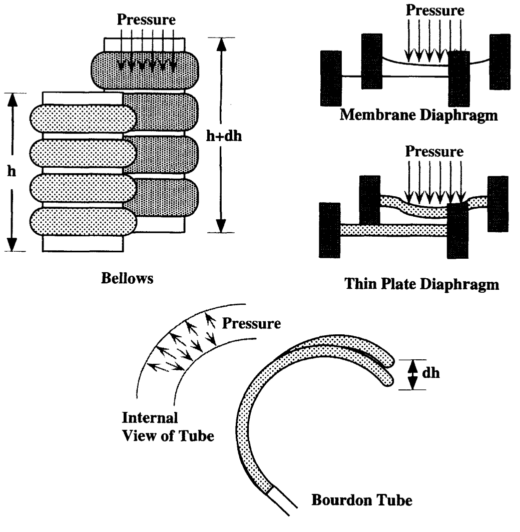

FIG. 8. Traditional pressure measurements rely on the elastic deformation of a mechanical member, such as a diaphragm, bellows, or Bourdon-tube element.

Other implementations of the Bourdon-tube technique include the spiral and helical Bourdon elements. The former is a series connection of many sequential C tubes, in a spiral configuration with only the final element sealed off; the latter is simply the helical analog. As a result of the longer internal surface area, these tubes are more sensitive and have higher resolution. They may thus be used for much lower process pressures.

Diaphragm sensors indicate pressure through elastic deformation of a diaphragm, which may be in the form of a thin membrane, a plate, or a capsule. The deflection y of the plate diaphragm is dependent upon the pressure P, the thickness of the plate t, the radial position r with respect to the radius a, and the Poisson's ratio ν and Young's modulus E of the material:

$$y = \frac{3}{16} P \frac{(1 - \nu^2)}{Et^3} (a^2 - r^2)^2. \tag{8}$$

The diaphragm sensor may be used in an absolute-pressure mode, where one side of the diaphragm is evacuated, or the sensor may be used to indicate the differential pressure between sides of the element. Sensor sensitivity is increased by increasing the area of the diaphragm, providing a larger surface area upon which the pressure may exert force, and through selection of materials. Nonlinear deformation characteristics may be minimized by careful shaping of the diaphragm element, including *corrugation* of the surface. A force-balancing technique may also be used to alleviate nonlinearity by restricting deformation of the diaphragm with an alternative balancing element, such as a force bar.

The bellows sensor also indicates pressure through elastic deformation of a closed vessel, behaving as a series of interconnected capsule diaphragm elements. The bellows chamber inflates under pressure, with design features that cause preferential deformation in the axial direction of the bellows. The length of axial deformation indicates pressure, or the chamber may be force-balanced with an additional mechanical member to reduce nonlinearity. Increasing the overall length of the bellows increases the sensitivity of the measurement.

2.4 Piezoresistive Transducers

Measurement of deformation of a diaphragm, or other elastic elements of a pressure-sensing system, is traditionally performed using piezoresistors, materials with bulk resistivity that is dependent upon applied mechanical stress (Bau *et al.*, 1994, pp. 146–172). The bulk resistivity, i.e., the number of charge carriers and the mobility of these carriers, within a piezoresistor is influenced by the extent of lattice strain. This strain may result from unbonded contact with a pressure element, such as a piezoresistive wire stretched between the diaphragm and a fixed wall of the sensor; or bonded, where an entire surface of the piezoresistive element experiences the pressure-induced mechanical stress. The latter case is often employed in silicon-based sensor technology, as silicon provides a strong substrate, with high Young's modulus, and piezoresistive properties dependent upon impurity dopant levels. The effects of temperature-dependent resistance changes, a common concern for all piezoresistive transducers, may also be mitigated in silicon by employing extremely small feature sizes, increasing transducer isothermality and facilitating temperature compensation. Also, the silicon dopant levels may be tailored to decrease overall temperature sensitivity.

2.5 Linear-Variable Differential-Transformer (LVDT) Transducers

LVDTs are commonly employed to measure the displacement of an elastically deflected pressure member. Used predominantly for linear displacement measurements, the LVDT indicates the displacement of a transformer core coupled to the deformed pressure element. The transformer features dual secondary windings that are connected in series but are wound to produce opposing voltages. Under null displacement conditions, when the core is centered within the transformer windings, a zero indication results. Repositioning of the core to either side of the null position, however, creates a voltage output that is linearly proportional to the displacement.

2.6 Capacitive Deformation Transducers

Displacement of an elastically deformed member may also be measured capacitively. A capacitive diaphragm assembly is the simplest of capacitive-type pressure members, where the diaphragm *itself* acts as one plate of either a dual- or a multiplate capacitor. Capacitance between the plates is dependent upon the deflection y, the distance between the plates, d, the plate cross-sectional area A, the permittivity of free space, ϵ_0, and the dielectric constant of the material between the plates, ϵ_r:

$$C = \epsilon_r \epsilon_0 A/(d - y). \qquad (9)$$

In multiplate capacitive diaphragms, the gap between plates may be filled with gas, for high diaphragm displacement and sensitivity. A solid or liquid dielectric material may also be used to minimize dielectric spatial variability and to allow higher rangeability of the measurement by providing stiffness to the deformable member.

2.7 Piezoelectric Transducers

Piezoelectrics are materials that mechanically deform when subjected to voltage and, conversely, generate a surface charge differential when subjected to stress through electrical polarization. The piezoelectric effect is dependent upon lattice geometry, and the orientation of applied stress. For pressure sensing, the transverse piezoelectric effect, in which voltage is generated in a direction transverse to the strain, is generally used. The magnitude of voltage response U of a strained, $\Delta l/l$, piezoelectric is governed by the transverse piezoelectric modulus d, the mechanical modulus along the axis of deformation s^E (for a constant electric field E), the transverse thickness t, and the transverse permittivity of the material ϵ^T (for a constant stress, T). Bau *et al.* (1994, pp. 616–619) give a more detailed description of piezoelectric voltage generation:

$$U = \frac{d}{d^2 - s^E \epsilon^T} t \frac{\Delta l}{l} . \qquad (10)$$

Piezoelectrics typically feature high-frequency response and are often selected for dynamic pressure measurement and generation. On account of their high-frequency response, environmental vibration isolation or compensation of the piezo crystal may be necessary for improved signal-to-noise ratio. Temperature compensation is also often required, because of temperature sensitivity of the piezoelectric materials. As the piezoeffect is dependent on crystal geometry and the orientation of loading, crystal geometry can often be tailored to decrease temperature sensitivity of the mechanical system.

2.8 Optical Deformation Measurement

A variety of optical techniques may be applied for the measurement of elastic member deformation. Both Udd (1991) and Krohn (1992) provide extensive material on optical implementation of pressure measurements. Optical reflectance may be used to measure the deformation of a reflective diaphragm using a fixed-position source and detector. In this system, pressure deforms the diaphragm altering the amount of reflected light coupled back to the detector. The variation in reflected light intensity at the detector is used to indicate pressure.

Various types of optical interferometers may also be employed to measure the displacement of an elastic member. These techniques rely upon the linear superposition of electromagnetic waves, typically coherent light, experienced when the incident wave form interacts with reflected wave fronts from a surface. A Fabry-Pérot etalon is a planar reflective interferometric device conducive to micromachined construction of pressure elements. The etalon is comprised of two planar, parallel reflectors with transmission and reflectivity dependent upon the wavelength of incident radiation and the separation of the mirror surfaces. Elastic deformation of one, or both, surface due to pressure will alter the mirror separation, changing the transmission of the overall cavity. A change in reflected, or transmitted, intensity may thus be used to provide a measurement of pressure.

2.9 Resonance Pressure Transducers

In contrast to the aforementioned deflection-based measurement techniques, resonance transducers measure pressure by observing the pressure-dependent resonant frequency of a vibrating mechanical member. The pressure dependence of these structures, which may be micromachined cantilevers or conventionally scaled elements such as Bourdon tubes, may be evaluated by viewing the structure as a spring-mass-damper system. The effect of each of these components upon the pressure-dependent resonance differs depending on the measurement conditions. Under near-ambient pressure conditions within a gaseous environment, the pressure dependence of the resonant element is dominated by the *mass* component of this system. Oscillatory motion of the resonant structure will carry with it a small, additional mass of surrounding air in consequence of the no-slip condition resultant from fluid viscosity (see Sec. 3.2). Over a limited range and provided the amount of additional mass is much less than the mass of the resonant structure, the resonant frequency will be linearly proportional to the pressure of the system, through the resultant fluid density (Bau *et al.*, 1994, p. 223). Under vacuum conditions, the gaseous environment becomes rarefied, resulting in a longer mean free path for fluid molecular motion. Within this regime, resonant frequency is dominated by pressure dependence upon molecular momentum transfer. Collisions with the resonant element are governed by the Maxwell–Boltzmann velocity distribution, resulting in a linear dependence upon pressure (Bau *et al.*, 1994, p. 224). Under high pressures, and within liquid media, fluid viscosity dominates the pressure dependence of resonant elements, altering system response through its *damping* component. Regardless of the pressure-dependence mechanism of a resonant structure, temperature will also have a considerable impact on the structure's resonant frequency. Temperature dependence is dominated by materials issues, i.e., modulus of elasticity, resulting in changes in the spring component of the system.

2.10 Hall-Effect Transducers

The Hall effect describes the generation of an electric field, $\mathbf{E} = \mathbf{j} \times \mathbf{B}$, across a conductor due to the drift velocity imparted to the electrons of a current **j** by a magnetic field **B** (Kittel, 1986). The magnitude of the electric field is dependent upon the magnitude of the current and magnetic field, and the Hall sensitivity of the material. The Hall sensitivity is dependent upon the charge mobility and resistivity of a material and has been studied for several group III–V semiconductors, in particular, gallium arsenide. As these latter properties are determined by lattice structure, Hall sensitivity is dependent upon pressure. The sensitivity of gallium arsenide has been shown to feature highly linear dependence upon pressure from ambient to approximately 70 MPa (Selim, 1995).

2.11 High-Pressure Ruby and Alexandrite Fluorescence

Extremely high-pressure measurement, >1 MPa, or measurements within harsh chemical environments cannot be performed using traditional elastic-member deformation techniques, because of materials limitations under the extreme conditions. The pressure-dependent fluorescence of some refractory phosphor materials, such as ruby and alexandrite, may be used to measure these intense pressures under extreme conditions. Short-wavelength (ultraviolet to visible) photons will cause these materials to fluoresce. The Stokes form of Raman scattering will cause photon emission at a longer wavelength. For example, ruby, when excited with green or blue light, will downshift the frequency and emit red light. Both the wavelength and persistence, or lifetime, of the fluorescent emission are strongly pressure and temperature dependent, as a result of altering transition probabilities within the crystal lattice. Over a fairly wide range (1 MPa–43 GPa), the lifetime and wavelength shift of the emission are both linearly dependent upon pressure (Grattan and Zhang, 1995). Compensation for temperature variation may be performed by simultaneously measuring fluorescence lifetime, which is highly temperature dependent (Hirschfeld and Haugen, 1988).

2.12 Low-Pressure Thermal-Conductivity Gauge

Below approximately 10^{-4} mm mercury, or Torr, direct indication of pressure through the mechanical deformation of an elastic member is not practical (O'Hanlon, 1989). Rarefaction of the fluid medium, and the resultant increase in mean-free-path length, decreases the occurrence of molecular collisions necessary for diaphragm deflection. This same decrease in collisions, however, may be employed for pressure detection by observing the resultant decrease in thermal conductivity of the fluid medium. Provided the mean free path is sufficiently large, such that the actual geometry of a device is much less than the mean free path, the loss of thermal energy from a heated wire within a rarefied volume will be strongly dependent upon the pressure (Fig. 9). This dependence results from the increased probability of

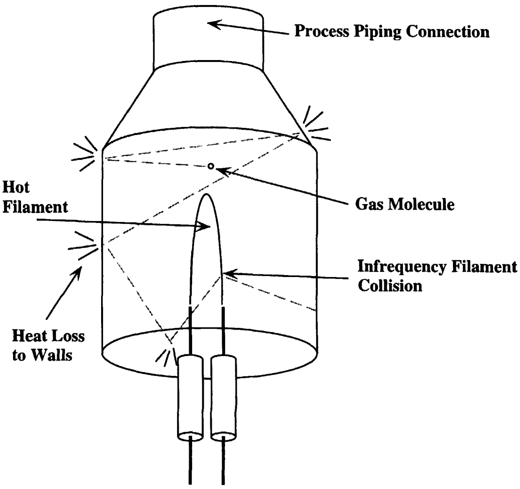

FIG. 9. Thermal conductivity vacuum gauges measure thermal losses from a heated filament caused by infrequent collisions of molecules within the rarefied atmosphere. Provided the mean free path of molecular motion is much greater than gauge dimensions, molecules achieve isothermality with wall boundaries, and the heat transfer is primarily dependent upon molecular density, and thus pressure.

molecules, acting as thermal carriers, interacting with volume boundaries as opposed to the heated wire. As the mean free path increases, fewer molecules will interact with the wire. Those that do will have a high probability of being at the boundary temperature, as the majority of collisions are with the solid boundary. Lower pressure limits exist with thermal-conductivity techniques because of radiative heat losses from the wire, and conductive losses through the wire and wire supports.

2.13 Low-Pressure Ionization Gauge

Lower vacuum pressure measurement may be performed by ionization gauges, which ionize gas molecules through electron impact and measure the particle density of the generated ionic current. Provided temperature remains constant within the fixed volume of the ion gauge, particle density is proportional to pressure through the ideal-gas law. Traditionally, ion gauges are classified as either hot- or cold-cathode. The former depends on thermionic emission of electrons from a hot filament that are accelerated by an electric potential to a velocity sufficient to ionize any gas molecules within their path. This collision produces positive ions, which are preferentially collected by a negatively biased electrode, allowing the evaluation of positive-ion density. The electrons are captured on the acceleration-inducing, positively charged grid. Below 10^{-6} Torr, electron collision with this grid generates x rays, which create a photocurrent that is also collected upon the negatively biased ion collector, resulting in aberrant readings (O'Hanlon, 1989). The Bayard–Alpert gauge (Fig. 10) addresses this problem by protecting a fine-wired positive-ion collector within the electron charge collector. The minimized cross-sectional area limits interaction of the positive-ion collector with emitted x rays from the electron-collection grid, and allows operation to 10^{-8} Torr.

The cold cathode employs a grounded cathode and a wire anode at a high bias voltage (thousands of volts). A permanent magnet of 0.1 to 0.2 T surrounds the sensor tube. The interaction of the magnetic fields with the electron current within the tube causes the electrons to follow an increased-path-length, spiral trajectory before colliding with the anode. The increased path length increases the probability of molecular impact during flight and enhances the ionization efficiency of the gauge.

3. GENERAL CONCEPTS OF FLOW AND FLOW INSTRUMENTATION

3.1 Nature of Flow and the Conservation Laws

Fluid flow processes are most commonly described using laws of conservation of mass and energy, wherein the total mass and energy within a closed system must remain constant. Within this light, fluid systems are easy to visualize, as they are typically well-bounded control volumes, with discrete input and output features, i.e., closed systems such as pipes and ducts, or bounded systems such as weirs and flumes. Mathematically, the conservation of mass, or the *continuity statement* as applied to fluid flow, may be expressed as

$$-\frac{\partial\rho}{\partial t} = \frac{\partial}{\partial x}(\rho v_x) + \frac{\partial}{\partial y}(\rho v_y) + \frac{\partial}{\partial z}(\rho v_z), \qquad (11)$$

where the rate of accumulation of mass in a system, or the change in density (ρ) with respect to time, must equal the total mass flux into the system, represented here in rectangular coordinate components as the partial differential of the product of the density and respective components of velocity **v**. For steady-state conditions, where the rate of mass accumulation into the system is zero, the continuity statement simplifies further to state that the mass flow into the system must equal the mass flow out. Many velocimetric styles of flowmeters apply this principle to derive total volumetric flow rate $\dot{m}/\rho$ by measuring velocity v through a known cross-sectional area A, where

$$\dot{m}_{\text{in}} = \dot{m}_{\text{out}} = \rho A v = \text{const.} \qquad (12)$$

Conservation of energy applies the same principles to total energy of the system, which is expressed in several *mechanical* forms for flow problems; kinetic, potential, and static energy. Kinetic energy is the energy due to velocity of the mass in the system. Potential energy is the energy of the mass in the system capable of performing work against gravity. Static energy is the energy capable of performing work against a pressure gradient. In the 18th century, Bernoulli expressed the law of conservation of energy with respect to these three terms respectively as

$$\bar{v}^2/2g + z + P/\rho = \text{const.}, \qquad (13)$$

where kinetic energy is represented as average flow velocity $\bar{v}$, potential energy as the height z of fluid above a reference plane acted upon by gravity g, and the static energy as the static pressure P of the system. The principles of Bernoulli's law have been applied to create a wide array of flowmeter styles, including orifice plates, venturis, pitot tubes, and both variable-area rotameters and spring-loaded apertures.

Bernoulli's formulation of the law of conservation of energy applies only to closed systems that perform no work. In reality, no flow system operates without consuming some energy through work, typically in the form of frictionally generated heat. The amount of energy lost can range from major, as from frictional losses with solid boundaries, or minor, as from losses created by acceleration of the flow in fittings, contractions, etc.

Many monographs exist on fluid transport and flow properties. The interested reader is directed to Bird *et al.* (1960), Crane (1976), or Fox and McDonald (1978) for more in-depth coverage.

3.2 Fluid Properties

Flow situations are classified predominantly by the physical properties associated with the flowing fluid. Of these, density and viscosity are the two most influential. Flows in which density variations may be assumed negligible are termed *incompressible* and include most liquid flows and slurries. Gas and vapor flows, however, are considered *compressible*, and density variations play a significant role in fluid behavior. An important result of fluid density, in both cases, is that the density of a moving fluid creates an inertial force, due to the momentum imparted by moving particles, which may be employed to indicate fluid flow.

Viscosity (μ) represents the amount of shear force imparted to a fluid due to a velocity gradient within a flow stream, with units of mass/(length × time). For most fluid systems, viscosity gives rise to the "no-slip" condition, which indicates that a fluid in contact with a solid boundary will have a velocity equal to that of the boundary. A velocity gradient within the flow stream is formed dependent on distance from that solid boundary. This spatial variation in fluid velocity is termed the *flow profile.*

A useful classification of flow systems arises from a comparison of density-dependent fluid inertial forces to viscosity-dependent viscous forces. This relationship is indicated through a dimensionless parameter, the Reynolds number, in terms of a characteristic dimension L of the flow, such as a pipe diameter or duct width:

$$\text{Re} = \rho v L/\mu. \qquad (14)$$

Evaluation of the Reynolds number allows any fluid system to be categorized according to the ratio of these forces. Although no definite values exist because of variability of systems, flows with Reynolds number of less than ~2000 are dominated by viscous forces and are termed *laminar,* indicating that mixing across fluid layers parallel to the direction of flow is insignificant. For Reynolds numbers above ~4000, flow is considered turbulent, with significant inertial forces of molecular collisions causing mixing between adjacent fluid layers superimposed upon the mean motion of flow.

3.3 Fully Developed Flow

Many measurement systems infer a bulk fluid condition from a measurement of a small, localized portion of the flow. Development of the flow profile is an important condition that must be accounted for in these flowmetering systems. By reason of both inertial and viscous effects, a flow profile does not immediately change when boundary conditions along the flow path change. Flow-path irregularities, curves, restrictions, expansions, etc., will cause velocity profile changes within flow streams, but the momentum and viscosity of the flow will cause those changes to be propagated at different rates through the flow field. *Fully developed flow* describes flow fields for which the velocity profile no longer changes as the flow moves downstream. For most engineering flow conditions, 10–20 pipe diameters of straight, uniform flow path are required prior to a flow measurement to insure that flow has fully developed (ASME, 1988).

3.4 Flowmeter Classifications

Flowmeters may be classified by the general method in which flow information is extracted from the fluid system. They may be *inferential,* in which a physically measurable parameter of the flow stream other than flow or velocity is used to indicate the flow rate. Velocity may also be *directly* measured. Alternatively, *energy additive* flowmeters inject additional energy into the flow stream to create a useful, measurable parameter.

Inferential flowmeters are, by far, the most widely used form of flowmeter. Common types of this flowmeter include the orifice plate, venturi, sonic nozzle, and pitot/pitot-static tube, which all infer flow rate from a differential pressure measurement imparted by an *inertial* change in flow velocity. Laminar flow elements also measure flow velocity from an inferential, *frictionally* generated differential pressure basis. The variable-area flowmeters, including the rotameter and spring-loaded variable aperture, as well as the drag-body or target flowmeter, vortex-shedding flowmeter, and fluidic or Coanda flowmeter also use an inferential basis to measure flow.

Direct-measurement flowmeters include the positive-displacement flowmeter and the turbine, or paddle, flowmeter, which directly measure volumetric flow rate and velocity, respectively.

Energy-additive flowmeters include the magnetic flowmeters, thermal mass flowmeters, tracer-dilution methods, and Coriolis, ultrasonic, and nuclear-magnetic-resonance flowmeters. Each of these devices imparts additional energy into the system—thermal, acoustic, electric, etc.—and monitors the effects of the flow upon that energy.

3.5 Inferential Flowmeters

3.5.1 Differential Pressure Flowmeters

The most widely applied style of flowmeter within industry is the differential pressure flowmeter, which applies Bernoulli's principle by creating a measurable pressure change within a flow system through variation of flow kinetic energy. Many varieties of the differential pressure, or DP, flowmeter exist, most of which create a localized pressure change in the flow by restricting the flow path (see Fig. 11). Conservation of mass entails that, with the cross-sectional area of the flow restricted, the flow velocity through the restricted area will increase. For incompressible flows, this velocity increase may be expressed by a rearrangement of the continuity equation,

$$v_{\text{restriction}} = A_{\text{flow}} v_{\text{flow}} / A_{\text{resriction}}. \tag{15}$$

For compressible flows, the local variation in fluid density imparted by the restriction complicates the situation; however, the overall end result is still a localized kinetic energy increase. Provided no elevation changes occur within the flow path, Bernoulli's principle requires that the overall system energy must remain constant, resulting in a concurrent decrease in static energy. The static-energy decrease is expressed as a localized drop in pressure across the restriction. The

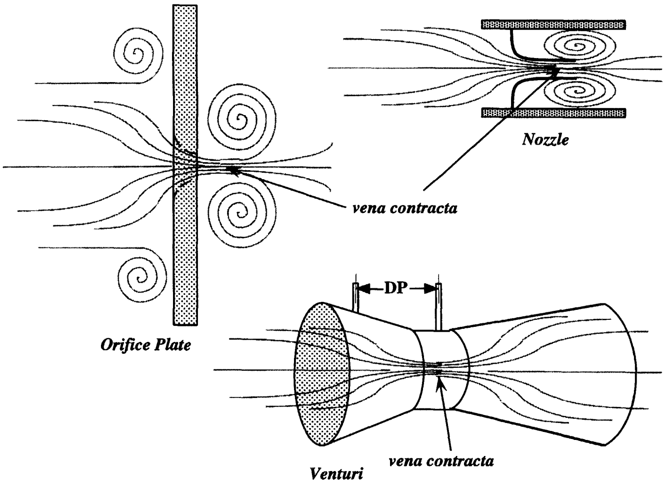

FIG. 11. Differential-pressure flowmeters restrict the flow path, causing a localized increase in velocity, and a concurrent decrease in static pressure of the system. A square-root relationship between pressure drop and flow velocity results.

magnitude of the pressure drop is often a convenient parameter to measure and may be used to infer the velocity of the fluid, and thus the flow rate.

3.5.2 The Orifice Plate The most common DP flowmeter in use today is the orifice plate, which exemplifies the simplicity of differential-pressure flow measurement. The orifice plate is typically a flat metal plate that is inserted perpendicular to a flow stream. It is simple to install and maintain, and may be interchanged for different flow situations by inserting an orifice plate with a differently sized opening.

The relationship of volumetric flow rate Q to pressure drop across the orifice is typically presented as

$$Q = CA\sqrt{\Delta P/\rho}, \tag{16}$$

which is merely an algebraic rearrangement of Bernoulli's principle. The coefficient C is conventionally termed the discharge coefficient and accounts for *permanent* energy losses caused by the restriction. Often the discharge coefficient is represented as two separate factors: C_c, the contraction coefficient, and C_v, the velocity coefficient. The contraction coefficient arises from incomplete development of the flow within the short confines of the sharp-edged orifice. Rather, the actual location of maximum flow contraction, or *vena contracta,* occurs downstream from the orifice. This further contraction reduces the virtual cross-sectional area of the flowmeter, necessitating the use of a contraction correction. The velocity coefficient reflects nonideal, reduced velocity conditions within the *vena contracta* due to frictional energy losses. As both of these loss mechanisms are density and viscosity dependent, the overall discharge coefficient is functionally dependent upon the Reynolds number of the flow, allowing the orifice plate to be conveniently implemented on a variety of fluids and flow conditions. Typical orifice styles, with sharp edges and resultant abrupt changes in cross-sectional area, provide more predictable discharge coefficients at higher Reynolds numbers as a result of a more randomized distribution of nonaxial velocities. Orifice design may vary to improve this predictability for lower Reynolds number flows, with smooth-contoured orifices allowing good results at Reynolds numbers as low as 250 (Spitzer, 1991). Other orifice design modifications, such as nonconcentric orientation of the flow opening, may be implemented to allow better performance in slurries, dirty gases, and two-phase flow scenarios. Design modifications, such as rounding of orifice edges, may also be employed to decrease the permanent pressure loss, caused by intermolecular frictional losses of nonaxial fluid collisions within the restriction and by eddy formation upstream and downstream of the insertion. On account of these factors, permanent pressure loss is significant in orifice plates.

Actual flow measurement is performed by a differential pressure sensor across the orifice. Placement of pressure taps is important, as the velocity profile, and concurrent pressure change, form gradually as the flow profile develops. Caution is also necessary to insure symmetry of the flow in the direction of flow, as singular pressure taps require flow symmetry to reflect bulk flow conditions correctly.

3.5.3 The Venturi and Nozzle The variation of orifice discharge coefficient with lower Reynolds number, and the tendency of the orifice plates to become fouled by eddy-deposited accumulation, promotes the use of the venturi and the flow nozzle as more accurate and reliable DP producers. A venturi is a flow restriction device designed such that the solid boundary of the restriction better matches the actual flow profile. Venturis feature longer, smooth-curved restrictions, with a pressure tap located at the position of maximum contraction, or throat, of the device. By shaping the solid boundary in the profile of the actual flow stream, the throat of the device and the *vena contracta* of the flow coincide, effectively reducing the contraction coefficient C_c to zero. The end result is that the venturi is much more predictable and repeatable than the orifice plate for widely ranging flow conditions. Further, the smooth flow profile of the device minimizes frictional abrasion and the accumulation of deposits within the meter, increasing reliability. The reduction of frictional losses also promotes improved pressure recovery in the flow stream.

Flow nozzles feature a smooth entrance, lengthened similar to a venturi, and a sharp exit, characteristic of an orifice plate. The frictional losses of the sudden radial expansion at the exit cause high permanent pressure losses, as with the orifice, but the entry pressure loss is typically lower than in a similar-sized orifice, because of the smooth entrance. Thus, the overall unrecoverable pressure drop across the entire system is lower than with an orifice plate.

For higher accuracy and repeatability, venturi meters and nozzle flowmeters may employ multiple pressure taps axisymmetrically through the solid boundary. The multiple taps are channeled to the individual upstream and downstream ports of the differential pressure device, and effectively integrate these individual pressure conditions. Asymmetric variations are thus averaged out and bulk flow conditions are better inferred.

3.5.4 The Pitot and Pitot-Static Tube The pitot and pitot-static flowmeters infer fluid velocity by generating a highly localized velocity stagnation pressure at the tip of a tube placed normal to a flow stream. Per Bernoulli's principle, all kinetic energy at this impact point is converted to static energy, in the form of a pressure increase. A pressure tap in communication with the impact port will indicate total system pressure, including the prevailing pressure of the moving fluid, in addition to the pressure created by velocity stagnation. By a subsequent measurement of the prevailing pressure, the velocity stagnation pressure may be isolated to indicate velocity of the flow. In a pitot-static tube, an annular pressure port is provided within the pitot tube assembly for measurement of the static pressure component of the total system pressure. If this provision is not available, as in a pure pitot tube, an additional pressure port must be provided to determine the static pressure within the system.

Because of the highly localized nature of a stagnation velocity measurement, the pitot and pitot-static tube flowmeters are commonly used to map flow profiles. By positioning the measurement point of the pitot tube at various insertion depths into the flow stream, localized fluid velocities may be determined and an accurate flow profile may be obtained. Considerable care must be taken, however, to insure proper positioning of the pitot assembly within the flow, as slight misalignment of the tube within the flow may cause significant measurement error due to incomplete stagnation of flow at the impact port. To reduce this error mechanism, pitot tube assemblies often employ symmetrical pressure ports along the measurement tube. These ports are connected to differential pressure indicators to indicate unbalanced velocity distribution between the ports, indicative of misalignment of the probe with respect to the flow.

3.5.5 The Laminar Flow Element The previous DP-producing flowmeters all apply Bernoulli's principle to create a measurable static pressure change in the flow, dependent upon changing fluid velocities, while intentionally minimizing frictional energy losses of the system. In conventional terms of fluid dynamics, these devices have harnessed measurability from the *minor* energy losses of flow systems attributable to pressure changes due to sudden expansions and contractions of the flow stream, while minimizing *major* energy losses attributable to frictional losses with the solid boundary. Bernoulli's principle indicates that velocity and flow-rate measurements from this basis will always be governed by a "square-root" relationship with the pressure drop across the measurement system. In contrast to this, the laminar flow element is considered a linear device.

The laminar flow element is a DP-producing flowmeter that is typically composed of many small-diameter flow paths bundled into a single assembly that is inserted into a flow path. The purpose of the multiple small-diameter flow paths is to force the flow into the laminar regime by reduction of the radial path length of turbulent, i.e., nonaxial, flow. Laminar pipe flow subscribes to a linear velocity/pressure-drop relationship, as formulated for internal pipe flow by Hagen and Poiseuille:

$$\nu = (\Delta P)\pi r^2/8\mu L, \qquad (17)$$

where the differential pressure drop is caused by frictional energy losses of shearing fluid layers along a pipe of length L and radius r. Although predominated by linear viscous losses, some inertial losses will be generated at the entrance and exit of a laminar flow element, where the flow stream is accelerated into and out of the laminarizing restrictions of the assembly. These losses will cause the laminar flow element to operate with some nonlinearity, due to the square-root relationship of pressure drop with these unavoidable velocity changes. For very low–Reynolds-number flows (i.e., <200), either density or velocity is sufficiently low that the inertial effects are minor and can usually be neglected.

3.6 Variable-Area Flowmeters

The variable-area flowmeters operate on the same principles as differential pressure flowmeters, but they employ a changing cross-sectional flow area, as opposed to a pressure measurement, to indicate flow rate. The two most common variable-area flowmeters are the rotameter and the spring-loaded variable aperture, although many variations exist on the common themes of these two styles.

3.6.1 The Rotameter The rotameter is most traditionally employed as a demarcated, tapered glass tube, containing an indicating float that is free to move vertically within the tube in response to the rate of fluid flow moving vertically through the assembly (see Fig. 12). The tapering of the tube and the fixed diameter of the float provide for a variable annular cross-sectional area for the flow, dependent upon the position of the float within the tube. The variable area, in turn, allows for a variable velocity and resultant pressure drop across the float as dictated by conservation of mass and Bernoulli's principle. The indication of flow rate thus results from the vertical positioning of the float, which occurs where all forces upon the float, including gravity, buoyancy, viscous drag, and differential pressure, become balanced. A mechanical free-body diagram assists in visualizing the required force balance.

The weight of the float is fixed and dependent upon the float material selected. The buoyancy force is caused by the displacement of fluid by the suspended float and is usually a relatively minor force component as typical float materials are very dense, i.e., stainless steel or sapphire. The viscous force upon the float is attributable to the average shear on the surface of the float and is thus dependent upon the velocity of flow past the float, viscosity of the flow, and float geometry. A large proportion of rotameter floats are spherical balls, for which viscous drag may be evaluated using Stokes's drag relationships (Bird *et al.*, 1960). To increase application of rotameters through a range of fluids, float geometry is often tailored to reduce these viscous drag forces. These float models feature very sharp downstream flow edges that serve as sharp-edged orifices, minimizing frictional viscous losses while creating significant inertial forces as velocity increases through the resulting annular orifice.

3.6.2 The Spring-Loaded Variable-Aperture Flowmeter The spring-loaded variable-aperture flowmeter operates on the same principles as the rotameter, with fluid

forces opposing a spring force in addition to the weight of a vertically oriented float. A plunger restricts fluid flow through a sharp-edged orifice, creating an inertially driven pressure differential across the plunger. This pressure differential exerts a force upon the plunger, which is opposed by a spring force dependent upon the position of the plunger. The balance of forces upon the assembly results in steady-state positioning of the plunger, resulting in a pressure drop linearly proportional to the flow rate. Horizontal orientation removes the effects of weight and buoyancy on the plunger. System behavior is thus dominated by the opposition of inertial forces with spring forces, with the latter increasing rangeability of the device over other DP producers.

3.6.3 The Drag-Body or "Target" Flowmeter In the event that fluid properties restrict either the use of moving parts, as in the variable-area flowmeters, or the presence of pressure taps for differential-pressure flowmeters, the drag-body or "target" flowmeter may provide an acceptable alternative (see Fig. 13). The drag body operates on the same principles of inertially driven differential pressure forces and viscous drag forces

Flow

FIG. 13. Target, or drag-body, flowmeters indicate flow through the inertial and viscous displacement or straining of a cantilevered element placed into the flowstream.

but employs a mechanically constrained target to provide measurement of fluid flow. This target acts as the traditional flow obstruction, restricting flow cross-sectional area and causing localized velocity increases. These increases cause the Bernoulli-explained differential-pressure drivers, which exert force upon the target. Additionally, fluid flow around the target exerts viscous drag forces. These forces upon the constrained target may be measured using strain measurements, or the relatively small changes in target position with response to the flow forces may be mechanically amplified for direct, mechanical indication of the flow. Rangeability of the device may be altered by simply changing the size or shape of the target element.

3.6.4 The Vortex-Shedding Flowmeter

The vortex-shedding flowmeter, or bluff-body flowmeter (Fig. 14), is another device that may be used when flow conditions prohibit pressure taps or moving parts. If a bluff body, or strut, is placed perpendicular to a flow stream, the localized velocity distortion around the bluff body will cause an unstable wake behind the obstruction. Eddy currents will be created that grow into vortices and are shed from each side of the bluff body in a repeatable, oscillatory nature. Opposite rotation direction will result for eddies from opposing sides of the bluff body by reason of the "no-slip" interface on each side with the solid boundary. Oscillation occurs because of the localized pressure increase of swirling eddy separation from the body. The frequency of oscillation f is linearly dependent of the velocity of the flow stream and the characteristic diameter d of the bluff body:

$$f = St\, v/d. \tag{18}$$

The Strouhal number St is a dimensionless constant of proportionality for this frequency–velocity relationship and is dependent on the Reynolds number of the flow with respect to the characteristic diameter of the strut. Over a wide range of Reynolds numbers (with respect to bluff-body dimensions) within the turbulent regime, the Strouhal number is essentially constant. Below this, the Strouhal number decreases with decreasing Reynolds number. Within the low laminar regime, vortex formation does not occur as viscous forces tend to reduce eddy formation, and pressure fluctuations around the bluff body are not sufficient to toggle the eddy wake. The specific Reynolds-number cutoffs are highly dependent upon bluff-body geometry (Spitzer, 1991, p. 298). However, above this cutoff value, the vortex-shedding flowmeter can be widely applied to a large range of flow conditions, including steam, clean liquids, and gas.

By measuring the frequency of oscillatory vortex generation, an indication of flow rate may be obtained. Many different methods are available for vortex detection. A widely applied method is to measure the strain induced upon a cantilevered strut, which acts like the previously discussed drag element of a target flowmeter. The shedded vortices create oscillatory drag upon the strut, which may be measured as strain in the strut's cantilevered suspension. Piezoelectric elements may also be employed to generate voltage potential due to the oscillatory strain of the strut. The vortices may also be counted downstream of the strut by various ultrasonic methods. Vortices shed from opposing sides of the bluff body will have opposite rotational spins. Vortex counting may make use of this by timing the transversal speed of an acoustic pulse. During the first half of a clockwise spinning vortex and last half of a counterclockwise vortex, transversal speed will be increased through the summation of mean sound velocity and the vortex angular velocity. During the latter half of a clock-

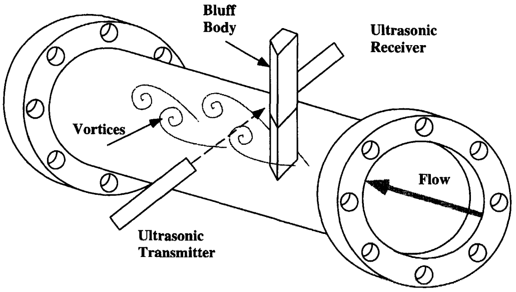

FIG. 14. A bluff body, obstructing fluid flow, will create a bistable wake of vortices at a frequency linearly proportional to flow velocity. This vortex flowmeter counts shed vortices by measuring the propagation rate of an ultrasonic signal across the flowstream. Clockwise spinning vortices shed from one side of the bluff body will increase signal velocity, counterclockwise vortices will decrease signal velocity.

wise, and front half of a counter-clockwise spinning vortex, transversal speed will be decreased by the negative effect of the vortex angular velocity. Thus, the opposing vortices may be counted by differentiating between the transversal time of the acoustic pulse. Another counting method is to rely on the acoustic focusing and defocusing effects of the fluid angular velocity upon a cross-stream transducer/receiver pair.

3.6.5 The Coanda, or Fluidic, Flowmeter The Coanda flowmeter operates on the same principles as the vortex-shedding flowmeter, by monitoring the same oscillatory nature of a bistable fluidic *jet,* as opposed to the vortex *wake.* In the near presence of a solid boundary, a fluid jet will attach itself to the solid boundary according to no-slip principles, and the associated effects of boundary-layer fluid velocity. A Coanda flowmeter applies this phenomena by allowing two separate fluid/boundary jet paths, with fluidic feedback from each path to toggle the flow from one path to the other. Under similar Reynolds-number limitations as a vortex meter, the toggling frequency of the bistable jet path is linearly related to the fluid velocity through the Strouhal number.

The frequency of fluid jet toggling may be measured in a variety of ways. The pressure within a single fluid path may be monitored, or optical methods may also be employed if the fluid is optically dense. Another technique is to employ a self-heating temperature element, which is cooled by the flow during the presence of the jet through one path, and reheats when the flow is in the other path.

3.7 Direct-Measurement Flowmeters

3.7.1 The Positive-Displacement Flowmeter Positive-displacement techniques split the flow into known-volume collection chambers, which are counted, or *totalized,* to indicate flow. The oldest form of this style of meter is the reciprocating piston, in which two separate piston chambers are alternately filled with fluid. The reciprocating motion of the displaced pistons may be mechanically counted, or end-position switches may be employed to count fill cycles of the chambers. Other chamber configurations may employ a rotary vane of equally sized volumes, sets of rotating lobes, or a nutating disk. Each method requires a means of counting chamber fill cycles to totalize the flow. Counting methods may be as simple as a mechanical counter, or may employ optical or electrical proximity techniques, most commonly in the form of a variable-reluctance, i.e., magnetic, pick-up. The latter are often used to totalize rotary vane passes, or end-positioning of linear pistons.

3.7.2 The Turbine Flowmeter The turbine flowmeter is very similar to a rotary-vane positive-displacement flowmeter, but does not require known-volume collection chambers. Rather, vanes of a turbine placed perpendicular to the flow stream will be forced to turn with an angular velocity that is linearly proportional to the flow velocity of the stream. Like the positive-displacement flowmeter, vane rotation may be counted using a variable-reluctance pick-up or other proximity-style detection methods, with the resultant frequency indicative of flow. Above a specific flow rate, at which frictional losses of the turbine system become negligible, turbine meters perform with a very stable frequency-to-flow-rate relationship.

3.8 Energy-Additive Flowmeters

3.8.1 The Magnetic Flowmeter For electrically conductive fluids, Faraday's law of induction may be used to measure volumetric flow rate magnetically (see Fig. 15) (Spitzer, 1991). Faraday determined that a changing magnetic field could induce a voltage proportional to the time rate of change of the current that produced the magnetic field. Applied analogously to flow, the relative average motion $\bar{v}$ of an electrically conductive fluid flowing perpendicular through a magnetic field of density B over a path length L will generate a voltage E proportional to the volumetric flow rate by a constant c:

$$E = cBL\bar{v}. \tag{19}$$

The generated voltage is influenced by the total cross-sectional area of the flow experiencing the magnetic field, and the measurement is thus independent of velocity profile of the flow and the parameters involved with

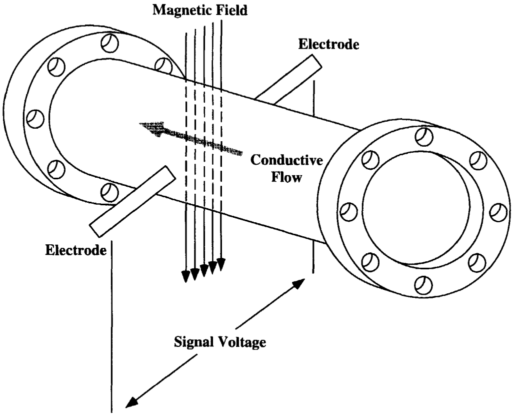

FIG. 15. For conductive fluids, magnetic flowmeters apply Faraday's law, indicating flow through the generation of an electric potential at right angles to a magnetic flux perpendicular to the direction of flow.

this profile, i.e., density and viscosity. The magnetic flowmeter thus provides a measurement independent of Reynolds number of the flow, and of typical flow-measurement restraints such as straight pipe lengths upstream of the measurement area. Further, this flowmeter is inherently nonintrusive, as the magnetic field and subsequent voltage measurement can be generated and sensed external to the flow system. Magnetic flowmeters therefore feature small pressure losses, limited only by "straight path" frictional losses of the piping system.

3.8.2 The Thermal Mass Flowmeter and Hot-Wire Anemometer Another flow technique that may be used noninvasively is the thermal mass flowmeter. Used extensively in semiconductor manufacturing, these flowmeters indicate mass flow rate by observing the effects of heat energy added to the flow stream as governed by the equation of heat transfer (Tison, 1996),

$$Q = \dot{m}C_p\Delta T. \tag{20}$$

A typical application of this technique is to wrap a thin-walled, thermally conductive flow path with heating elements, which serve in dual capacity as temperature sensors. Under no-flow conditions, the thermal profile of the fluid between these heaters will achieve a steady-state symmetric profile as depicted in Fig. 16. Under flowing conditions, however, this thermal profile will become skewed, as heat is carried downstream with the flow. Under laminar flow conditions, this skewing is linearly related to flow rate, and the temperature difference between the heating elements may be used to indicate mass flow rate, dependent primarily upon the heat capacity of the fluid. To maintain laminar flow, the measurement flow path is typically a small capillary tube capable of handling only low flow rates (~cubic centimeters per minute). For higher flows, an appropriately sized laminar bypass flow path may be used in parallel to the sensing flow path to increase rangeability of the device. Provided both paths remain laminar, and minimum minor pressure losses occur between them, the flow splitting between the paths will remain constant, and the sensor flow indication will be

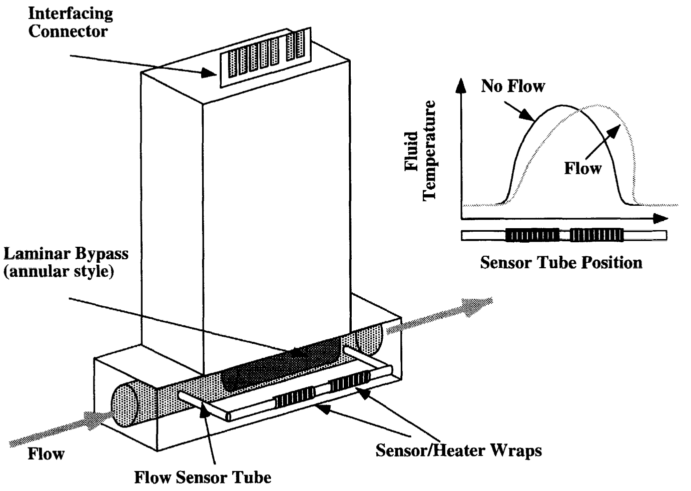

FIG. 16. The thermal mass flowmeter measures flow by detecting the skewing of a thermal profile due to convective transport by the flow stream. This configuration uses a pair of dual-capacity heaters/sensors to heat and measure the average upstream and downstream fluid temperatures. A bypass is used to increase rangeability of the flow.

linearly proportional to total flow of the system.

Localized, as opposed to bulk-fluid, mass flow rate may be obtained using a hot-wire anemometer. This flowmeter employs the same principles as the thermal mass flowmeter by typically measuring the heat loss from a heated wire maintained at constant temperature, and the temperature of the flow stream with an unheated wire. The heated wire, serving in dual capacity as a thermometric element, will lose an amount of the heat to the flow depending upon the Reynolds number and heat-transfer characteristics of the fluid, and the mass flow rate. Typically very fast, because of the low thermal mass of the wire element, these devices are often used for profiling flows.

3.8.3 The Tracer-Dilution and Cross-Correlation Flowmeter The tracer-dilution flowmeter is based on mass conservation methods and depends on measuring the dilution of a known amount of tracer added to the flow. Dilution techniques require adequate mixing of tracers, and thus are typically employed for high-velocity, highly turbulent flows. Tracer materials include chemical salts, fluorescent dyes, and radioactive materials, in addition to other materials that lend themselves to easy measurement within the flow system. Administration of tracers may be performed either at a constant rate of injection or as a periodic injection of a slug of material. Downstream dilution measurement techniques include fluid electrical conductivity, scintillation detection, and optical-based methods such as fluorometry, transmissivity, etc.

Provided the tracer input quantity is known, tracer dilution techniques do not require knowledge of the geometry of the flow path. Flow is determined by measuring the dilution of the *known* amount of tracer. For applications where the flow geometry is well characterized, tracers may also be applied in a cross-correlation technique, where the administration and measurement of a tracer is performed within a known path length. The cross-correlation measurement under these conditions provides a time-of-flight indication of flow rate, which, with appropriate geometry information, may be used to indicate volumetric flow rate.

3.8.4 The Coriolis Flowmeter Flowmeters in this category apply inertial Coriolis forces to measure flow. Coriolis force is produced by introducing an oscillating acceleration, about an axis, to a pipe containing a flowing mass of fluid (see Fig. 17) (Bau *et al.*, 1994). The elemental Coriolis force is quantified as two times the elemental mass times the cross product of the angular velocity and the velocity of the fluid perpendicular to the axis of rotation,

$$df_c = 2dm\boldsymbol{\omega} \times \boldsymbol{v}. \tag{21}$$

A common implementation of Coriolis mass-flow measurement is the vibrated u-tube, in which flow is directed through a horseshoe-shaped pipe of low stiffness. At the apex of the horseshoe, the tube is oscil-

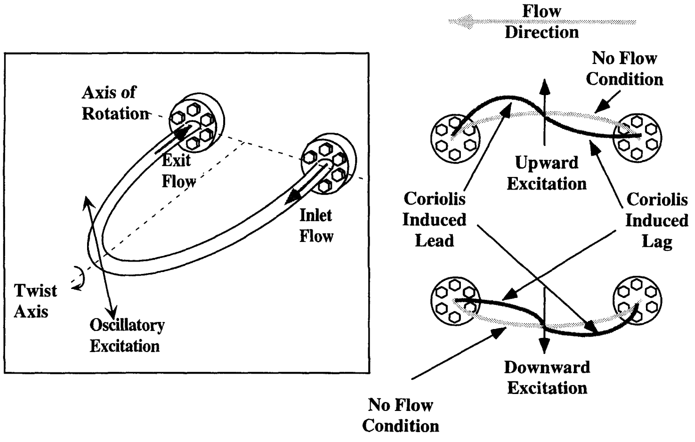

FIG. 17. The U-tube Coriolis flowmeter excites the flow path in an oscillatory pattern. Velocity perpendicular to the axis of rotation causes a torsional force about the twist axis.

lated (about an axis passing through the tips of the horseshoe) at a natural frequency. This oscillation equates to an angular velocity about the axis of rotation. Along the inlet and outlet legs of the horseshoe, a torsional force is produced as the fluid flow lags the pipe wall motion. This force is of opposite direction and equal magnitude in the inlet and outlet legs of the horseshoe. Through displacement measurement of the magnitude of the oscillating twist in the horseshoe, the mass flow rate of the fluid may be obtained. Often, to balance the effects of the torsional forces of the u-tube on process piping, a dual u-tube flow path will be used, with the tubes oscillated at 180° out of phase. The resultant torsional forces of the tubes then destructively cancel one another, resulting in a net balance of forces at the process piping.

3.8.5 The Ultrasonic Time-of-Flight and Doppler or Laser-Doppler Flowmeters The ultrasonic flowmeter monitors the effects of a flow stream on either the time of flight or the scattering of an acoustically propagated signal (Bau *et al.*, 1994). In the former case, the *time-of-flight,* or *transit-time,* flowmeter measures the transit time of an acoustic signal between an upstream and downstream pair of transceivers. These transceivers are set on opposite sides of the flow path from one another and are carefully adjusted such that the acoustic signal travels at the fixed angle between them. The propagation speed of the signal will be the vector sum of the temperature-dependent speed of sound through the medium, plus the additive (for downstream propagation) or subtractive (for upstream) effect of the moving fluid. Dependence upon fluid speed of sound may be eliminated by beating signals from upstream-to-downstream and downstream-to-upstream transceivers. The beat difference between upstream and downstream propagation is dependent only on fluid velocity, the fixed angle between transducers, and the linear path length between them. Time-of-flight measurements are indicative of average fluid velocities, as the propagation rate of the signal will be influenced by the fluid velocity profile throughout the path length between transceivers. Multiple-path transceivers may be employed to indicate bulk volumetric flow better by averaging the measurement across many different acoustic paths.

The Doppler flowmeter is another propagation method for determining average flow rate. Inhomogeneous inclusions within a flow stream will cause reflection of a wave front propagating through the medium (see Fig. 18). The relative motion between the inhomogeneities and the wave front will create a Doppler shift in the frequency of the reflected signal. Provided the inclusions are traveling at the fluid velocity, this Doppler shift is linearly proportional to the velocity of the fluid. Within liquids, entrained air and dirt may act as reflectors and an ultrasonic transceiver may be employed to measure their Doppler shift. In gases, where acoustic propagation is diminished, lasers may be employed, with entrained solids such as dust or condensing water vapor acting to the same effect. The latter are often termed laser-Doppler velocimeters or laser-Doppler anemometers.

3.8.6 Nuclear-Magnetic-Resonance Flowmeters Nuclear-magnetic-resonance (NMR) flowmeters provide a noncontact method for measuring fluid flow of materials with a nuclear magnetic moment (odd number of protons). NMR flowmeters apply a radio-frequency (rf) field to sense resonance interaction between an externally applied magnetic field and the magnetic moments of the material being measured. Hydrogen has the largest nuclear magnetic moment of any element, and thus NMR flow measurements are particularly well suited to hydrogenous materials. One particularly advantageous situation for NMR flowmeters is the imaging of blood flow within intact, functioning human hearts.

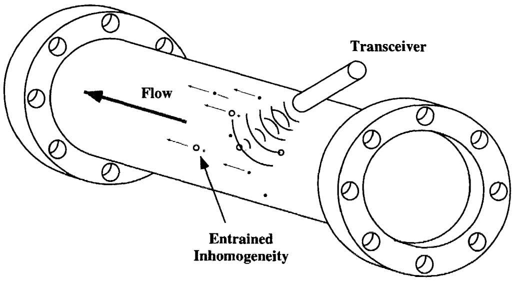

FIG. 18. Ultrasonic Doppler flowmeters measure flow velocity by observing the Doppler frequency shift imparted to a propagated wave form by the relative motion of entrained inhomogeneities in the flow stream.

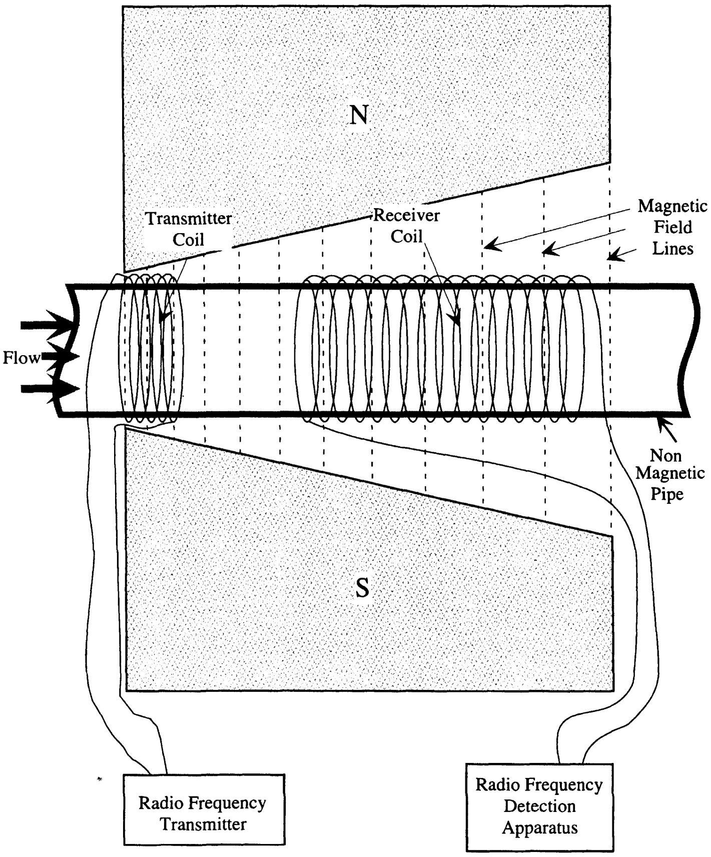

FIG. 19. Gradient-field–type nuclear-magnetic-resonance flowmeter.

Several different implementations of NMR flowmeters have been developed. An approximate grouping scheme for these methods is one-coil inflow and outflow, two-coil labeled time-of-flight, and field-gradient techniques. The field-gradient technique is selected here to illustrate the concepts underlying NMR flowmeter technology (see Fig. 19, derived from King and Riewerts, 1985).

In this implementation, the nuclear spins of the flowing fluid material are aligned by a transverse magnetic field. A linear gradient magnetic field along the flow is simultaneously applied. rf pulses at the material's magnetic resonance frequency are briefly applied to rotate the magnetic moment relative to the externally applied static magnetic field. In the gradient field, only a narrow slice of the flowing material has its resonant frequency attuned to the rf pulse. After the termination of the rf pulse, the subatomic particles realign to the external magnetic field and radiate electromagnetic fields that induce measurable voltages in an rf sensing coil. As the excited slice of the material moves into a field region of different magnetic intensity (flows downstream), the frequency of the signal emitted by the particles, as they realign with the magnetic field, changes proportionately. The signal intensity indicates the number of particles realigning with the external magnetic field. The combination of signal time delay (relative to the applied rf pulse) and signal frequency indicates the particle velocity.

INTRODUCTION

A transducer is a device that converts energy from one form to another. An electroacoustic transducer transforms electrical energy into acoustic energy, or vice versa. An electromechanical transducer transforms electrical energy to mechanical energy or movement, which then may transmit energy. These are the energy transformations that will be involved in the transducers mentioned in this article. Understanding and design of transducers is multidisciplinary and involves a knowledge of materials, physics, acoustics, electrical engineering, mechanical engineering, and chemistry. Fortunately, there are many guidelines that can be followed in which the beginner can understand the various disciplines involved. Some people call the successful fabrication of transducers a "black art." This is an overworked term; transducer design and fabrication follow a well thought-out path, but do require a broad knowledge in the sciences and engineering. They also require learning how acoustics interacts with different materials and their acoustic impedances. Baffles, housings, and resonant structures typically surround the transducer and can have a major impact on its performance. Just like in most fields, the "bugs" need to be "worked out" from the design for the transducer to be an integral part of a measuring system.

Landmarks in the history of electroacoustics were Bell's invention of the telephone (1876) and Edison's work on the carbon microphone and the phonograph. Langevin and others used steel-quartz-steel resonator plates, which form a composite underwater projector transducer for the detection of submarines. Equivalent circuits that describe the action of piezoelectric resonators were developed by Van Dyke (1928) and Mason (1934, 1948), and good introductions can be found in Wilson (1985), Stansfield (1990), Hunt (1982), Berlincourt *et al.* (1964), Kinsler *et al.* (1982), and Bobber (1988). The discovery of

the large piezoelectric effects in ceramics (e.g., barium titanate, 1946) led to the development of the technology of modern piezoelectric ceramics, and to the improvement in the performance of electromechanical transducers.

There are many different types of transducers that can be discussed. A good list of the different types of transducers used in the field of acoustics can be seen in the *Journal of the Acoustical Society of America* index under the listing 43.38, "Transduction; Acoustical devices for the generation and reproduction of sound." The transducer types from this list that are generally used in underwater acoustics are magnetostrictive transducers, electromagnetic and electrodynamic transducers, piezoelectric and ferroelectric transducers; transducer arrays, acoustic interaction effects in arrays, hydroacoustic and hydraulic transducers, and impulse transducers. Acoustic transducers of various types must satisfy the application needs over a frequency range of seven decades. In Fig. 1 is shown a convenient comparison of the large acoustic frequency range, the application, and devices and materials. This article is devoted mostly to describing underwater transducers, how they are tested, and how they operate. An excellent introduction to underwater electroacoustics can be found in Wilson (1985) and in Kinsler *et al.* (1982).

1. OPERATING ENVIRONMENT

Operating a transducer in an underwater environment is dramatically different from operating in air, and significantly affects how the transducer is designed and the types of materials used in the design. To gather an understanding of the difference, the relative pressure for a given particle displacement in air and water is now determined. The ratio of acoustic pressure p to particle velocity v is equal to the specific acoustic impedance of the medium ρc, where ρ is the density and c is the sound velocity. The particle displacement is given by

$$\chi = v/\omega = (p/\omega)\rho c, \tag{1}$$

where $\omega = 2\pi f$ is the angular frequency and f is the frequency. The acoustic impedance ρc for water is 1.5×10^6 Rayls (Rayl = kg/m^2·sec) and for air is 415 Rayls. For a given pressure and frequency, the ratio of the particle velocities is equal to the ratio of the medium impedances; hence, 3600 times more motion is needed in air than in water to create the same pressure level. From this it is obvious that a transducer in air must be much more compliant than in water (e.g., a compliant loudspeaker versus a stiff ceramic).

2. MATERIALS

Materials typically used in an underwater environment undergo a length or volume change when an alternating electric or magnetic field is applied to the material. They can be generally grouped into piezoelectrics, ceramics, composites, polymers, and magnetostrictive materials.

2.1 Piezoelectric Materials

The piezoelectric effect arises because of the asymmetries in the crystal structure, which create an electric dipole moment in the crystal lattice that is sensitive to both elastic strain and applied electric field.

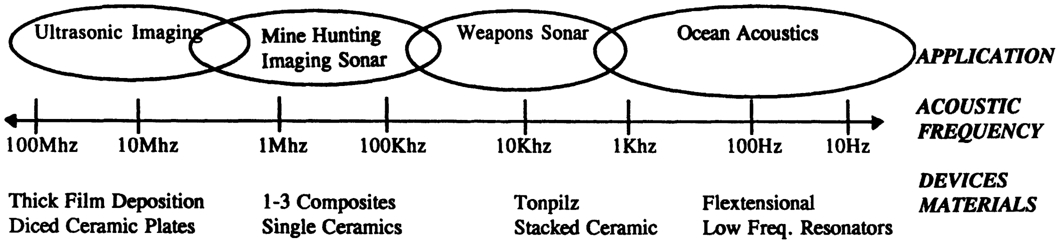

FIG. 1. Acoustic frequency range for transducers.

Quartz is one of the earliest materials discovered with the piezoelectric effect. It is rarely used for underwater projectors; however, its very low internal losses and very high mechanical *Q* lead to the use of quartz in stable resonant circuits in the communication and electronics fields. Rochelle salt, an extremely active piezoelectric material, was used for early underwater projectors and hydrophones, and as phonograph pickups and microphones. It is very sensitive to moisture, which can dissolve the crystal, and hence was replaced by more environmentally stable materials for underwater transducers. Ammonium dihydrogen phosphate (ADP) replaced Rochelle salt in the 1940s. Modern transducers use piezoelectric ceramics, which are sintered polycrystalline materials polarized by large electrical fields while they are cooling from temperatures near or above the Curie point (typically 200–400 °C), a characteristic temperature above which a ceramic element shows no sign of piezoelectric activity. In practice, the operating temperature should be limited to about half of the Curie point. Ceramics can have their properties tailored to fit specific applications. In addition to the ceramics, piezorubber and piezoelectric polymers such as polyvinylidene fluoride (PVDF) have come into use. Also, a matrix material called "1–3 composites" (because of the orientation direction of its small PZT rods) is coming into use for large transducer systems.

Other piezoelectric materials that are sometimes used are these: Lithium sulfate ($LiSO_4 \cdot H_2O$) is used for hydrophones; tourmaline has been used in the calibration of hydrostatic pressure devices and in the measurement of blast wave pressures; lead metaniobate ($PbNb_2O_6$) has a very high Curie temperature and a low mechanical *Q*, and is used for deep submergence hydrophones; lead titanate ($PbTiO_3$) has a large hydrostatic piezoelectric constant, which allows this material to be used as a volume expander. A volume expander means that all surfaces of the material expand in phase, allowing simple hydrophone mounting materials to be used.

2.2 Piezoelectric Ceramics

The most widely used ceramics for underwater transducers are made from lead zirconate titanate (PZT). The materials used for ceramics are polycrystalline, which have Curie temperatures between about 200 and 400 °C. Ceramic materials are quite variable in their properties, are difficult to maintain consistency between batches and manufacturers, and have nonlinear properties, and their properties change with age. Even with these problems, ceramics are the predominant type of piezoelectric material used today. A good description of the properties of piezoelectric materials can be found in Wilson (1985). The technology of barium titanate (B) and lead zirconate titanate (PZT) has been relatively stable so that their physical properties can be listed with some degree of confidence. A list can be obtained from any manufacturer or from many of the references given above.

Because the U.S. Navy procures ceramics for their sonar systems, a standard was developed for obtaining reproducibility of transducer characteristics from one manufacturer to another. The military specification is known as MIL-STD-1376(SHIPS), and classifies ceramics in this way:

Classification. The ceramic shall be of the following types:

Type I—Hard lead zirconate-titanate, such as PZT-4, with a Curie temperature equal to or greater than 310 °C.

Type II—Soft lead zirconate-titanate, such as PZT-5, with a Curie temperature equal to or greater than 330 °C.

Type III—Very hard lead zirconate-titanate, such as PZT-8, with a Curie temperature equal to or greater than 290 °C.

Type IV—Barium titanate with additives and a Curie temperature equal to or greater than 100 °C.

Type V—A high dielectric constant material similar to type II.

Type VI—An extremely high dielectric constant material, such as PZT-5H, similar to type II.

The type I compositions are hard materials developed for high-power projectors. Type I has a high electric field, high coupling coefficient, and low dielectric loss properties under high drive fields. The low dielectric loss is important so that heating effects are minimal. Type III materials provide high stability for high drive levels and very low dielectric losses. Types II, V, and VI are soft materials developed for hydrophones and have high dielectric constants with high sensitivity, but also have high dielectric losses. Type VI has an extremely high dielectric constant and is often used in very high-frequency medical transducers.

The words hard and soft refer to how difficult it is to depolarize the ceramic. Unless the manufacturing process is well controlled, the values for a particular ceramic may vary as much as 10%. A solution to the varying properties from different batches and manufactures is to purchase all of the ceramic that will be needed, plus spares, from a single batch.

The piezoelectric constant *d* expresses the ratio of the field developed along an axis to the applied stress. It quantifies the movement (motion) of the ceramic when a voltage is applied. A high value of *d* is looked for in ceramic used for a high-power projector. The piezoelectric constant *g* expresses the ratio of strain developed along an axis to the applied field. It quantifies the output voltage of the ceramic when a motion, or pressure, is applied. The product of the two piezoelectric strain coefficients, *g* and *d*, is a very useful measure of "goodness" per unit volume of a piezoelectric material when minimization of the hydrophone internal noise is a major design criterion. Lists of piezoelectric properties can be obtained from any manufacturer or in Wilson (1985).

2.3 Composite Ceramics

Considerable effort has been directed to the development of new composite configurations of the PZT ceramics with nonactive materials. Piezorubber is composed of ceramic particles imbedded into a rubber matrix. It is very flexible, is used as hydrophones, and is called a 0-3 composite material. The 0 means that the ceramic particles do not touch one another, and the 3 means that it is used in the thickness mode. Another new material is composed of many small parallel ceramic rods imbedded vertically in a matrix material. These are called 1-3 composites because the ceramic is connected in one direction, and it is used in the thickness direction. This 1-3 composite is available in large sheets and can be used as a projector as well as a hydrophone. Large-area sensors can be used because of the minimal planar vibration modes and the capability to electroplate the surfaces. This material is finding many applications in underwater transducers.

2.4 Piezoelectric Polymers

Large piezoelectric effects are present in the polymer material polyvinylidene fluoride (PVDF or PVF_2). When the material is stretched along one axis and polarized, it becomes a very useful sensor. It is available in sheets with electrodes on the surfaces. For hydrophone uses, thicknesses of the order of 500 μm are used. PVDF has the advantages of flexibility, an impedance close to that of water, and a high hydrophone sensitivity relative to thickness. It is a poor transmitter and can be used only up to a temperature of about 100 °C. PVDF can be used where a very thin sensor is needed and where complex shapes can be etched into its surface. There are many other applications where a continuous sensor material that does not have any significant planar vibration modes can be used.

2.5 Magnetostrictive Materials

The magnetostrictive effect occurs when a magnetic field is applied to a material and causes a strain that is a nonlinear function of the applied field. The most important magnetostrictive materials are nickel and Terfenol-D. Nickel was used in the 1930s and 1940s in the construction of sonar projectors and hydrophones. Its use diminished because of its low electromechanical coupling coefficient, which relates the amount of kinetic energy available in the material to its total energy. Recently, the development of Terfenol-D by Clark (1980) has made available a high electromechanical coupling coefficient and a high electromagnetic strain. This material appears to have a chance to replace ceramics in some sonar transducers, especially in low-frequency projectors. A combination of Terfenol-D and ceramics in a single transducer has some interesting properties as described by Butler *et al.* (1990).

3. TESTING OF UNDERWATER TRANSDUCERS

To be able to use transducers properly, certain characteristics of the transducer and arrays of transducers must be measured and

Table 1. Calibration formulas.

Calibration test	Abbr.	Eq. No.	Formula	Units
Free-field voltage sensitivity	FFVS, M	2	$M_s - E_s + E_x$ $E_x - E_t - \mathrm{TVR}_s + 20 \log D$	dB re 1 V/μPa

understood. Equally important is knowing the various tests that can be performed on transducers and how to calculate the transducer parameters; see ANSI (1972). The term "transducer" as presented here implies that the device can be used either as a projector (transmitter) or as a hydrophone (receiver). When the term "projector" or "hydrophone" is mentioned, the characteristic being discussed will only apply to that type of device. For example, the directivity pattern of a transducer will be the same whether it is used as a projector or as a hydrophone. Efficiency is only associated with a projector. For quick reference, a tabulation of calibration formulas is presented in Table 1, and a definition of variables is listed in Table 2.

3.1 Calibration Formulas

The *free-field voltage sensitivity* (FFVS) of a hydrophone (or receiver) is the open-circuit electrical output of the hydrophone per

Table 2. Definition of variables used in Table 1.

E_s	Measured open-circuit voltage of standard hydrophone (dB)
E_x	Measured open-circuit voltage of test hydrophone (dB)
E_t	Transmit voltage (dB)
e_t	Transmit voltage (V)
M_s	FFVS of standard hydrophone (dB)
D	Separation distance (m)
I_t	Transmit current (dB)
i_t	Transmit current (A)
ϕ	Voltage/current phase angle (deg)

P_0	Output acoustic power (W)
R	Equivalent series resistance of hydrophone (Ω)
d	Diameter of piston (m)
L	Length of line source (m)
λ	Wavelength in water (m)
h	Depth
f	Frequency (kHz)

unit free-field pressure. The symbol M is typically used and was derived from the word "microphone," the air equivalent of a hydrophone. The open-circuit voltage measurement is made with a preamplifier with a high input impedance. The free-field pressure is what would exist at a given location without the presence of reflections. The easiest method to obtain the FFVS is by comparing the unknown hydrophone with a standard hydrophone when placed into the same acoustic field (usually a pure tone burst of sufficient time). A standard hydrophone will typically have a table of decibel signal level versus frequency. The signal level received by the hydrophone is determined by measuring the level within a time-gated portion of the signal that corresponds to the direct path. This way, interference due to reflected pulses are ignored, and a high signal-to-noise ratio is obtained. The FFVS, M, is given by

$$\text{FFVS(dB)} = M_x\text{(dB)} = M_s - E_s + E_x, \tag{2}$$

where M_s is the FFVS (in dB) of the standard hydrophone, E_s is the measured open-circuit voltage (in dB) of the standard hydrophone, and E_x is the measured open-circuit voltage (in dB) of the hydrophone being calibrated. The subscript x denotes the unknown or test hydrophone, and the subscript s the standard hydrophone. All units are decibels referenced to 1 V per micropascal (dB re 1 V/μPa). Sometimes this is called the receive voltage sensitivity (RVS).

The *transmitting voltage response* (TVR) of a projector is the transmitted free-field pressure produced for a 1-V signal applied across the electrical terminals of the transducer and referenced to a distance of 1 m. The symbol S is commonly used and stands for "speaker." The measurement is made by monitoring the output voltage of a standard hydrophone placed in the acoustic far field (defined below) of the projector. The TVR, S, is given by

$$\begin{aligned}\text{TVR(dB)} &= S_x\text{(dB)}\\ &= E_s - M_s - E_t + 20 \log D,\end{aligned} \tag{3}$$

where E_s is the measured open-circuit voltage (in dB) of the standard hydrophone, M_s is the FFVS (in dB) of the standard hydrophone, E_t is the projector transmit voltage (in dB), and D is the separation distance in meters. The units are decibels referenced to 1 micropascal per volt at 1 meter (dB re μPa/V @ 1 m).

The *far-field distance* x from a square or circular transducer is conservatively defined as

$$x = \text{area}/\lambda, \tag{4}$$

where λ is the wavelength in water. The far-field distance x from a line or thin cylinder is conservatively defined as

$$x = L^2/\lambda, \tag{5}$$

where L is the line length.

The *transmitting current response* (TCR) of a projector is the transmitted free-field pressure produced for a 1-A signal applied to the electrical terminals of a projector and referenced to a distance of 1 m. The measurement is made by monitoring the output voltage of a standard hydrophone placed in the far field of the projector. The TCR is given by

$$\text{TCR}_x\text{(dB)} = E_s - M_s - I_t + 20 \log D, \tag{6}$$

where E_s is the measured open-circuit voltage (in dB) of the standard hydrophone, M_s is the FFVS (in dB) of the standard hydrophone, I_t is the projector transmit current (in dB), and D is the separation distance in meters. The units are decibels referenced to 1 micropascal per ampere at 1 meter (dB re μPa/A @ 1 m).

The *transmitting power response* (TWR) of a projector is the transmitted free-field pressure produced for a signal of 1 W applied to the electrical terminals of a transducer and referenced to a distance of 1 m. The TWR is given by

$$\begin{aligned}\text{TWR} &= E_s - M_s + 20 \log D\\ &\quad - 10 \log(e_t i_t \cos \phi),\end{aligned} \tag{7}$$

where E_s is the measured open-circuit voltage (in dB) of the standard hydrophone, M_s is the FFVS (in dB) of the standard hydrophone, D is the separation distance in meters, e_t is the projector transmit voltage, i_t is the projector transmit current, and ϕ is the voltage/current phase angle. The units are decibels referenced to 1 micropascal per watt at 1 meter (dB re μPa/W @ 1 m).

Using Eqs. (3) and (7), the TWR can be written as a function of TVR as

$$\mathrm{TWR} = \mathrm{TVR} + 10\log(R_p), \tag{8}$$

where R_p is the equivalent parallel resistance of the projector and is given by

$$R_p = |z|/\cos\phi. \tag{9}$$

It is evident that either a standard hydrophone or a calibrated projector is required to obtain the transmit or receive response of an unknown transducer. Hydrophones that have calibration response data can be purchased, or can be sent to a calibration facility.

An absolute method to calibrate transducers without the need of a standard is called a *reciprocity* calibration. The reciprocity calibration allows an absolute calibration without the need of a transducer with a known response (see ACOUSTICAL INSTRUMENTS). It requires three transducers, one of which is a projector, one a hydrophone, and one which is reciprocal. A reciprocal transducer has the ratio of its receiving sensitivity M (when acting as a hydrophone) to its transmitting current response S (when acting as a projector) equal to a constant called the *reciprocity parameter, J*:

$$J = \frac{M_e}{S_i} = \frac{\mathrm{FFVS}}{\mathrm{TCR}}. \tag{10}$$

For spherical waves,

$$J_s(\mathrm{dB}) = 20\log(2/\rho c) = 354 + 20\log f, \tag{11}$$

where $\rho = 1000$ kg/m^3 is the density of water, $c = 1500$ m/s is the sound velocity, and f is the frequency. All units are MKS. Fortunately, most ceramic transducers are reciprocal. Details of this calibration method will not be presented here, as there are several excellent discussions available; see Albers (1965) or Bobber (1988).

The phase response of a projector is not of concern in most calibrations. When measuring phase response, the best reference is a standard, omnidirectional hydrophone having a constant sensitivity and operating well below its resonance frequency. In this region the phase of its transduction is constant and well suited as a reference. Comparison phase measurements are obtained by reference to the phase of the drive voltage.

The *source level* (SL) of a projector is the transmitted free-field pressure produced by a signal of the applied power or applied voltage to the electrical terminals of a projector and referenced to a distance of 1 m. The SL is given by

$$\mathrm{SL(dB)} = \mathrm{TWR} + 10\log P_t, \tag{12}$$

$$\mathrm{SL(dB)} = \mathrm{TVR} + E_t, \tag{13}$$

where P_t is the projector input power (in watts) and E_t is the projector input voltage (in dB). The units are decibels referenced to 1 micropascal at 1 meter (dB re μPa @ 1 m).

The power delivered to a projector is dissipated in either the electrical or the mechanical resistance within the transducer, or it is radiated into the water. The *efficiency* (η) of a projector is the ratio of the total acoustic output power to the total electrical input power. The TWR, Eq. (7), and SL, Eq. (12), can also be written as functions of efficiency,

$$\mathrm{TWR(dB)} = 170.8 + \mathrm{DI} + 10\log\eta, \tag{14}$$

$$\mathrm{SL(dB)} = 170.8 + 10\log P_t + \mathrm{DI} + 10\log\eta, \tag{15}$$

where P_t is the input power, DI is the directivity index (see Sec. 3.2), and the quantity 170.8 dB accounts for the ρc of the medium and the reference of 1 μ Pa. The directivity index is very difficult to measure because it involves the total power radiated and requires the measurement of directivity patterns in several planes (Sec. 3.2 shows the calculation of DI). The DI needs to be accurate to 0.1 dB for a good efficiency calculation, which for most projectors ranges from 50% to 80%.

3.2 Calculated Parameters

One of the major parameters of a transducer or transducer array is the directivity pattern (often called beam pattern), which is the response level of the transducer as a function of the incident angle of the sound. A transducer will have the same directivity pattern whether operating as a projector or a hydrophone. It is a function of the aperture and frequency and is used to calculate the power and efficiency parameters of the transducer. A high directivity indicates that the acoustic power of a projector is concentrated into a small region, and for a hydrophone high directivity allows high imaging resolution and reduces the influence of ocean isotropic noise. The *directivity index,* DI, of a transducer is a very important parameter that quantifies the sharpness, or directionality, of the pattern and is closely associated with the beamwidth. Approximate equations (Stansfield, 1990) for the half-power (−3 dB) beamwidth BW and directivity index DI of a circular piston in an infinite baffle are

$$\mathrm{BW} \approx 60\lambda/d, \tag{16}$$

$$\mathrm{DI} = 10\log(4\pi \times \mathrm{area}/\lambda^2). \tag{17}$$

The approximate equations for the half-power (−3 dB) beamwidth BW and directivity index DI of a continuous line are

$$\mathrm{BW} \approx 50\lambda/L, \tag{18}$$

$$\mathrm{DI} = 10\log(2L/\lambda). \tag{19}$$

The beamwidth of a square radiating surface uses Eq. (18), where L will be the side of the square, and Eq. (17) for the DI. Parameters for rectangular and elliptical radiating surfaces can be found in Albers (1965) or Stansfield (1990). The beamwidths at the −10-dB level and between the first nulls can be obtained by using a multiplying factor:

$$\mathrm{BW}(-10\ \mathrm{dB}) \approx 1.8\mathrm{BW}(-3\ \mathrm{dB}), \tag{20}$$

$$\mathrm{BW(btwn.\ nulls)} \approx 2.3\mathrm{BW}(-3\ \mathrm{dB}). \tag{21}$$

These equations apply for dimensions greater than one wavelength of sound in water.

The *equivalent thermal-noise pressure level* is important in determining the lowest signal that can be developed in a hydrophone. This noise level of the hydrophone can be associated with an equivalent sound-pressure level in the ocean. The open-circuit voltage E_n developed by thermal agitation in a 1-Hz band is called the Johnson noise,

$$E_n = \sqrt{4KTR}, \tag{22}$$

where K is the Boltzmann gas constant (1.38×10^{-23} J/K), T is the absolute temperature in kelvins, and R is the equivalent series resistance of the electrical impedance of the transducer in ohms (in general, this is a function of frequency). The equivalent noise sound-pressure level, SPL_n, is

$$\mathrm{SPL}_n = E_n/M, \tag{23}$$

and written in decibel form for a temperature of 15 °C is

$$\mathrm{SPL(dB)} = 10\log(R) - M - 198. \tag{24}$$

For example, a 1000-Ω impedance hydrophone with a FFVS of −200 dB re 1 V/μPa will have an equivalent thermal-noise sound-pressure level of 20 dB re 1 V/μPa.

3.3 Cavitation

The onset of cavitation occurs when the motion of the radiating face creates a partial vacuum that is greater than the vapor pressure of the water. The cavitation threshold is the point where the power applied to the projector is sufficient to start the formation of bubbles at its face. An empirical curve (Urick, 1975) that shows the frequency dependence of the cavitation threshold P_c, using continuous-wave (cw) data in fresh water at atmospheric pressure, is

$$P_c(0) = 0.00025f^2 + 0.045f + 1 \quad \text{(atmospheres)}, \tag{25}$$

where $P_c(0)$ is the cavitation threshold at zero depth and f is the frequency in kHz. This is approximately valid up to frequencies of a few hundred kilohertz. As the depth of operation is increased, the cavitation threshold increases as

$$P_c(h) = P_c(0) + h/10 \quad \text{(atmospheres)}, \tag{26}$$

where $P_c(h)$ is the cavitation threshold at depth h and h is the depth in meters. The cavitation threshold can be approximately expressed as occurring when the acoustic intensity at the radiating face of the transducer is equal to

$$I_c = 0.15[P_c(0) + h/10]^2\ \mathrm{W/cm^2}. \tag{27}$$

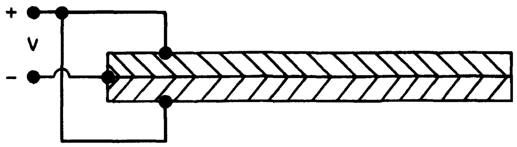

FIG. 2. Schematic of a basic bilaminar flexural disk transducer (Wilson, 1985).

In practice the intensity can be 2 to 3 times higher before cavitation will affect the source level. A value of 0.3 is used by Wilson (1985). The intensity at the surface of a transducer or array can be calculated by multiplying the acoustic output power by the area of the transducer. The cavitation threshold is sensitive to temperature, dissolved-air content, frequency, acoustic pulse length, depth, and acoustic hot spots on the transducer face. Quantifying the onset of cavitation is difficult and, if important, should be determined experimentally. See Urick (1975) and Stansfield (1990) for more information.

4. LOW-FREQUENCY TRANSDUCERS (10–5000 Hz)

The design of transducers and arrays capable of radiating power at frequencies less than about 1 kHz has the basic requirement of producing large displacements efficiently. The size and weight of the transducer becomes an important issue at these low frequencies, since the source level depends upon the amount of volume of water that is moved. Radiation loading, which determines the amount of sound radiated, is also typically small because the size of the transducer is small relative to a wavelength. At 1 kHz the wavelength of sound in water is 5 ft; at 100 Hz it is 50 ft. Fortunately, for most low-frequency active transducers, the output power requirements are not as high as those for transducers operating at higher frequencies. To design high-power transducers at low frequencies in a moderate size, they need to be less stiff than a ceramic thickness vibrator. To accomplish this more compliant transducer design, use is made of a mechanical amplification such as a lever. This provides a mechanical impedance transformer resulting in a lower stiffness. One technique for doing this is to use flexural motion of plates and shells that have a lower stiffness and a lower mechanical resonance frequency for the same overall dimensions of the structure. Other methods involve the use of a gas-filled enclosure as the stiffness element of electromagnetic or hydraulic systems. The general characteristics of these designs are discussed in the following.

4.1 Flexural Disk

An example of a transducer that involves flexure is the flexural plate transducer; see Fig. 2. The basic principal of a flexural disk is that if a force is applied to one face of a thin metal disk, it will be displaced at the center, or flex, putting one side into compression and the other side into tension. A bilaminar disk will have two piezoelectric ceramic disks bonded together. An electrical field across the ceramics will result in an expansion in the ceramic disk that has the field and the polarization in the same direction, and a compression in the ceramic that has the field and the polarization in the opposite direction. The result is to cause a bending of the pair of disks converting a small displacement in the ceramic into a larger displacement of the surface radiating into water. For more efficiency, a double bilaminar disk transducer can be used, which has two faces radiating in opposite directions to act as a volume expander, Fig. 3. Basic design pa-

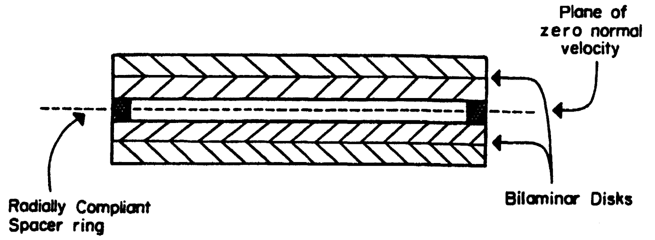

FIG. 3. Double bilaminar disk (Wilson, 1985).

rameters were derived by Woollett (1960) and can serve as further reading.

A metal plate can be inserted between the two ceramic disks, a trilaminar design, or one of the ceramic disks can be replaced with a metal plate. Typically, the ceramic is placed on the outside of the metal so that under a hydrostatic load the ceramic will be in compression so that it will not fracture. Limitations on hydrostatic pressure can be overcome by providing air pressure compensation. This, however, adds complexity and affects performance.

Flexural disk transducers are good as small, modest-power sources at low frequencies. Mechanical values of Q typically range between 10 and 15. They are relatively low cost because of their simple construction, and hence will be an economical and compact solution for not too demanding an application. Flexural disks are extensively used as low-frequency hydrophones because of their low cost and high sensitivity.

4.2 Flextensional Transducer (300–3000 Hz)

This device also utilizes flexure motion, but instead of using the ceramic itself in flexural motion, it uses a mechanical gain to transform the thickness-mode vibration in the ceramic into a larger displacement. The basic features of the flextensional transducer are illustrated schematically in Fig. 4. A stack of ceramics operates in the thickness mode and is connected to a surrounding shell. When the stack expands, the major axis of the shell moves outward, and the minor axis moves inward. This produces a large volume displacement, transforming the high-impedance, small motion of the stack into a lower-impedance, larger movement of the shell. Several different types of design use this mechanism and are divided into classes of flextensional transducers. Flexural transducers primarily are designed to resonate in the frequency range of 300 to 3000 Hz, and generally have higher power outputs than the flexural disks, although at a higher cost (Stansfield, 1990).

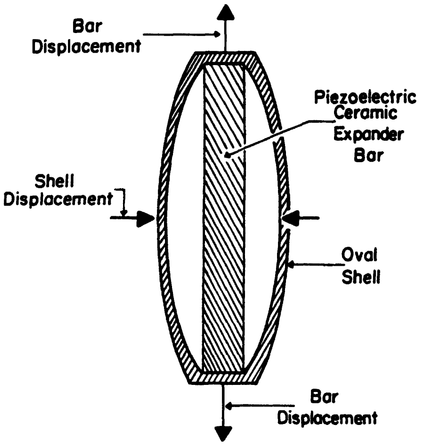

FIG. 4. Schematic of a flextensional transducer (Wilson, 1985).

A Class I flextensional transducer is a three-dimensional structure created by rotating about an axis along the stack; see Fig. 5. If it is rotated about an axis normal to the stack, a ring-shell projector is obtained, a Class V flextensional. The ceramic in a Class V flextensional is also extended in the third dimension and forms either a disk, which drives the shell by radial stress in the disk, or a ring around the circumference joining the two half shells.

Another configuration is an elliptical cylinder generated by extending the figure out of the plane of the sketch and capping it on both top and bottom. This is called a Class IV flextensional transducer and has been studied more thoroughly than other classes. Design characteristics have been calculated by analytical and by finite-element analysis; however, the design depends on a number of parameters and does not lead to any simple design equations. The resonance frequency and the maximum hydrostatic pressure that an elliptical shell can withstand depend on the major and minor axis, wall thickness, and material properties of the shell, with the stack having a lesser influence. A rule of thumb is that eccentricity should not be greater than about 3. The use of a glass-reinforced plastic shell helps achieve a low resonance frequency and wide bandwidth.

The size of flextensional transducers is generally much less than a wavelength in water at their resonance frequency; hence, they tend to have an omnidirectional directivity pattern in the plane perpendicular to their axis. Values of mechanical Q down to 2 are achievable. Compared to a flexural disk of the same size, the Q of a flextensional

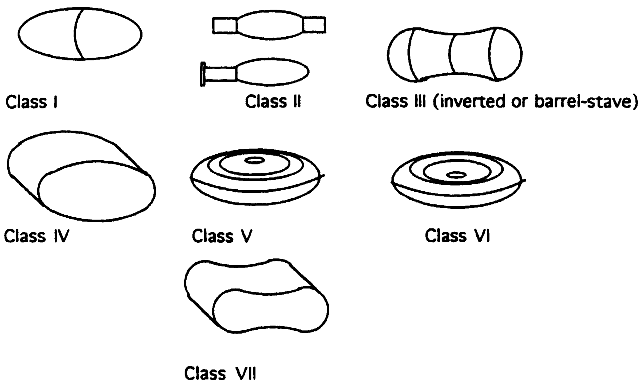

FIG. 5. Flextensional transducer classes (McCollum *et al.*, 1992).

transducer can be lower by a factor of 2–4. Also, a flextensional can be smaller than a flexural disk when hydrostatic pressure is the limiting requirement.

A compressive prestress must be applied to the stack in order to achieve high power output. It is usually accomplished by squeezing the minor axis, which expands the major axis, then inserting the stack into the shell. The relaxation of the shell applies the proper preload needed for the stack. It must also be realized that the hydrostatic pressure, which applies force to the shell, will also compress the minor axis and reduce the preload on the stack. The preload must be sufficiently designed so that hydrostatic pressure does not adversely affect its performance. Finite-element analysis is needed to detail the static stresses in the shell under hydrostatic pressures. Material fatigue during high-power operation must also be taken into account.

In summary, flextensional transducers constitute useful sources within the band of about 300–3000 Hz. They can provide significant power from a compact size, can operate at high hydrostatic pressures, and have wide bandwidths, especially when compared to other designs such as the air-backed flexural disk. The cost, however, is higher. The design process needs considerable care, using finite-element analysis to account for the complex interactions between parameters.

4.3 Free-Flooded Ring

A cylindrical ring that is open to the water (a free-flooded ring) can be used for low-frequency projectors that are independent of hydrostatic pressure. This transducer operates in the ring, or circumferential, mode of vibration. The radiation from the inner and end surfaces of the ring oppose that from the outer surface and can lead to partial cancellation of the radiation. It is possible, however, to design the height of the ring such that cancellation effects are not too great. Because it can be free flooded, no pressure compensation mechanisms are required. Since the resonance frequency is dependent on the diameter of the ring, a resonance of 1000 Hz would result in a ring of about 1 m diameter, which is impractical. The free-flooded ring can be typically used for frequencies above about 4000 Hz.

4.4 Mechanical Transducer

In the frequency range of 1–50 Hz an electric motor can be used to drive pistons to sufficiently large amplitudes of vibration. The frequency can be changed by varying the speed of the motor; however, it is not easy to change the amplitude of the oscillation, which limits the versatility of this approach. They are very useful when high power is required at frequencies below about 20 Hz.

4.5 Electromagnetic, Moving-Coil Transducers

Moving-coil electromagnetic transducers can be considered at audio frequencies. They are used as loudspeakers in air because large displacements are easily generated. In water they can be used as low-power, wide-bandwidth sources from 40 Hz to 20 kHz. The J9 transducer is a standard projector that has a moving coil mounted on a very compliant suspension system. It is necessary to balance the air pressure within the transducer to the external water pressure by means of an air-filled collapsible rubber bag. Beyond a depth of about 25 m an air compensation device is needed. The maximum power for the J9 is 20 W at frequencies above 200 Hz, but the efficiency is less than 1%. This device requires careful handling so that the suspension is not damaged. Also, the calibrated response may vary with drive level. It should be calibrated every time it is used.

4.6 Resonant Bubble Transducer

A gas-filled bag can be placed at the face of a moving-coil transducer to increase the radiation loading and increase the efficiency near resonance. The broadband low efficiency of a moving-coil transducer is transformed into a narrower-bandwidth, higher-efficiency transducer. The compliance in the bubble, or bag, provides a compact low-frequency source of modest power, narrow bandwidth, and a resonance frequency that varies with depth.

4.7 Helmholtz Resonator

The Helmholtz resonator is another resonant device that can be used as a low-frequency source. This resonator uses a rigid enclosed volume with a short neck of specified length and cross-sectional area. The outer end of the neck is exposed to the medium. The compliance of the cavity volume resonates with the mass of the fluid in the neck to form a simple mass–spring system. A transducer is placed in the wall of the cavity to excite the resonance. The resonance frequency is not dependent on density but is proportional to the sound velocity of the medium. Therefore, the resonance frequency of a Helmholtz resonator in water is about four times higher than in air. The mechanical Q_M is typically well above 20. The best way to reduce the resonance frequency is to maximize the cavity volume to a limit where the dimensions remain less than $\lambda/4$. One method of exciting the cavity is to place a flexural disk at one end of the cavity; another is to use ceramic rings in the wall of a cylindrical cavity. Cavitation can occur within the cavity at high source levels.

The Helmholtz resonator is a potential solution for a compact low-frequency projector that can operate down to great depths. In practice, to achieve rigid walls in a water environment requires thick walls, hence extra weight, and the narrow bandwidth and low efficiency have limited their usefulness. The use of this device, some specific design parameters, and their effects on the acoustic performance are addressed by Henriquez and Young (1980) and Kinsler *et al.* (1982).

4.8 Hydroacoustic Projector

The hydroacoustic projector, developed by Bouyoucos (1975), is a device that uses hydraulic fluid at high pressure to drive a flexing disk or a piston and is capable of large amplitudes of motion. A high-pressure hydraulic fluid flow is controlled by an electromechanical shuttle valve that causes the pressure oscillations in the acoustic drive cavity. This, in turn, exerts pressure oscillations on the flexural disks, which then radiate into the water. The electromechanical valve is typically a ceramic stack and provides control for the transducer. Power is derived from the high-pressure hydraulic fluid. The flexural disks, plus the various components, are designed to resonate over a fractional bandwidth of about 20%. It is an effective high-power source at low frequencies where weight and size are not critical. It is best used at frequencies below a few kilohertz and is not suitable for use as a hydrophone.

4.9 Spherical-Shell Transducer

A spherical shell composed of piezoelectric ceramic is another design for achieving a low-resonance frequency with a reasonable value of *Q*. One approach is to fabricate a large sphere with a number of triangular-shaped ceramic plates. These plates are cemented together into a mosaic to form a spherical shape, which radiates an omnidirectional pattern. A 30-in. diameter sphere has been fabricated with a usable frequency range from 0.5 to 2.0 kHz and a minimum efficiency of 75%.

4.10 Impulsive Transducer

Explosive sources are the most common impulsive source. Urick (1975) gives a good description of their use as underwater sound sources. These are commonly small charges of explosive materials ranging from a few grains to a few pounds. High velocity of detonation explosives such as TNT (>15 000 ft/s) are preferred over other materials such as black powder (0.1–1 ft/s), which has an explosion process called deflagration, or burning. The detonation introduces a shock wave normally followed by a series of pressure "bubble" pulses. Only one or two bubble oscillations are of practical significance. About 40% of the total chemical energy is radiated as acoustic energy. Most of the acoustic energy is concentrated between 5 and 1000 Hz. Explosive charges are easily portable and yield a short, omnidirectional, high-power, broadband pulse. The disadvantage is that explosives cannot be made repeatable, give a high background of reverberation, and cannot be coded for sonar applications.

The *sonar thumper* is an impulsive source generated by the repulsion of an aluminum plate by a large coil imbedded in a plastic matrix; see Albers (1965). A pulse of current in the coil induces eddy currents in the aluminum plate, causing it to be repelled by the coil. A large pulse of short duration (a capacitive discharge) needs to be passed through the coil. Although the pressure pulses are smaller than using an explosive, the thumper can be triggered and synchronized with a recorder system.

An *underwater spark source* acts as a small impulsive source but can be repeated for a number of pulses. A capacitive discharge across a gap between a pair of electrodes in the water generates the acoustic noise. It is a very simple transducer but has the disadvantage that the condition of the electrodes changes with use, which varies the pressure level of successive sparks. Peak pressures of 240 dB re 1 μPa at 1 m are possible. An *air gun* impulse source is created when high-pressure air is momentarily vented to the surrounding water to produce an air-filled cavity, which then collapses and radiates a transient pulse.

5. LONGITUDINAL VIBRATOR TRANSDUCERS (3 kHz to >100 MHz)

Longitudinal vibrators represent the standard transducer type used for a broad frequency range from about 3 kHz to above 100 MHz. *Tonpilz* transducers, which are a composite of ceramic and "head" and "tail" masses, predominate up to a frequency of about 100 kHz. Near the lower frequency of 3 kHz, the length and mass of the transducer becomes very large and other types become useful. Near 100 kHz the tonpilz transducer becomes very small, and it is more convenient simply to use the thickness vibration mode of a ceramic. The frequency range of 5–50 kHz is mainly used for weapon and detection sonars. From about 50 to 600 kHz, transducers are used for mine hunting, ocean bottom profiling, and fish finders. Frequencies from 600 kHz to 3 MHz are used for in-water high-resolution imaging arrays. Above about 3 MHz, transducers are used for medical ultrasound imaging and nondestructive testing. Ultrasonic microscopes operate up to the gigahertz frequency range.

5.1 Tonpilz Transducers

The tonpilz transducer is a longitudinal vibrator and gets its name from a composition of two German words, "sound" and "mushroom" or "singing mushroom." It is named, as can be seen, from its shape as shown in Fig. 6. These transducers are operated near resonance and typically are combined into arrays of many elements. Since arrays are often electrically phased to steer their directivity patterns to angles away from the normal to the plane of the array, the size of the radiating face needs to be about half of a wavelength in water. The tonpilz transducer has head and tail masses and a central ceramic (or magnetostrictive) motor section that are bonded together and put into compression by a central bolt. This creates a mass-spring-mass system that is a very efficient vibrator and radiator. The face of the head couples into water, and the tail has as light an acoustic load (such as air) as possible. A large radiated sound power can be achieved by this design.

There are four basic approaches to the tonpilz transducer design. The first approach is mentioned by Wilson (1985), who treats the transducer as a mass-spring-mass system. A second approach uses equivalent circuits or four-port networks as discussed by many authors. This is the most common method of tonpilz transducer design and requires electrical circuit programs or special codes to handle the complex, coupled equations. A third design approach is from Mc-

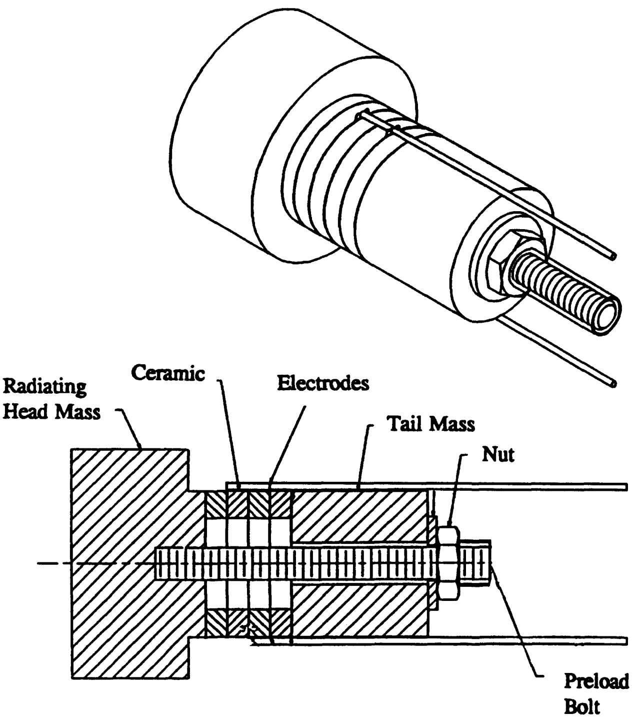

FIG. 6. Schematic of a tonpilz longitudinal vibrator.

Cammon and Thomson (1980), who treat the tonpilz transducer from an energy and waveguide basis, and a fourth approach uses finite-element analysis, which gives a very detailed vibration characterization, but is very time-consuming. Often the design is made by using a combination of the second and fourth approaches to generate an approximate design (within 10%) and then to detail the design. The first approach is not used very often but is more illustrative.

A tonpilz transducer can be used for frequencies from about 3 kHz to about 100 kHz. At frequencies above about 100 kHz, a thickness vibrator can be used. At 100 kHz a ceramic thickness vibrator made of a PZT-4 rod would have a length of 2 cm, and it would be less expensive. A tonpilz transducer, being a composite element, is used to reduce the overall length, make the stresses in the active material more uniform, make use of the piezoelectric material more effective, and reduce the mechanical Q. The radiating face typically has a larger area than the ceramic in order to increase the power output for a given strain in the ceramic and to obtain a better impedance match between water and the active transducer material. The head/ceramic area ratio is limited to about 3–10 by the need to avoid flexural resonances in the tonpilz head and to have a sufficient volume of ceramic.
